Using this background, initial studies were done to design an antenna resistant to detuning due to hand. The model of this initial design can be observed in Figure 133. The antenna is a dual-feed structure where the first feed is responsible for covering the LB (700-960MHz) and second feed for HB coverage (1.7-2.7GHz). The LB antenna consists of a short driven strip which capacitively excites a parasitic strip connected to ground plane through an inductor. A series inductor is used at the LB feed for impedance matching. The HB antenna is a separately fed monopole, with a two element MN at the feed. The antenna is totally printed on an FR4 substrate having dimensions of 130X60X0.8mm^3. A ground clearance region of 10mm is reserved for the antenna, making the ground plane 120mm long. The simulations of this antenna was performed in a commercial full wave electromagnetic solver, EMPIRE XCcel [12], in free space, with hand and with hand+head conditions(Figure 134).

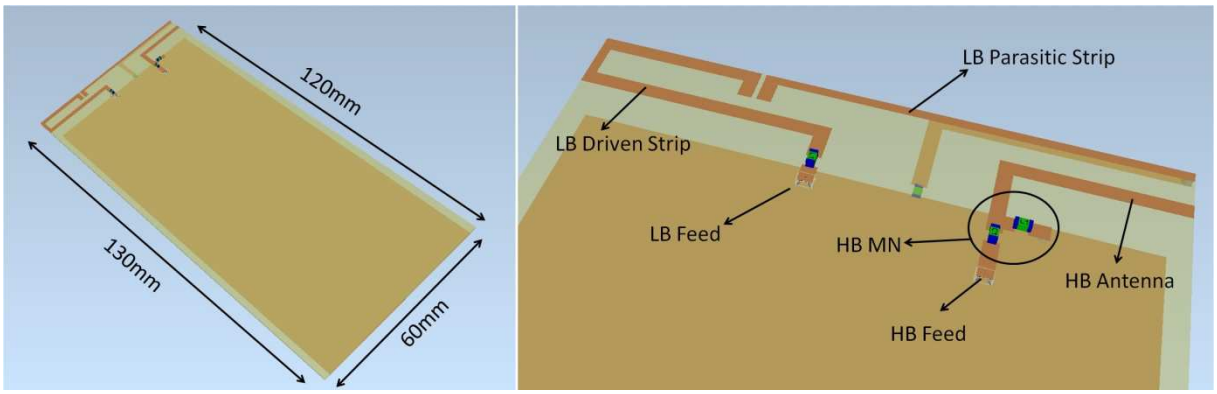

Figure 133 Simulation Model of the Antenna Resistant to Detuning

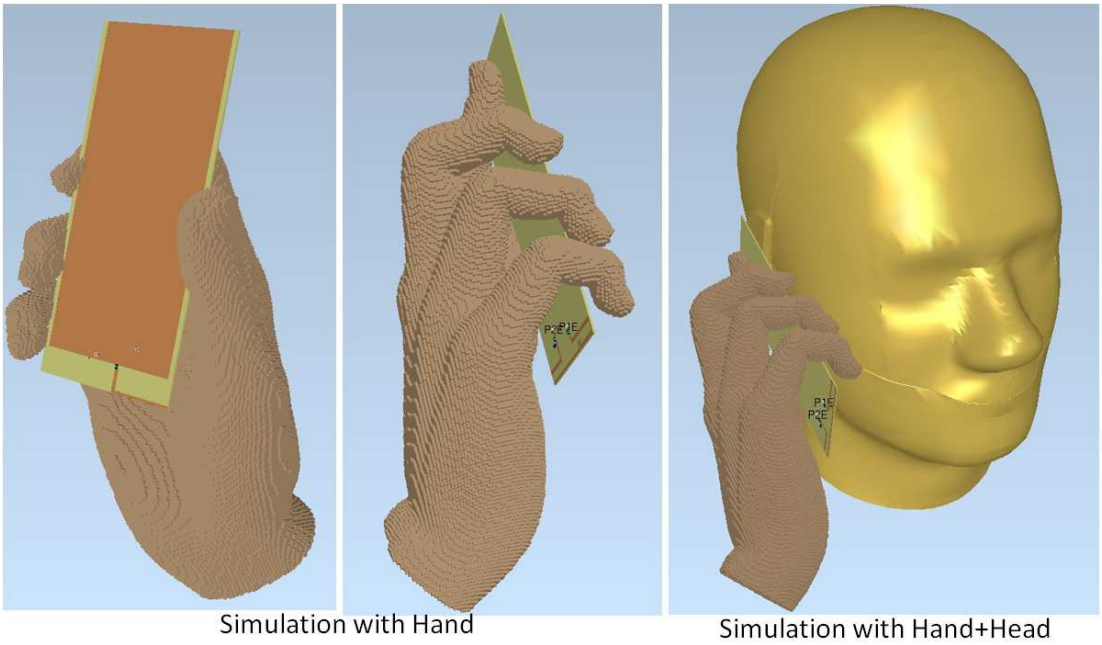

Figure 134 Simulation Models of the Antenna Considering the User

The simulated S-Parameters of the antenna in FS and "with Hand" conditions are given in Figure 135 and Figure 136. The antenna can cover the target bands with a reflection coefficient below -6dB in both FS and "with hand" conditions. In the LB, the matching bandwidth is reduced from 390MHz to 350MHz when the hand is introduced but this bandwidth is still enough to cover the LB.

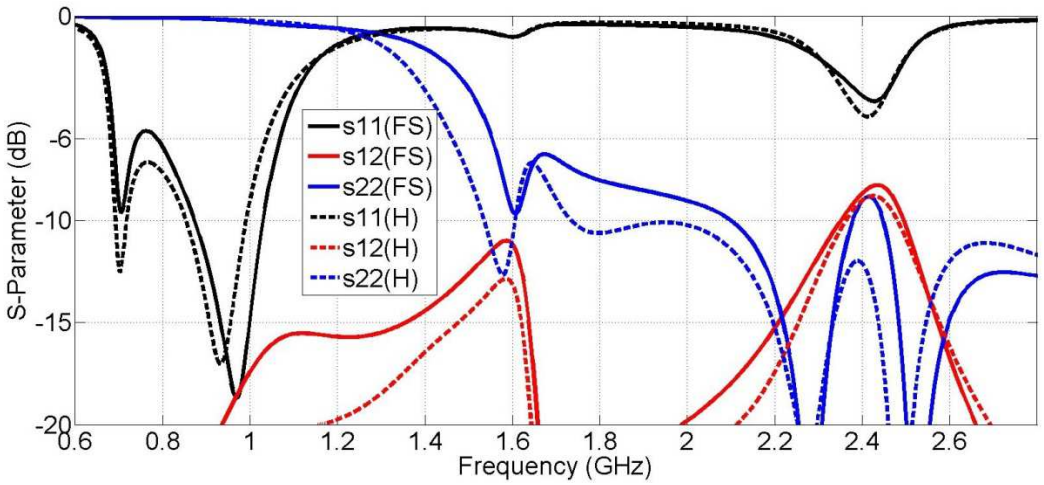

Figure 135 Simulated S-Parameters of the Antenna in FS and with Hand

The effect of the hand on the input impedance in LB occurs as foreseen. The loop in the smith chart shrinks and the high edge frequencies of the impedance are pushed out of the loop. Special attention was paid for situating the 960MHz point, such that it will not get out of the VSWR=3 circle so it will still be matched even with the hand. When the head is also taken into account in simulations, the antenna continues being matched in 700-960MHz with a reflection coefficient below -6dB(Figure 137).

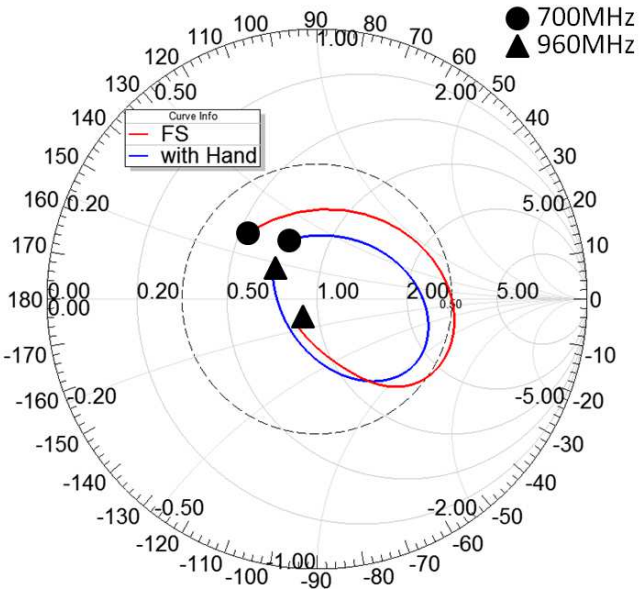

Figure 136 Simulated Input Impedance of the Antenna in FS and with Hand (Smith Chart)

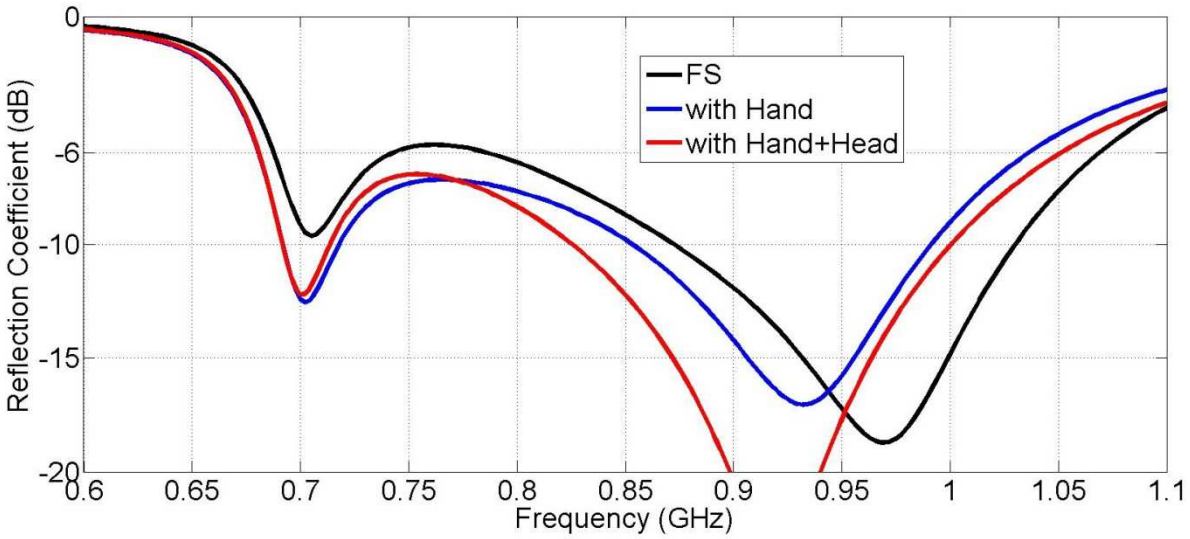

Figure 137 Simulated S-Parameters of the Antenna in LB

The proposed antenna has been manufactured. Figure 138 and Figure 139 presents a comparison of the simulated and measured S-Parameters of the antenna in FS. A good compliance can be seen between the simulations and measurements, except an overshoot in the LB, between 750-830MHz rising up to -4.5dB. However it can be told from the LB input impedance in Figure 139 that this overshoot is not something about the bandwidth potential, it can easily be overcome by tuning the component values in the LB MN.

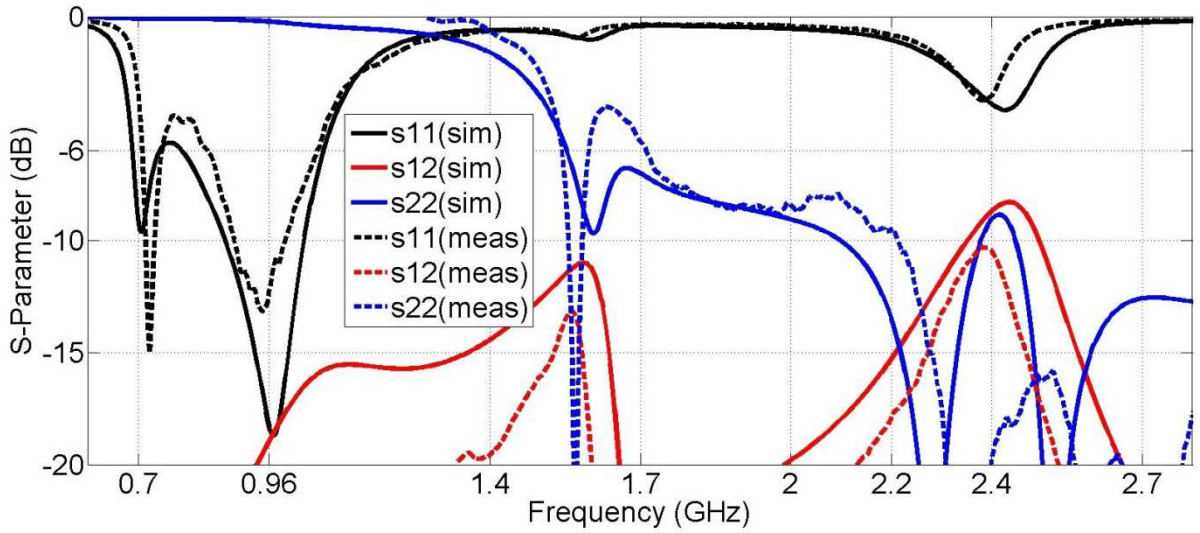

Figure 138 Simulated and Measured S-Parameters of the Antenna in FS

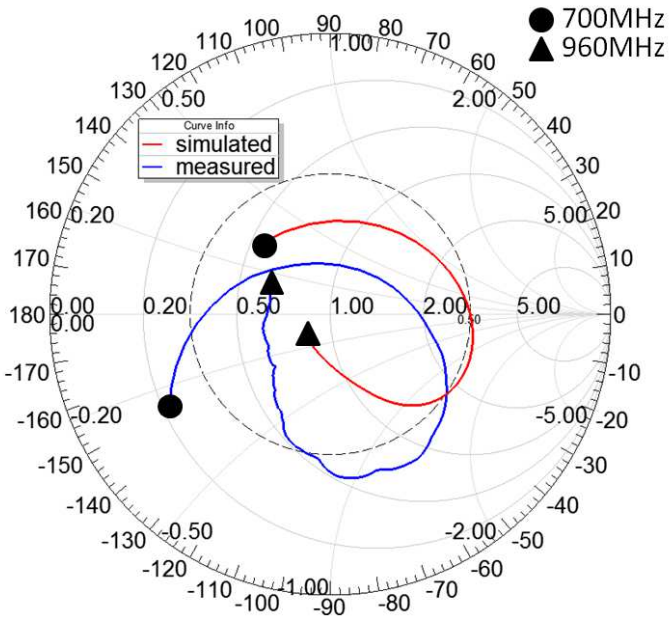

Figure 139 Simulated and Measured Input Impedance (LB Only) of the Antenna in FS (Smith Chart)

S-Parameter measurements were also performed for this manufactured prototype, using a real human hand in talking grip position when the antenna is on bottom of the PCB. The measured S-Parameters can be seen Figure 140 in dB format and also in Figure 141 for the Lb in smith chart. The antenna keeps its reflection coefficient below -6dB between 700-960MHz with LB antenna and between 1.7-2.7GHz with HB antenna, in the presence of a real user hand.

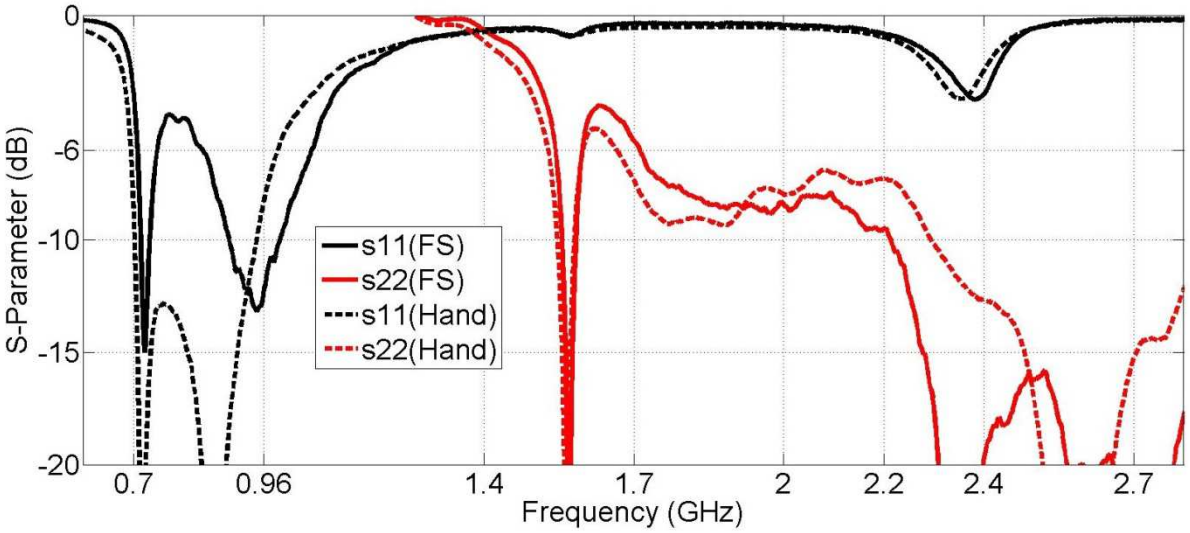

Figure 140 Measured S-Parameters of the Antenna in FS and with Hand

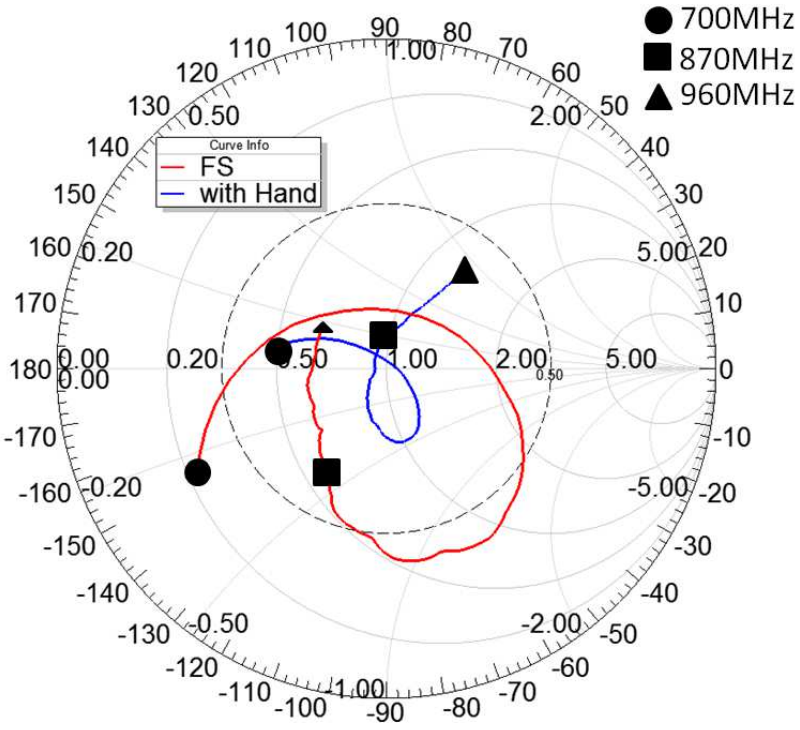

Figure 141 Measured Input Impedance of the Antenna (in LB) in FS and with Hand (Smith Chart)

For future studies, it is targeted to take this antenna as a basis and improve the design for better performance in the LB in FS condition. The S-Parameter and efficiency measurements are also next steps for validation of the concept.

CHAPTER V
EYEWEAR ANTENNAS

This section presents some eyewear antenna concept that can cover 700-960MHz and 1.7-2.7GHz, to be used on wirelessly connected eyewear devices. Since the antennas for eyewear devices operating in 4G cellular communication standard is a new subject, firstly a feasibility study is done for the bandwidth potential of the antenna in different placement alternatives. In all the study, coupling element (CE) antennas totally printed on FR4 substrates are used. To obtain a good compliance with the major use cases, the human head is always taken into account in simulations. Afterwards, three antenna designs are proposed, with a proper dielectric casing and frame. The SAR simulations are also performed and the effect of the user hand is also investigated.

1. USE CASE AND GENERAL INFORMATION ON EYEWEAR DEVICES

Wearable devices incorporating wireless connection with the peripherals has gained a significant popularity in the last years. Some examples of such devices can be considered as the wireless keyboard and mouse, cameras, USB keys, etc. In the recent years, wearable accessories like watches, rings and glasses have also gained importance as communicating devices. One of the most popular of these devices is the eyewears (or glasses), that currently has Wi-Fi 802.11b/g or Bluetooth connection with a peripheral mobile phone or a hotspot. There are currently many ongoing projects by different companies, who target the release of these "smart eyewear" devices in 2014 like [1-5]. Some examples of these devices are presented in Figure 142. Another example of such a device [1] can be seen in Figure 143. This device has a mechanical structure that can be integrated with any glass frame especially if it is optical or solar. The battery is placed behind the user's ear, together with the Wi-Fi/Bluetooth antenna. On the side of the head, a board is found which incorporates the electronics like the touchscreen and video/audio processors. The connection of the transceiver and the antenna is done using an RF cable passing through the plastic frame of the glasses. A camera is placed in the region corresponding to the front of the head. The display issue is solved by using a prism lens in front of the eye, in a way with no disturbances to the actual sight of the eye. A photo showing the positioning of the electronics in the eyewear device is given in Figure 144.

Figure 142 Different Eyewear Devices under Development

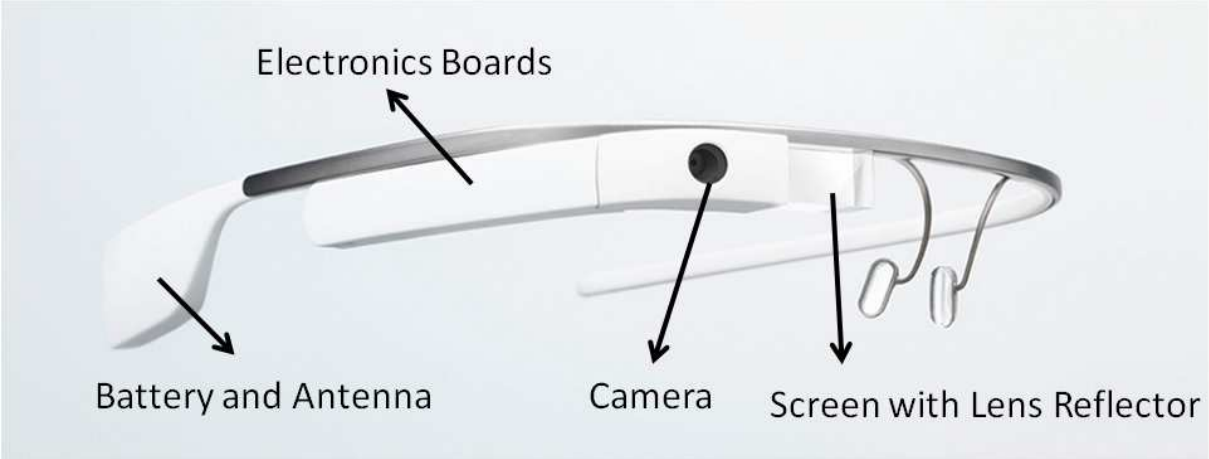

Figure 143 A Generic Eyewear Device Example

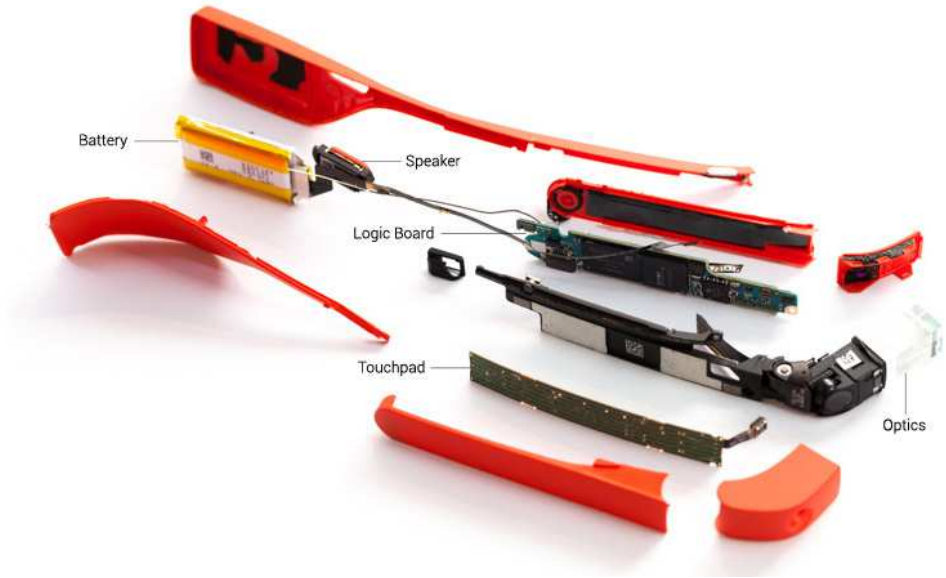

Figure 144 Teardown of the Google Glass

For now, the device can accept calls or use navigation systems by connecting to a mobile phone using Bluetooth. It also allows internet navigation if connected to a hot-spot. The antenna for this connection is placed behind the ear similar to headsets for mobile phones. This placement is practical for now, since the antennas of the same type with similar functionality were investigated extensively in the past in Bluetooth headsets[6-7]. The antenna design problem is relatively easy to solve since the space for the antenna is comparable to the wavelength at this frequency. Also since the power levels for Bluetooth are very small (generally 2.5mW), the SAR is out of concern and no regulation exists[8-9] However it is widely foreseen that these devices may replace mobile phones in the upcoming years. So, there is clearly a need for 4G cellular antennas for these eyewear devices, with satisfactory performance and compliance with the SAR requirements in the head of the user.

2. FEASIBILITY STUDY FOR EYEWEAR ANTENNAS

As an application example of coupling element (CE) antennas on eyewear devices, a feasibility study was first performed (simulations) taking into account a homogeneous user head. In the

simulations, CEs which are totally printed on the 0.8mm thick FR4 substrate were used in three different antenna locations (spotted to be available) and the bandwidth potentials and SAR values in these three locations were compared, using the commercial software EMPIRE XCcel [10]. Figure 145 shows the general model used in the simulations. The PCB that will support the antenna is modeled as FR4 substrate of 0.8mm thickness and with the dimensions given in Figure 146 (chosen as realistic dimensions versus a human head). A 90° bend is added to the PCB to stand for the region that extends in front of the eye. The CE is printed on the inner side of the PCB and the ground plane is on the outer side of the substrate.

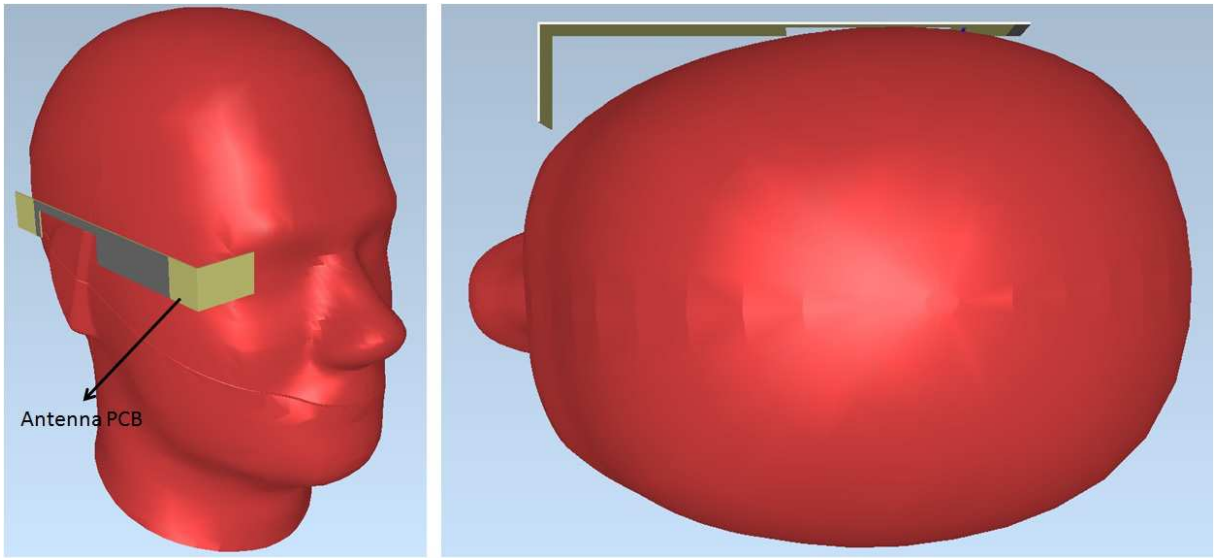

Figure 145 Simulation Setup for the Feasibility Study (3D view and top view)

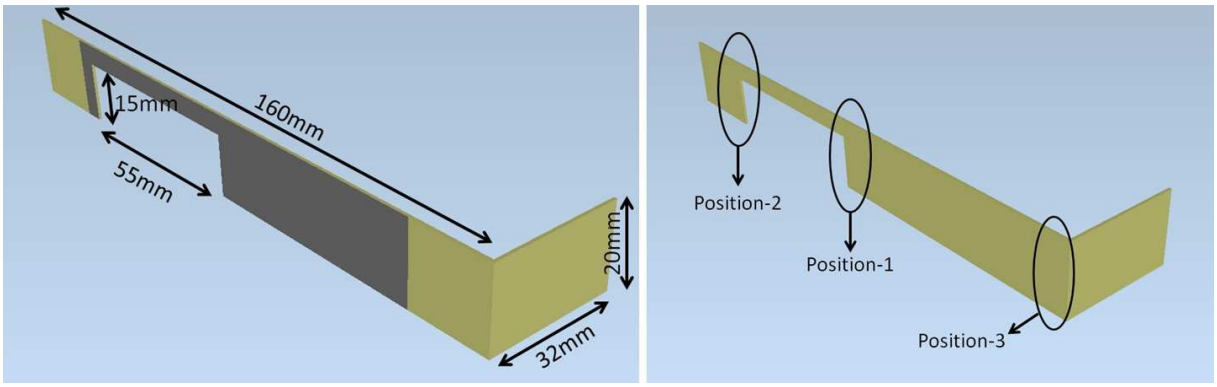

Figure 146 PCB Dimensions and Evaluated Antenna Positions

Three different antenna positions were evaluated in terms of bandwidth potential. These locations are: behind the ear, in front of the ear and close to the eye, as shown in Figure 146.

2.1. INVESTIGATION OF BANDWIDTH POTENTIAL IN POSITION-1

The simulated bandwidth potential of a basic printed CE (in the presence of the user head) in position 1 (in front of the ear) is presented in Figure 147. The bandwidth potential is computed using the Optenni Lab software using a two element MN at each frequency point as described in more detail in previous chapters, so it is an obtainable realistic value compared to theoretical values. To

cover the 4G frequency spectrum, a bandwidth potential of approximately 260MHz at 830MHz and a potential of 1GHz at 2.2GHz is necessary. It is worthwhile to note that these bandwidth potential values are the necessary values for single band coverage, with a two element MN. However since a dual-band coverage is necessary here, it was targeted to get "more than enough" bandwidth potential in the HB at the same time with enough potential in the LB. If Figure 147 is observed, it can be noted that the bandwidth potential may not be sufficient to achieve dual-band coverage (700-960MHz and 1.7-2.7GHz) with a simple MN, since the potentials in the LB and HB do not seem to be high enough. For this reason, this CE in position-1 was evaluated covering only the 1.7-2.7GHz with the introduction of a 2 element MN for SAR simulations. The simulated reflection coefficient with the MN can be seen in Figure 148.

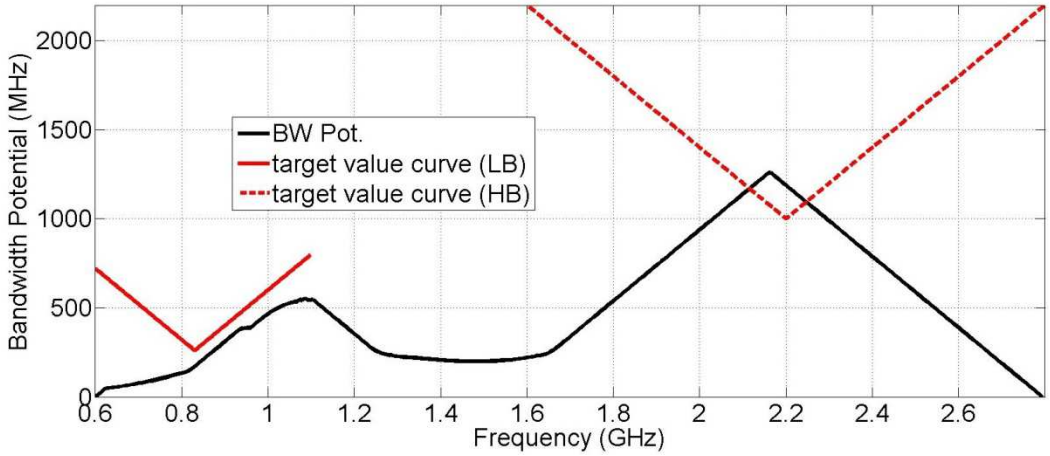

Figure 147 Bandwidth Potential for Position-1

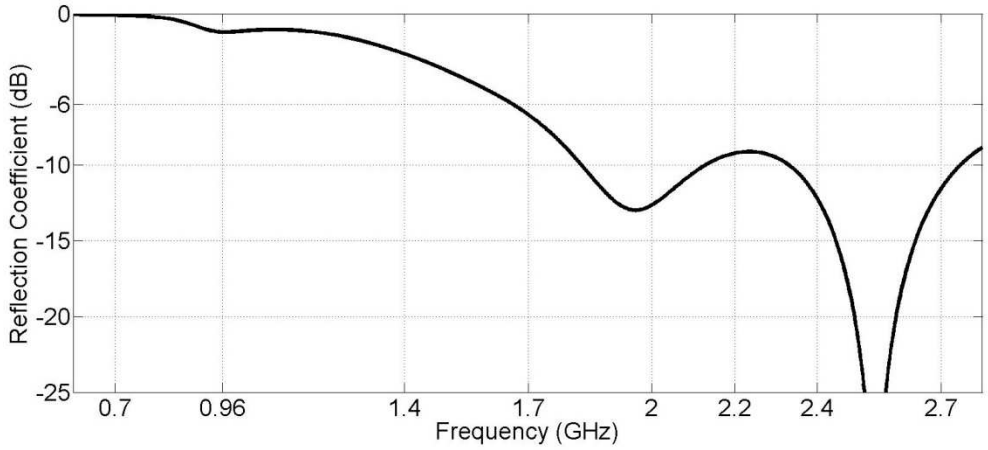

Figure 148 Reflection Coefficient for Position-1

The antenna has a radiation efficiency varying between -7.2dB and -4.4dB in 1700-2700MHz frequency range. It can be noticed that the efficiency of the eyewear antenna is considerably higher than the efficiency of mobile terminal antennas (in chapter IV) in hand+head condition, which was on average -10dB in HB. The main reason is the unnecessity of the user hand in the eyewear usage scenario, which enables getting rid of the losses due to detuning and absorption in the hand. The 3D gain pattern of the antenna at 2200MHz is presented in Figure 149. The radiation is concentrated through the direction away from the head. The gain is lower in the direction of the head due to absorption as expected. When the PCB is held in horizontal direction, the horizontal polarization is

dominant than vertical at 2200MHz with a small difference (0.7dB) between the gains of cross polarizations.

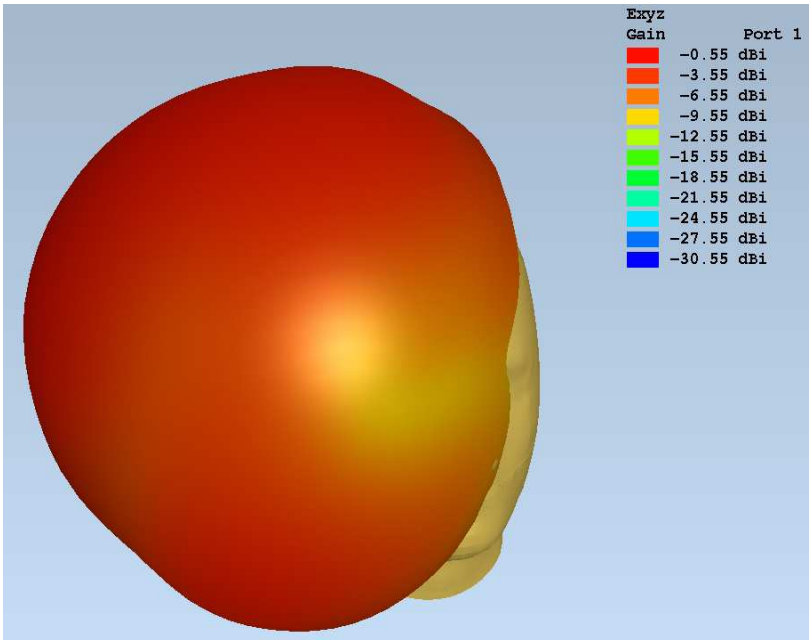

Figure 149 3D Gain Pattern for Position 1 (2200MHz)

2.2. INVESTIGATION OF BANDWIDTH POTENTIAL IN POSITION-2

The bandwidth potential for the CE printed on the substrate in position-2 (behind the ear) is presented in Figure 150. Placing the antenna in this position significantly has the advantage of higher bandwidth potential, sufficient for simultaneous coverage of LB and HB. The main reason of this higher BW potential especially in the LB is the stronger excitation of the ground plane in this position, when compared to previous one. A MN of two elements was inserted at the feed of the antenna and the reflection coefficient in Figure 151 was obtained for SAR simulations.

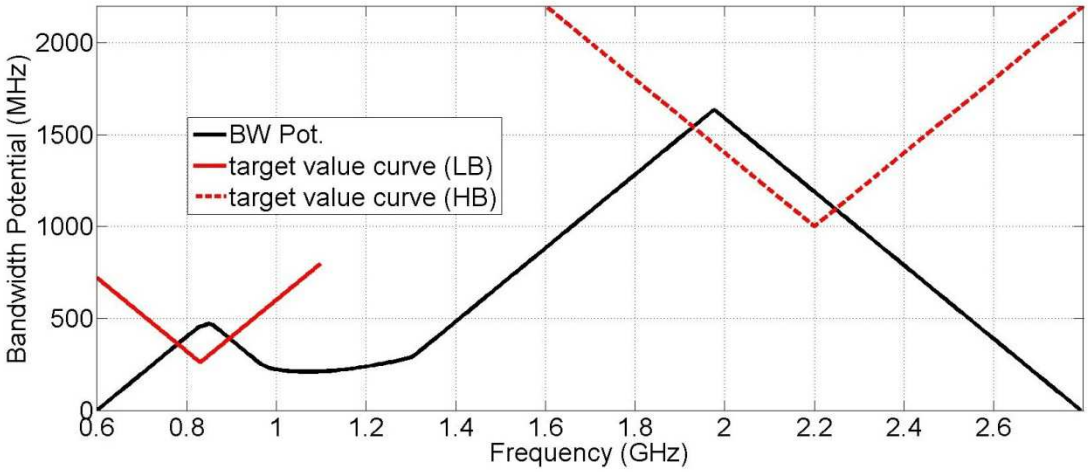

Figure 150 Bandwidth Potential for Position-2

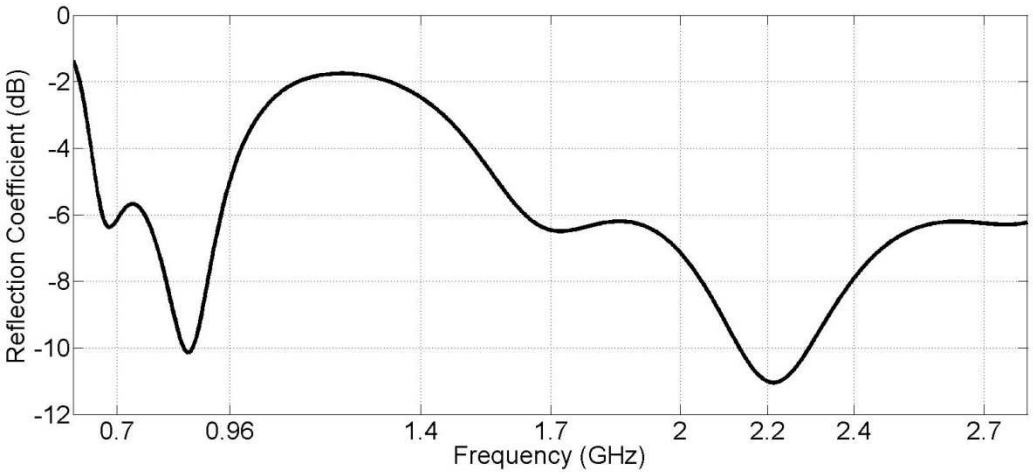

Figure 151 Reflection Coefficient for Position-2

The simulated radiation efficiency is between -11dB and -9.7dB in LB and approximately -7dB in the HB. As explained before, the radiation efficiencies are considerably higher than the general efficiencies of mobile terminal antennas (-14dB in LB and -10dB in HB for antennas in Chapter IV). The 3D patterns can be observed in Figure 152 for two different frequencies, showing the radiation away from the head. The cross polarization level is about 9dB in LB and 5dB in HB where the horizontal polarization is dominant.

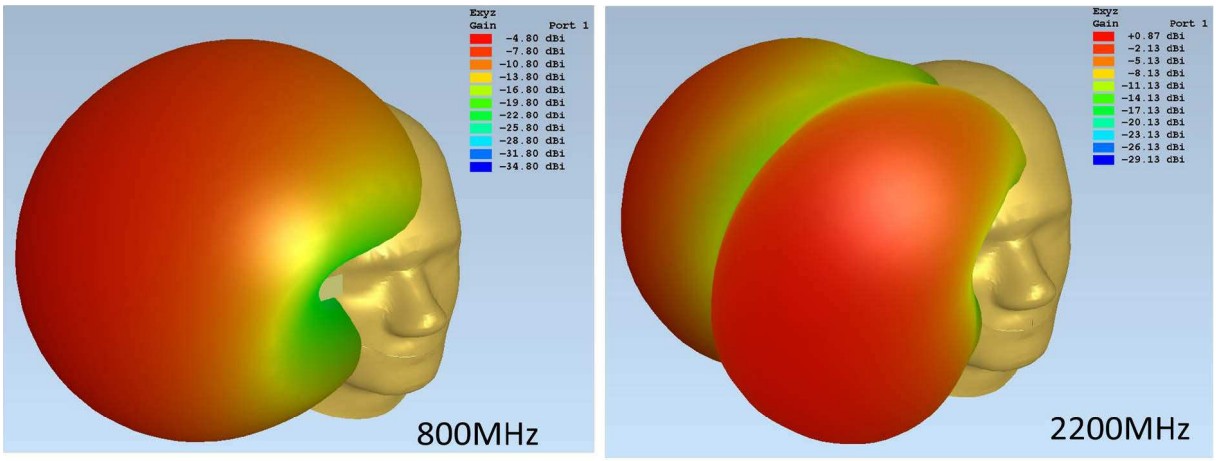

Figure 152 3D Gain Pattern for Position 2

2.3. INVESTIGATION OF BANDWIDTH POTENTIAL IN POSITION-3

The simulated bandwidth potential and the reflection coefficient of the antenna (with a three element MN) in position-3 (close to the eye) are given in Figure 153 and Figure 154 respectively.

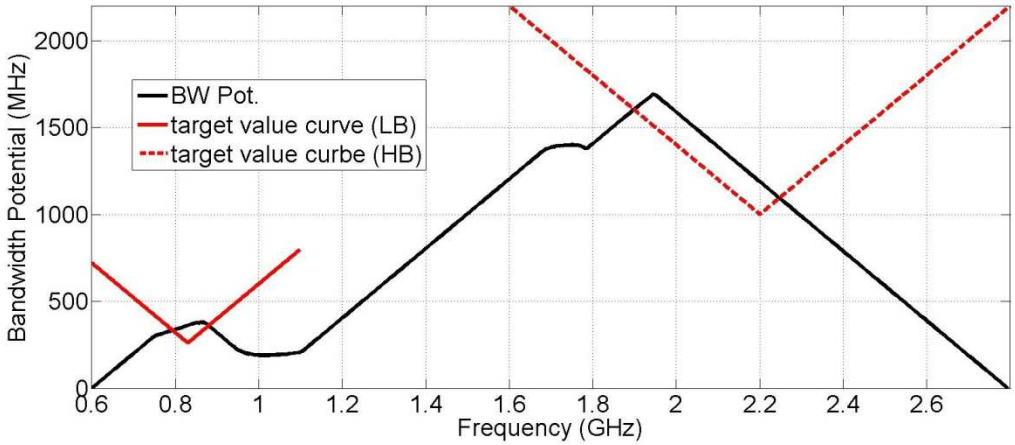

Figure 153 Bandwidth Potential for Position-3

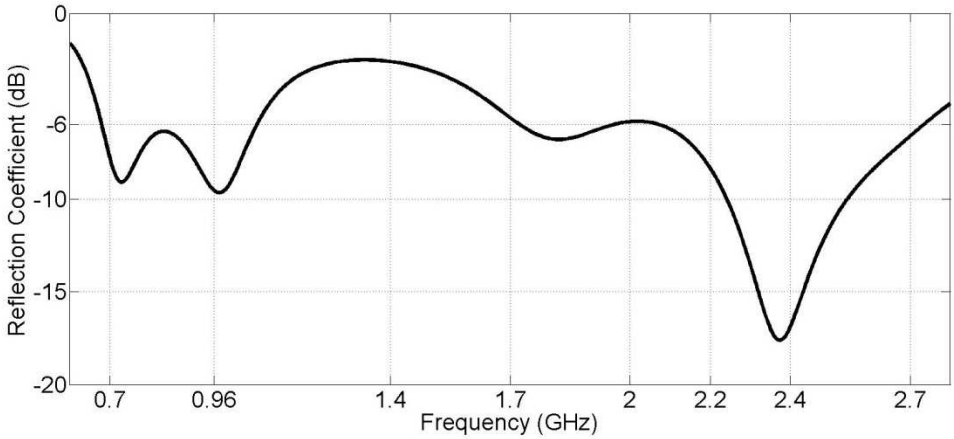

Figure 154 Reflection Coefficient for Position-3

The radiation efficiency is simulated to be between -9dB and -8dB in the LB and between -4.8dB and -3.8dB in the HB. The efficiency values seen in this position are quite higher than previous positions since the CE is located further away from the head when compared to others. The 3D patterns are presented in Figure 155. The horizontal polarization is generally dominant with a cross polarization of 6dB in LB and 4dB in HB.

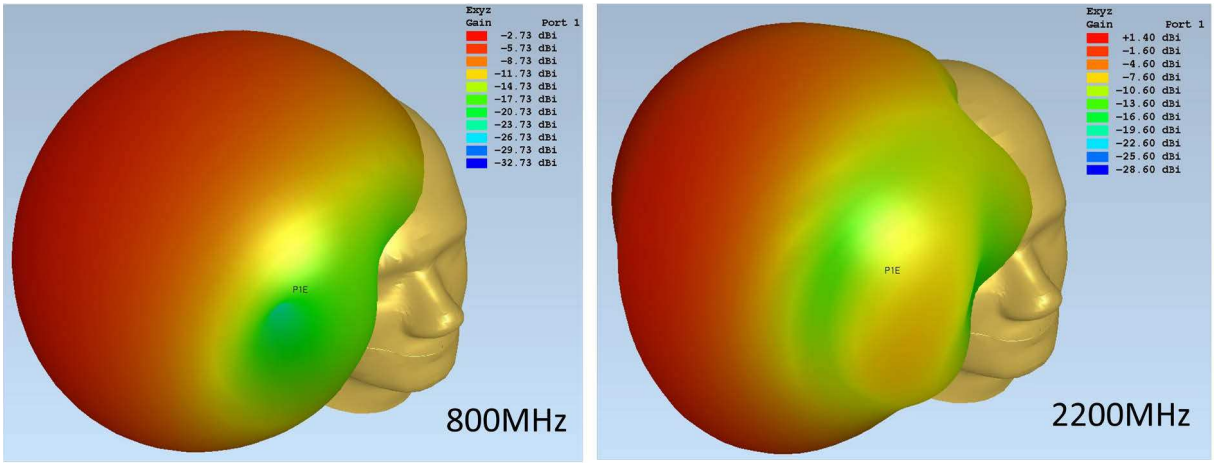

Figure 155 3D Gain Pattern for Position 3

2.4. COMPARISON OF SAR PERFORMANCES IN THREE LOCATIONS

Using the three CEs with associated MNs in the three different locations, a comparison about the SAR was performed. The simulation results are summarized in Table 6. The SAR results are presented both for the 1g SAR standard [11] (maximum limit 1.6W/kg, accepted in U.S) and 10g SAR standard [12] (maximum limit 2W/kg, accepted in Europe). The results are given also as normalized to 0.25W incident power (maximum of 2W in 1/8 second) and 0.25W antenna input after (at an incident power level to obtain 0.25W after mismatch). The SAR values that are below the allowed limit are shown in bold in the table. It can be seen that the SAR values are higher than the SAR values found from the measurements of a typical mobile phone, due to the proximity of the antenna feed to the head, the lack of a shielding ground plane under the antenna and also the lack of a dielectric casing material between the antenna and the head. It is also worthwhile to note that the radiation efficiency values are higher than a typical mobile phone, since for a mobile terminal, the antenna is covered by the hand in one direction and by the head in the other direction, which increases the losses due to absorption and mismatching. Another result to note is the lower SAR value of the location-3 in comparison to the other two locations, since the distance of the antenna element to the tissue is larger. As a conclusion, it can be told that the simulated 1g SAR values are above the standard limit, whereas 10g SAR values are generally acceptable or close to the limit.

Table 6 SAR Comparison for Eyewear Antenna Locations

			0.25W incident power		0.25W power after mismatch	
Position	Freq (MHz)	Radiation Eff (%)	1g SAR	10g SAR	1g SAR	10g SAR
1	1900	25	7.86	3.32	8.37	3.53
1	2200	36	4.31	2.07	4.88	2.35
1	2500	42	4.36	**1.54**	4.39	**1.55**
2	835	10	4.33	2.08	4.96	2.39
2	1900	20	2.97	**1.47**	3.89	**1.92**
2	2200	21	4.18	**1.99**	4.54	2.16
2	2500	21	3.68	**1.83**	4.69	2.33
3	835	13	4.17	2.03	5.50	2.68
3	1900	38	2.47	**1.18**	3.19	**1.53**
3	2200	33	2.22	**1.04**	2.60	**1.22**
3	2500	37	1.96	**0.82**	2.11	**0.89**
Limit			1.6	2	1.6	2

It is well known that the situation with a real head is different from the case with SAM phantom, since the real human head is composed of different tissues at different locations of the head. It was demonstrated in [13-15], that different parts of the body (for example the eyes) may resonate where the fields tend to increase and do not decay with distance. For this reason, a collaboration was established with Loughborough University to investigate the SAR with a visible human (VH) phantom in simulations (Figure 156). Comparisons using simulation results with different human head models were done in [16-17]. Here, the SAR simulation results with VH phantom give similar results with the simulation results using SAM phantom, except minor differences, due to small changes in the distance of the tissues to the head. It is observed that for all antenna positions and frequencies, the maximum SAR is observed on the side of the head. However, for antenna positions 1 and 3, secondary hot spots can be seen around the eye.

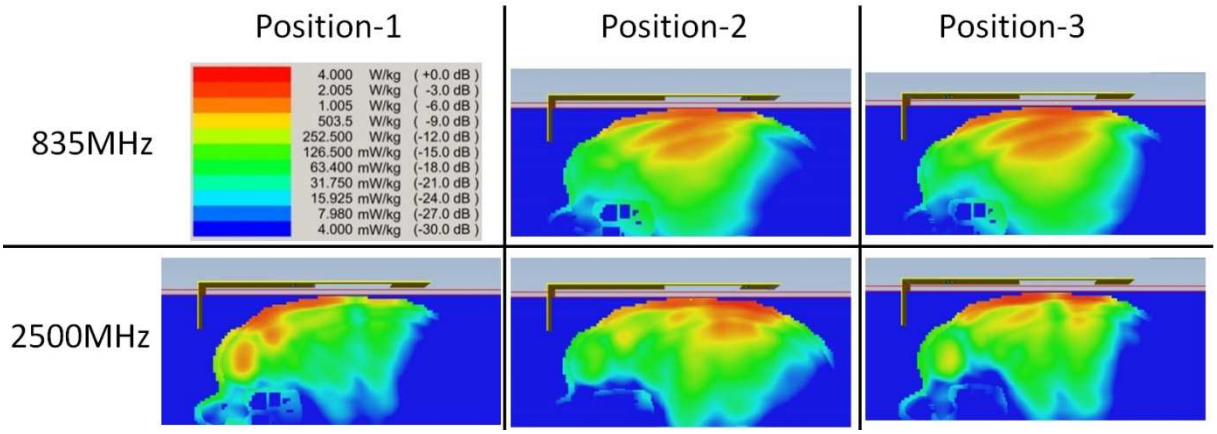

Figure 156 Simulated SAR with the Visible Human Phantom

3. EYEWEAR ANTENNA SOLUTIONS FOR 4G COVERAGE

Keeping in mind the results of the feasibility study, it was foreseen as possible to use printed CEs with corresponding matching networks, to obtain coverage of the 700-960MHz and 1.7-2.7GHz for 4G cellular communication standard. For this purpose three different CE antennas are proposed in this section. With the first antenna, the band between 700-2700MHz is continuously covered (including also the GPS operating frequency band), whereas the other two antennas can cover 700-960MHz and 1.7-2.7GHz simultaneously.

For a more realistic scenario, a dielectric casing with relative permittivity of 2.97 and a loss tangent of 0.029 was modeled and used in the simulations as seen in Figure 157. The 0.8mm thick FR4 substrate is fixed inside the casing using some slits. There is an air gap of 1mm between the PCB and inner edge of the casing (the edge close to the head) and a 3mm air gap between the PCB and outer edge of the casing. The thickness of the dielectric casing is chosen as 1mm. The excitation of the antenna is to be done using a WFL connector (Figure 158, [18]) on the outer side of the PCB, where the CE antennas are also printed. The other face of the PCB (the face towards the head) is used as the ground plane. Three holes are left on the outer face of the casing, to get the WFL cables outside of the casing, for three antenna structures fed from different points on the PCB. This way, a generic frame and casing is obtained, to be compliant with all three antenna prototypes. This model has been manufactured using 3D printing with a semi-rigid material in the facilities of Loughborough University. The manufactured prototype can be observed in Figure 159 on a SAM head phantom.

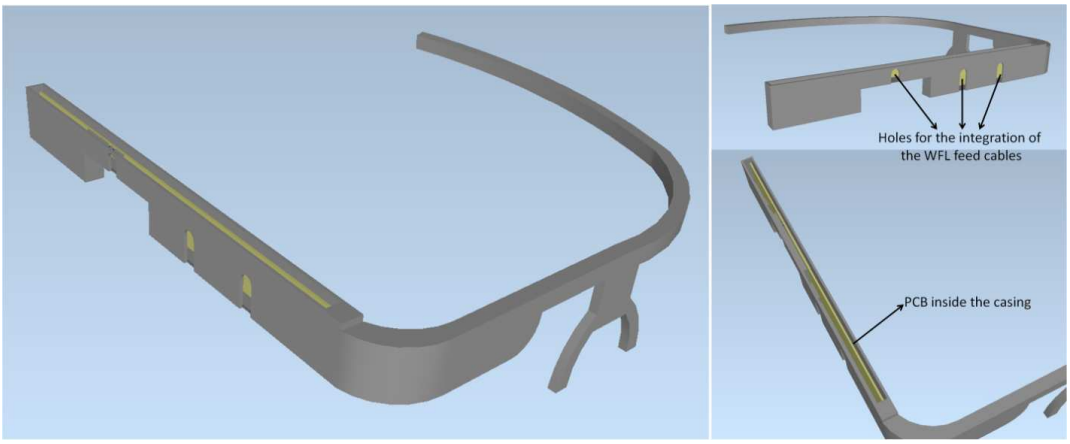

Figure 157 Eyewear Frame Model

Figure 158 WFL Connectors

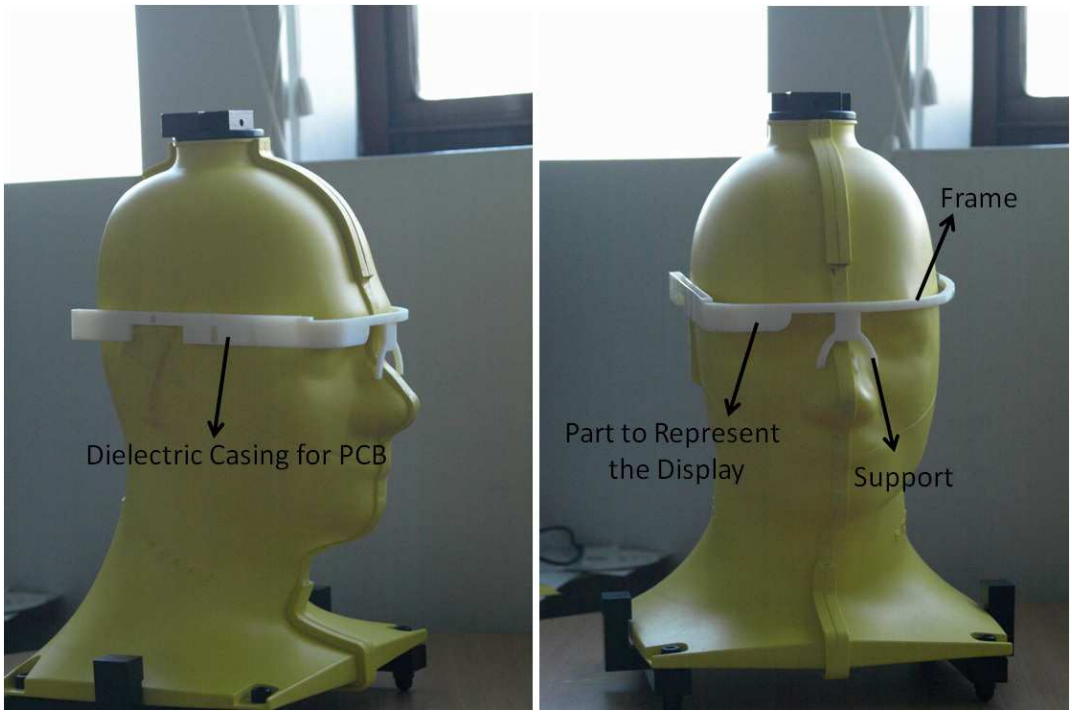

Figure 159 Manufactured Eyewear Frame

For the use cases of the eyewear antennas in real life, three scenarios were evaluated. The first scenario is the eyewear antenna and frame worn onto the head, which is foreseen as the major use case of the device. The antennas were designed and optimized for this scenario. Two other scenarios were also evaluated in the simulations, which are the free space condition and "with head+hand" condition. The free space condition can be evaluated as the use case, where the eyewear device is not worn by the user but should still be functional for the possibility of an incoming call. The other condition, "with head+hand" is the situation when the user changes the settings or the applications of the device, using the touch screen on the side with one or several fingers.

3.1. EYEWEAR ANTENNA-1

The first antenna designed is a CE, printed on the substrate, just behind the ear as seen in Figure 160. The feeding of the CE is done from the edge and a ground clearance is created at the bottom of

the CE. A matching network of 3 lumped components is introduced at the antenna feed. The simulation setups including the frame, casing, antenna, hand and the head can be observed on left of Figure 161 for the "head" configuration and on the right for the "head+hand" configuration.

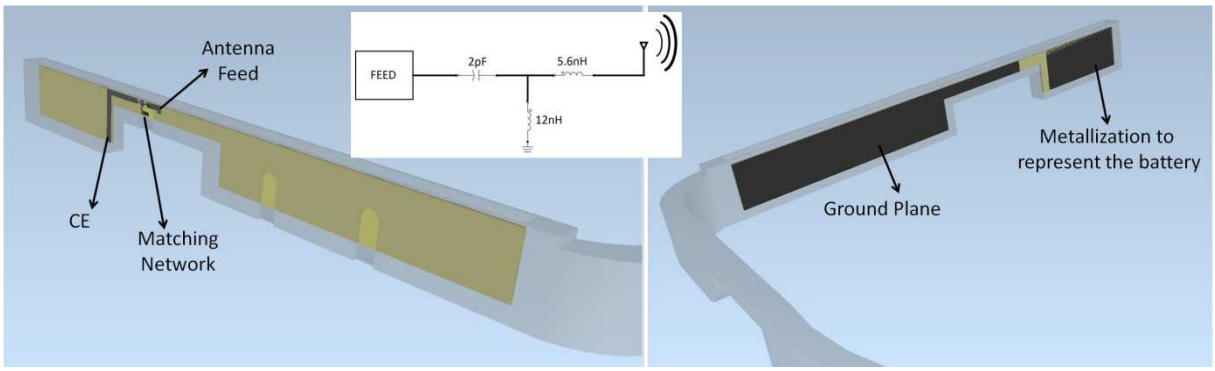

Figure 160 Eyewear-Antenna-1 Model

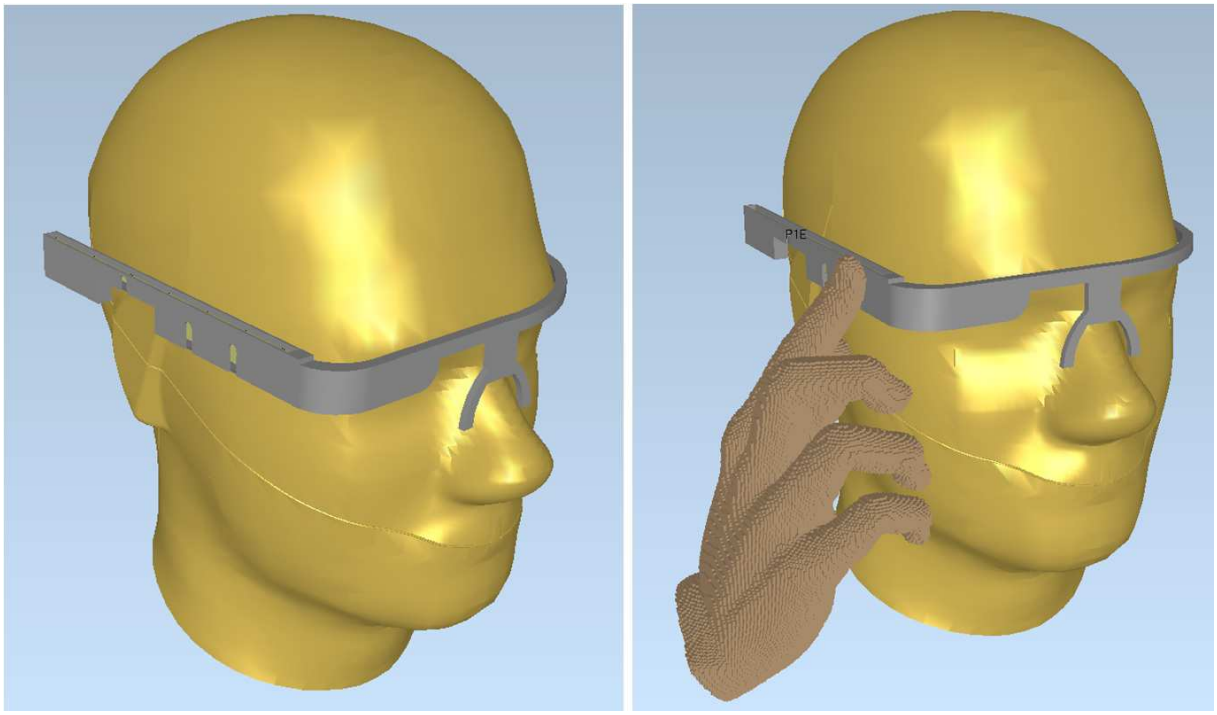

Figure 161 Positioning of the Head and Hand Phantom in Two Simulation Scenarios

The simulated input impedance, with and without the matching network can be seen in Figure 162 (in head configuration), in smith chart form plotted between 700-2700MHz. The corresponding reflection coefficient is shown in Figure 163. The antenna has a reflection coefficient below -6dB between 700-2700MHz, covering GPS operating frequency in addition to the 4G cellular communication frequency band.

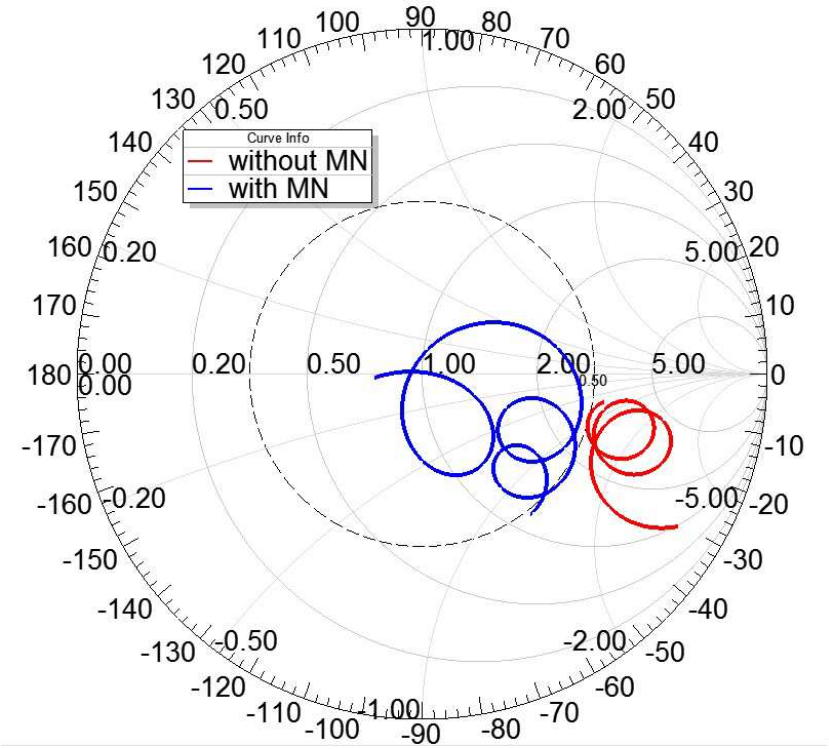

Figure 162 Simulated Impedance with Head (with and without MN) for Eyewear Antenna-1

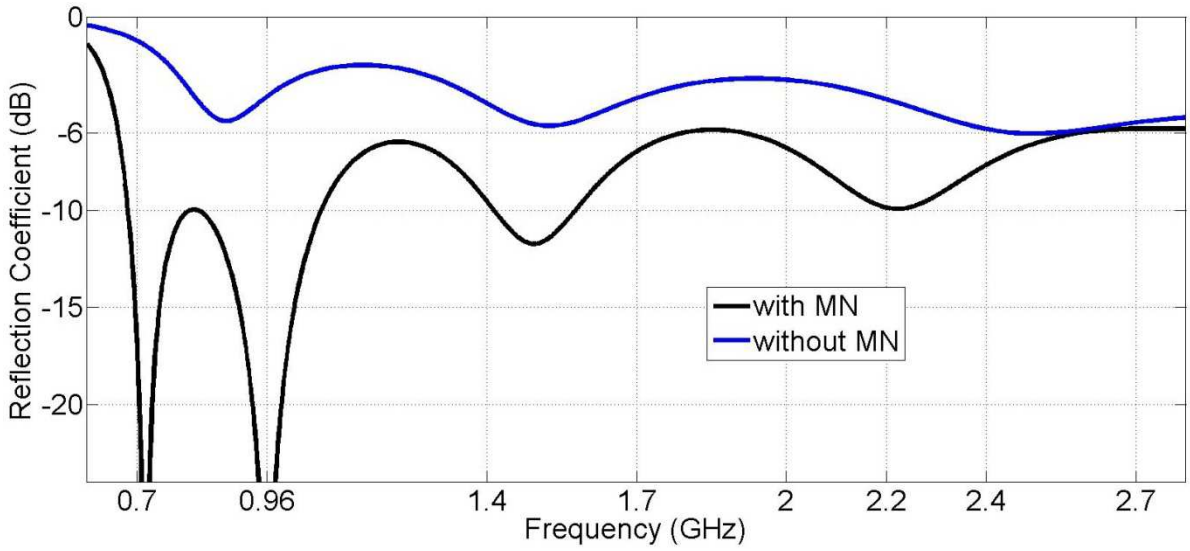

Figure 163 Simulated Reflection Coefficient (with and without MN) for Eyewear Antenna-1

Figure 164 shows the simulated 3D gain pattern of the antenna in 800Mhz and 2200MHz. The radiation is concentrated away from the head as expected due to the absorption by the head. Table 7 summarizes the simulated SAR values for three different frequencies both for 1g and 10g standards, normalized for 0.25W input power. As seen, the SAR values are high when compared to the limit in the standards (1.6W/kg for 1 gram of tissue and 2W/kg for 10 gram). The main reason is the proximity of the radiating element to the tissue in the eyewear device when compared to a typical mobile terminal, considering the antennas are generally placed on the bottom of the terminal. The SAR values can be lowered to some extent by arranging the output power from the transmitter or by increasing the distance of the antenna to the head, which will results in a thicker eyewear frame.

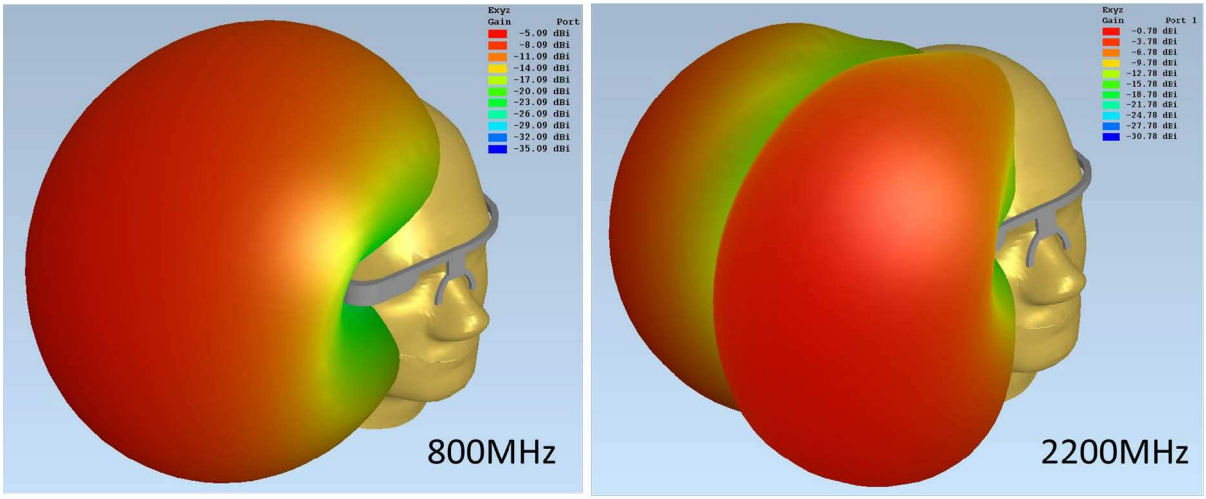

Figure 164 Simulated 3D Gain Pattern of Antenna-1

Table 7 Simulated SAR for Eyewear Antenna-1

	1g SAR	10g SAR
900MHz	5.17	2.99
2100MHz	11.28	4.90
2400MHz	8.75	3.28

The antenna was simulated also in the three use cases, mentioned before. The reflection coefficient "with head", "free space" and "with head+hand" can be observed in Figure 165. The effect of the finger close to the antenna casing do not show a significant impact on the antenna impedance and do not cause detuning, since the CE is further away from the finger. In free space, the reflection coefficient is still below -6dB in the LB, but it goes above -6dB (rising up to -3.5dB) between 1.85-2.35GHz in the HB.

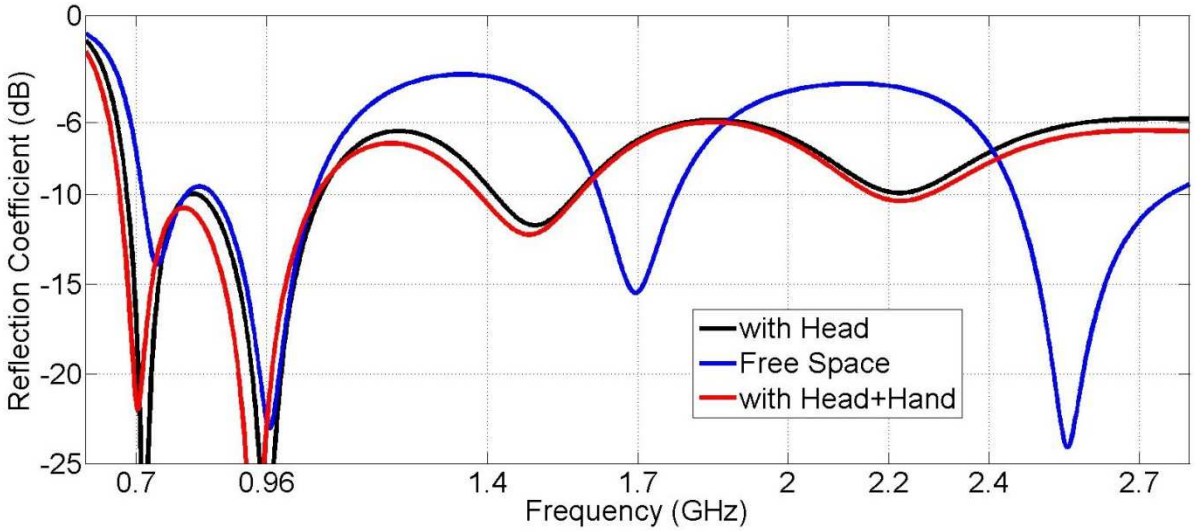

Figure 165 Simulated Reflection Coefficient for Eyewear Antenna-1 in Different Scenarios

The simulated radiation efficiency is between -13dB and -9.5dB in the LB and between -8.5dB and -6.5dB in the HB (Figure 166) in head condition. As also mentioned before, the efficiency values are considerably higher than a typical mobile terminal antenna, namely -14dB in LB and -10dB in HB for the antennas in chapter IV. The introduction of the hand do not cause significant change in the LB, but decreases the radiation efficiency by 0.5-2dB in the HB.

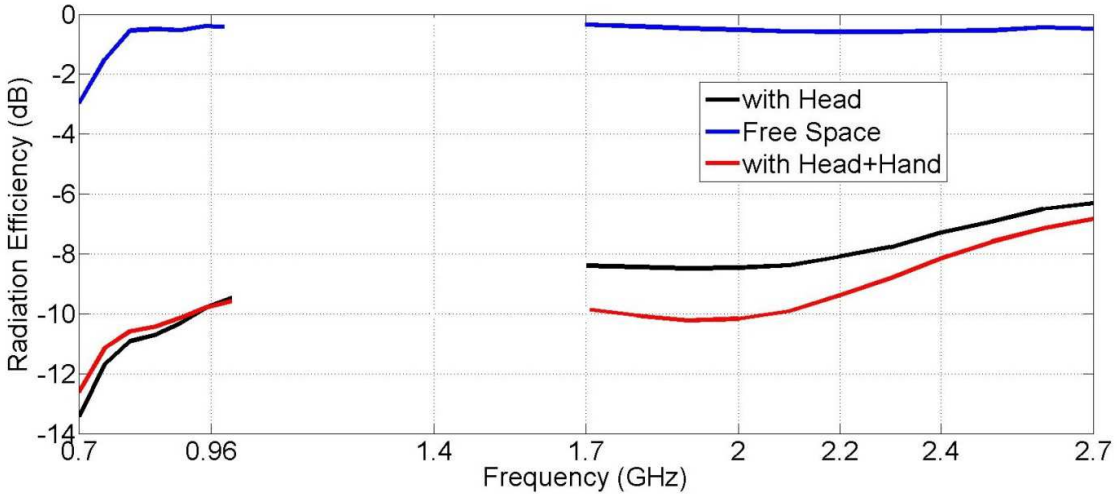

Figure 166 Simulated Radiation Efficiency for Eyewear Antenna-1 in Different Scenarios

3.2. EYEWEAR ANTENNA-2

For the second eyewear antenna design, the CE has been moved to the other edge of the PCB, close to the eye (Figure 167). There is again a MN of three lumped components at the antenna feed. The effect of the MN on the antenna input impedance can be evaluated in Figure 168, where the curves are plotted between 700-960MHz for the LB (smith chart on the left) and 1.7-2.7GHz for the HB (smith chart on right).

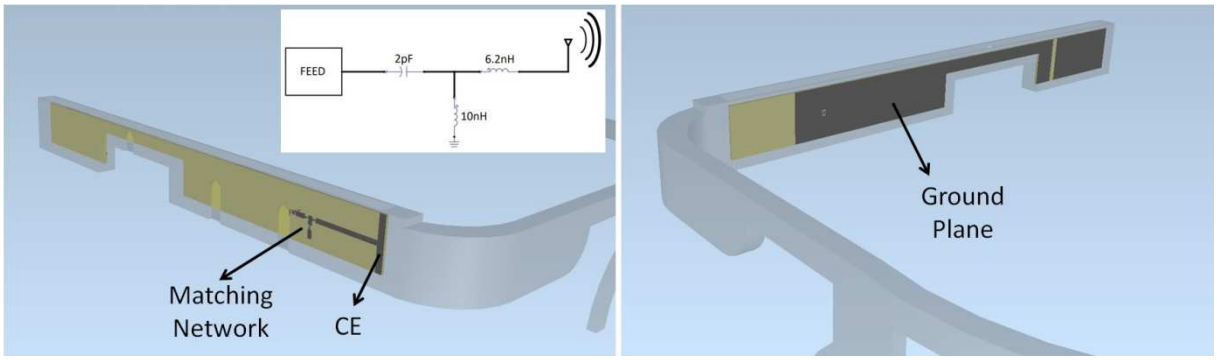

Figure 167 Eyewear-Antenna-2 Model

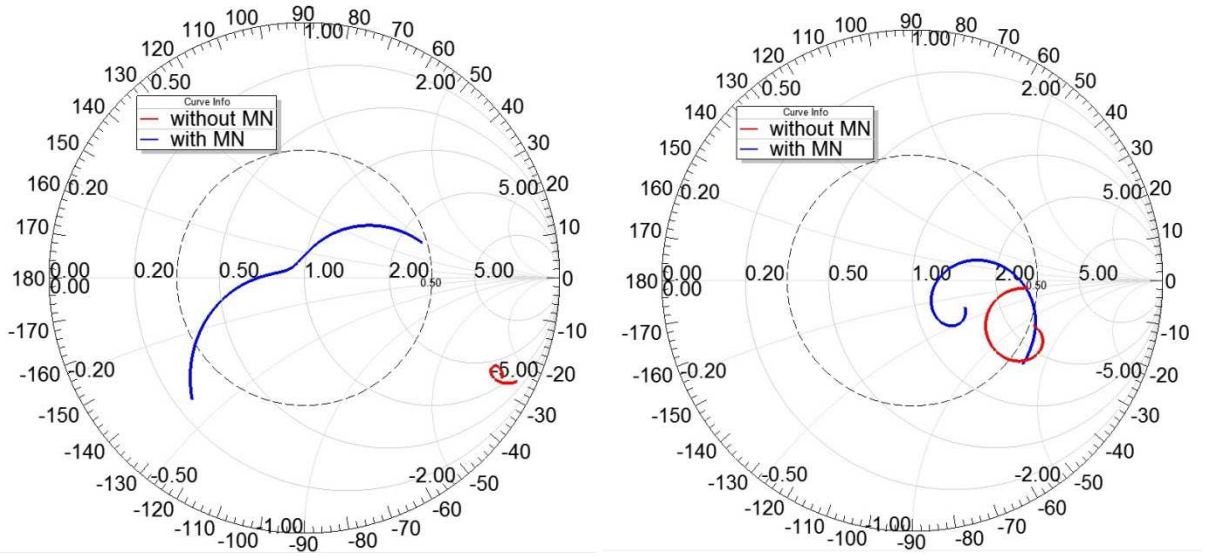

Figure 168 Simulated Impedance with Head (with and without MN) for Eyewear Antenna-2 (LB on left, HB on right)

The antenna has a reflection coefficient below -6dB between 710-960MHz in the LB and between 1.35-2.4GHz in the HB. There is slight overshoot of up to -5dB between 2.4-2.7GHz of the target band.

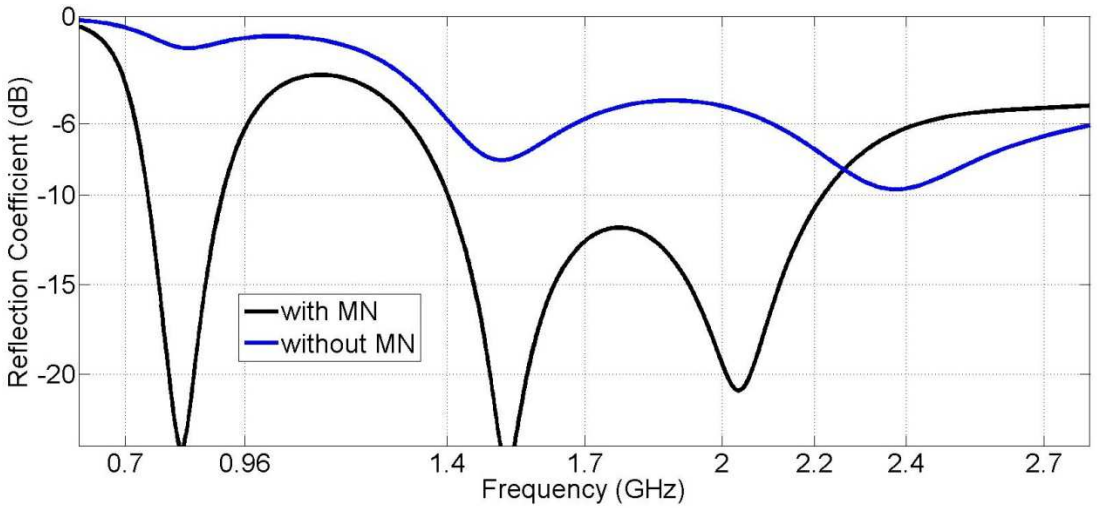

Figure 169 Simulated Reflection Coefficient (with and without MN) for Eyewear Antenna-2

Figure 170 presents the 3D gain pattern in two different frequency points. The simulated SAR values again yield high values (Table 8) as in the previous prototype, being higher than the maximum limit for 0.25W input power.

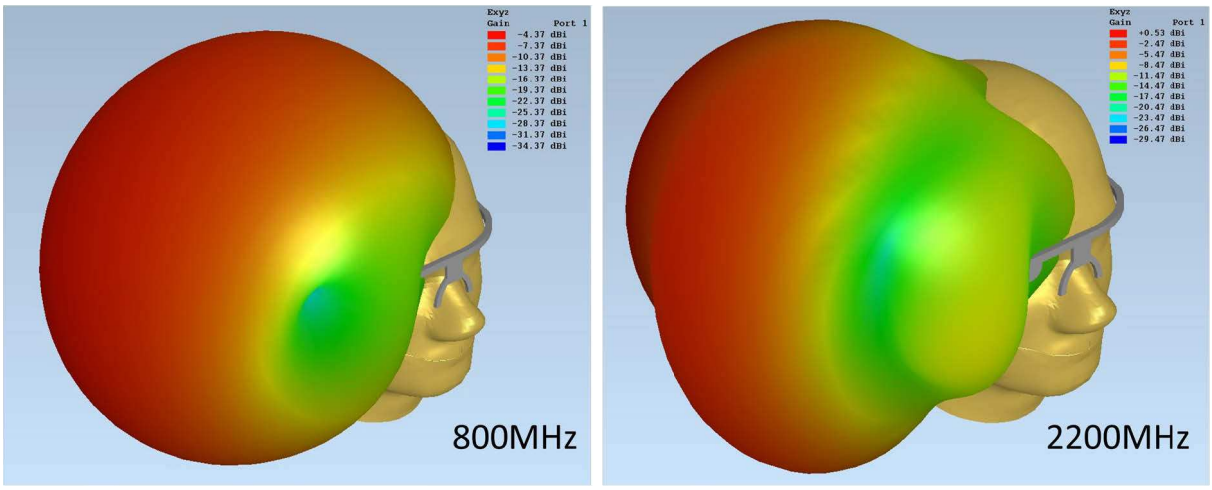

Figure 170 Simulated 3D Gain Pattern of Antenna-2

Table 8 Simulated SAR for Eyewear Antenna-2

	1g SAR	10g SAR
900MHz	4.13	2.39
2100MHz	9.80	4.62
2400MHz	7.25	3.13

When the reflection coefficient for different scenarios is observed in Figure 171, it can again be seen that the detuning is not effective due to the finger. However it is seen that the finger effect is more noticeable compared to previous antenna since the finger is closer to the radiating element. In free space, the LB performance is preserved but an overshoot up to -3.5dB is seen in HB above 2.4GHz.

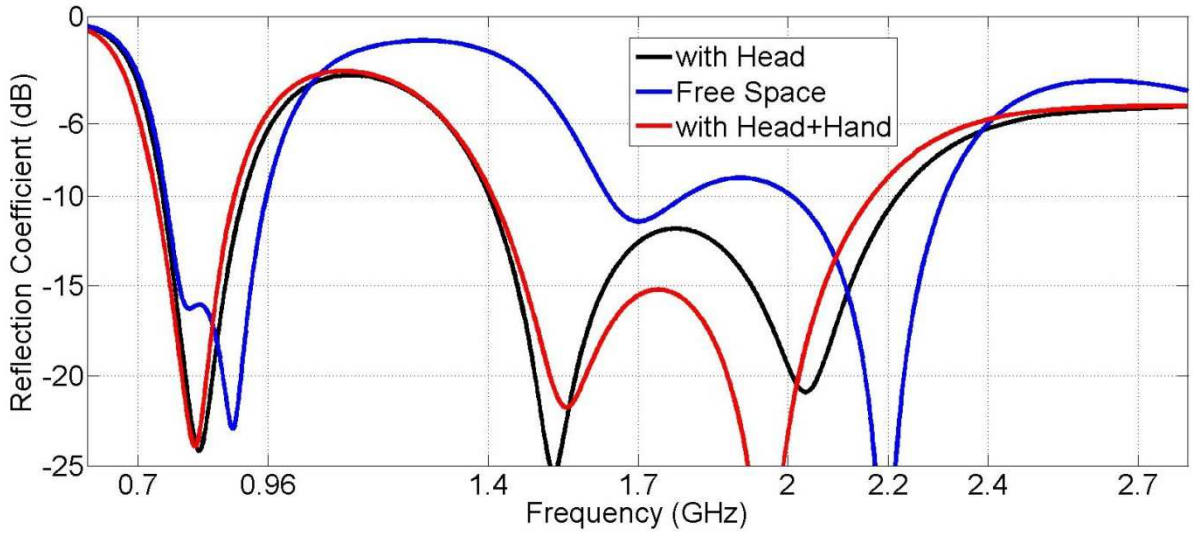

Figure 171 Simulated Reflection Coefficient for Eyewear Antenna-2 in Different Scenarios

The simulated radiation efficiency is between -11dB and -10dB in the LB and between -6.5dB and -5dB in the HB (Figure 172) for "with head" scenario. The effect on radiation efficiency is minimal

with the introduction of the hand in the LB, however a decrease of approximately 2dB is seen in the HB.

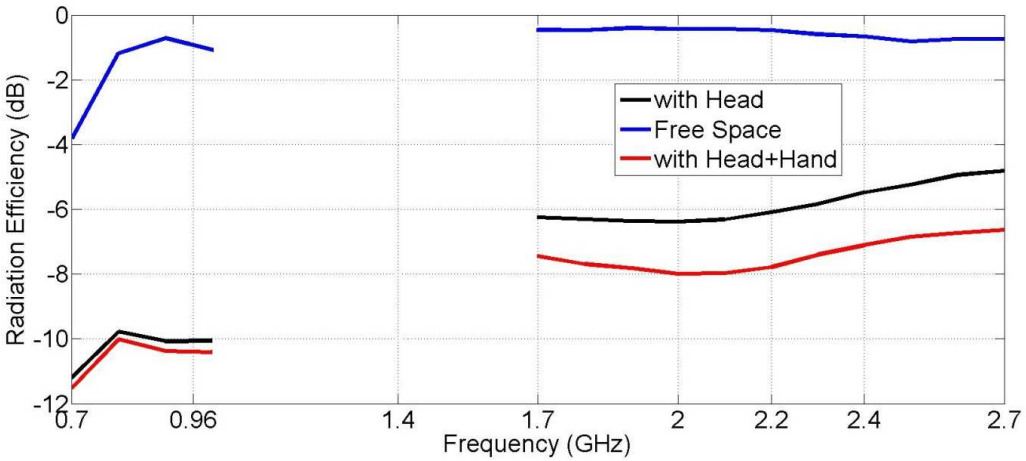

Figure 172 Simulated Radiation Efficiency for Eyewear Antenna-2 in Different Scenarios

3.3. EYEWEAR ANTENNA-3

For the third antenna design, the CE is located in the middle of the PCB section in front of the ear (Figure 173), with a MN of three lumped elements at the feed. The impedance of the antenna with and without MN is presented in Figure 174.

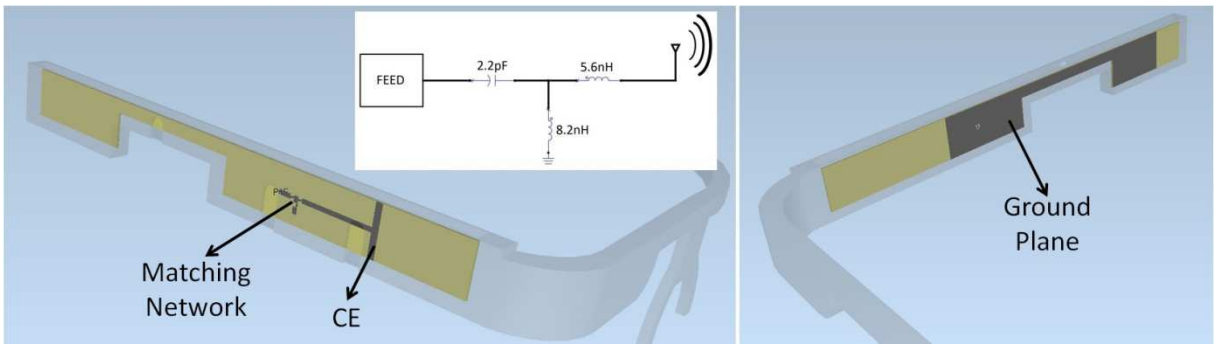

Figure 173 Eyewear-Antenna-3 Model

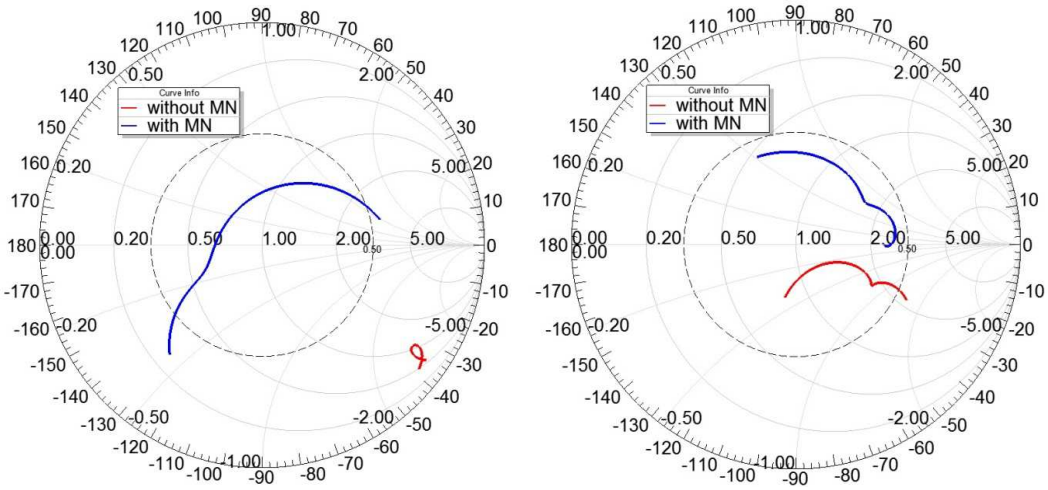

Figure 174 Simulated Impedance with Head (with and without MN) for Eyewear Antenna-3 (LB on left, HB on right)

The third antenna proposed, has a reflection below -6dB between 710-950MHz and 1.55-2.7GHz (Figure 175).

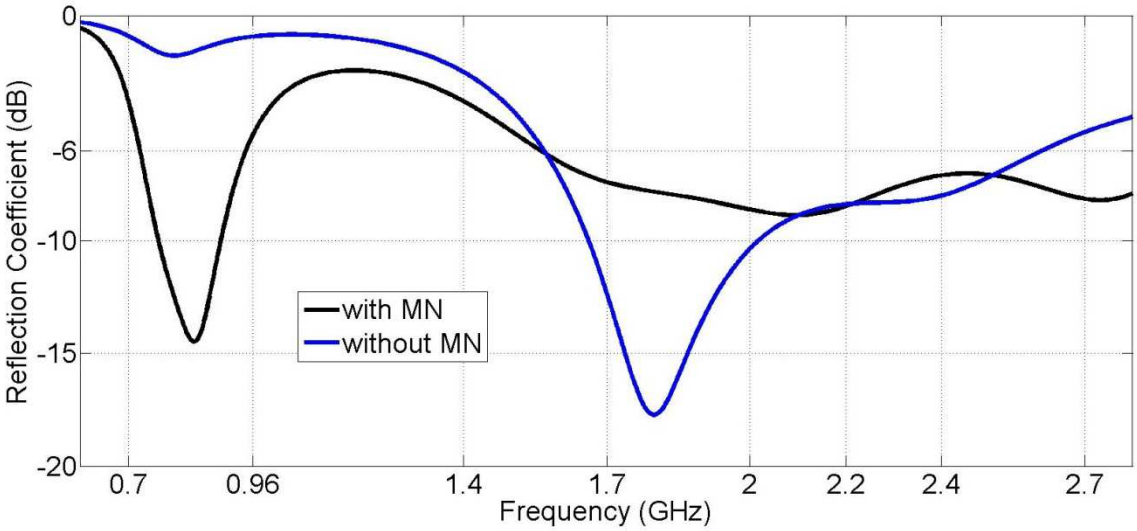

Figure 175 Simulated Reflection Coefficient (with and without MN) for Eyewear Antenna-3

Figure 176 shows the simulated 3D pattern of the antenna. The results of the SAR simulations for three frequency points are given in Table 9.

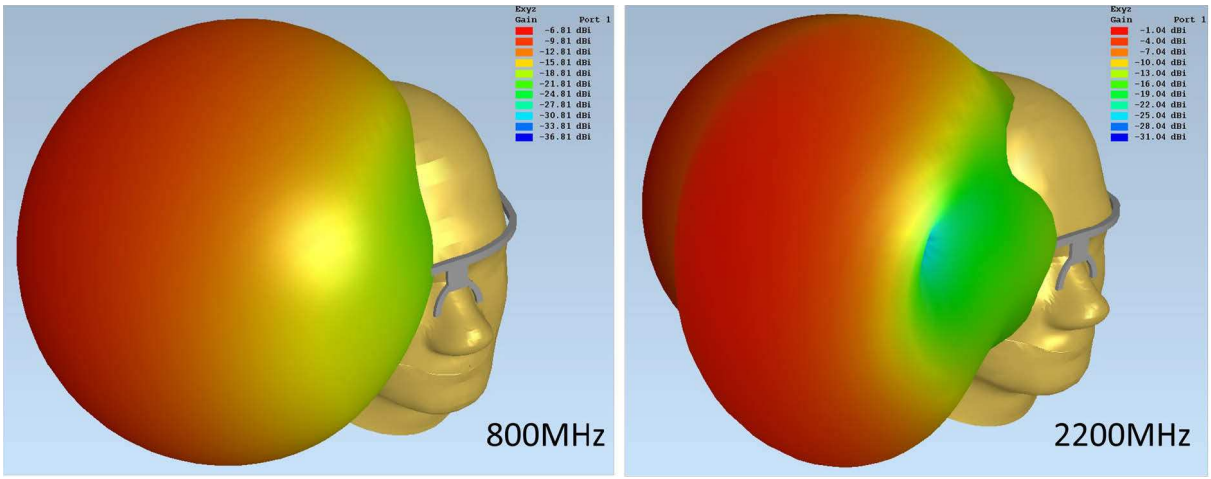

Figure 176 Simulated 3D Gain Pattern of Antenna-3

Table 9 Simulated SAR for Eyewear Antenna-3

	1g SAR	10g SAR
900MHz	4.67	2.55
2100MHz	8.77	4.18
2400MHz	7.76	3.51

As in previous designs, the hand does not cause any detuning on the antenna reflection coefficient(Figure 177). However, in free space condition, the HB coverage is effect significantly, having a reflection coefficient below -6dB only between 2-2.55GHz.

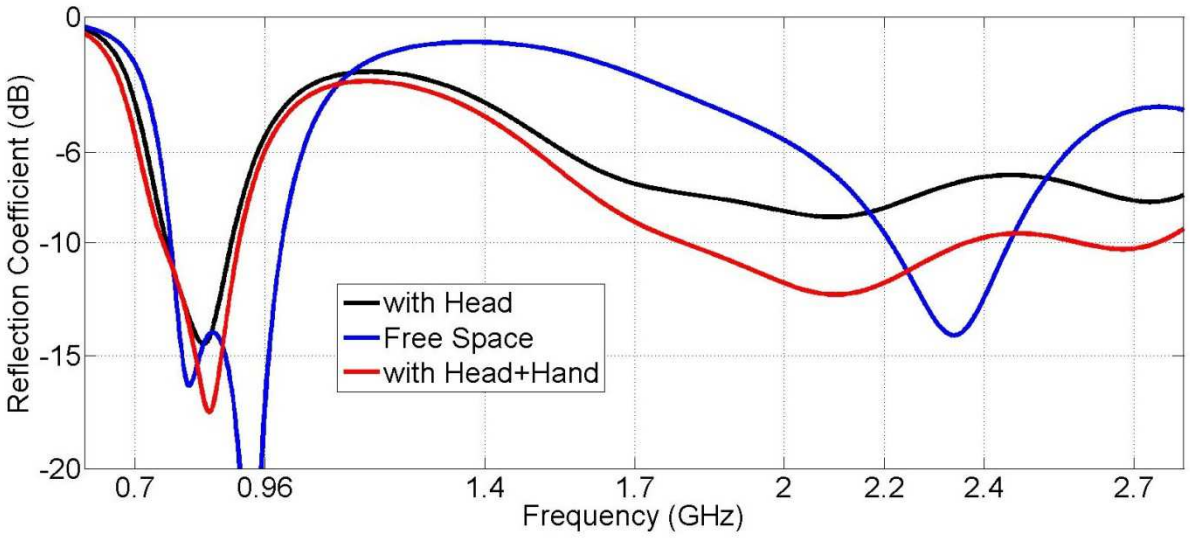

Figure 177 Simulated Reflection Coefficient for Eyewear Antenna-3 in Different Scenarios

The simulated radiation efficiency is between -14dB and -12.5dB in the LB and between -8dB and -6.5dB in the HB (Figure 178) with the head. The hand causes an efficiency drop of up to 1.5dB in the HB.

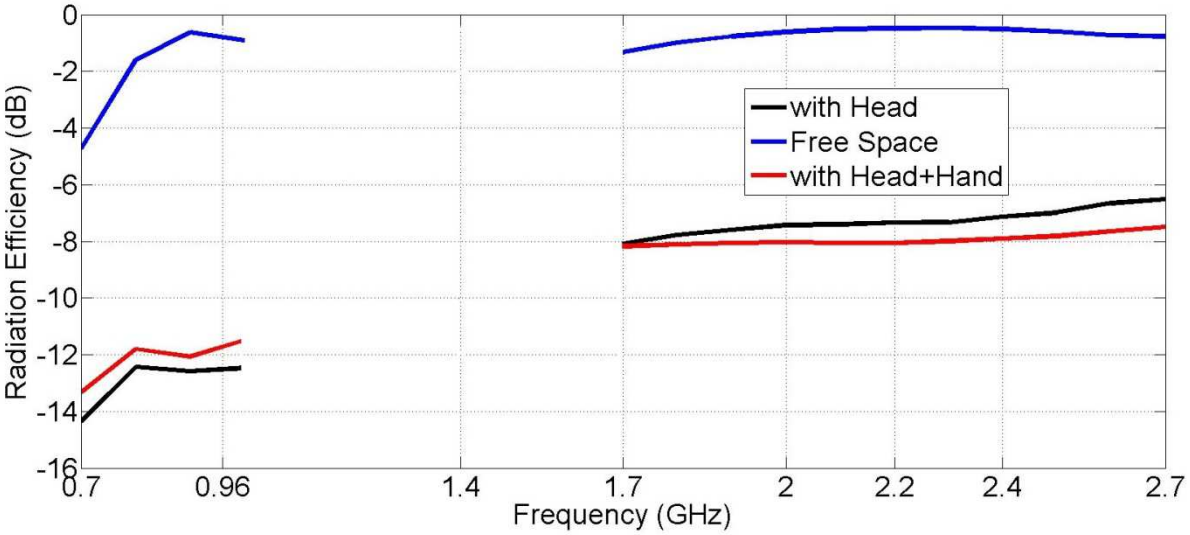

Figure 178 Simulated Radiation Efficiency for Eyewear Antenna-3 in Different Scenarios

4. CONCLUSION

In this chapter, an application example of CEs was presented, differently from mobile terminal antennas. The CEs were used to obtain coverage in the 4G cellular communication bands, in an eyewear structure, which are gaining popularity in the market as wirelessly connected wearable devices. Firstly, a feasibility study was performed using three different locations (behind the ear, in front of the ear and close to the eye) for the CEs, comparing the bandwidth potential and the expected SAR value. It was shown through the simulation results that placing the antenna just in front of the ear was giving the worst bandwidth potential. The potential was higher in "close to the eye" location and the highest behind the ear. It should be noted that these results are subject to

change due to modifications on the system ground plane. For the SAR, the minimum value was observed with "close to the eye" location since the radiating structure is further from the head when compared to the other two locations.

Taking into account the feasibility study, three antennas were designed, with a dielectric casing & frame. The first antenna, which is placed behind the ear, had the highest operating bandwidth with a continuous coverage from 700MHz up to 2.7GHz with a three element MN at the feed. The other two designs cover the 700-960MHz and 1.7-2.7GHz. The simulated radiation efficiencies are generally on the level of -12dB for the LB and -7dB for the HB. However, there is a significant increase in the radiation efficiency when the CE is placed close to the eye, since the head is further from the antenna, reducing the losses. For evaluating the real use case of the device, simulations were performed also with the user hand and in free space condition. It was shown through simulations that the hand does not cause a significant detuning, however poorer reflection coefficient behavior may be seen in free space, as expected.

5. PERSPECTIVES

The first target concerning the eyewear antennas is the fabrication of the antennas and the corresponding PCBs with MNs. Using the PCBs with the already manufactured dielectric frames, the measurements for the S-Parameters and total efficiency will be realized considering free space, with head and with hand+head conditions, as well as SAR measurements.

For the future steps, a MIMO scenario will be considered. The first idea about obtaining MIMO operation is to place one antenna on the right side of the head and the other to the left side. In this way, a good isolation level was observed in the initial simulations since the head acts as an absorbing element between the antennas, increasing the isolation. Considering the general characteristics of the radiation pattern (radiating away from the head), a low ECC value is also foreseen with this topology.

Another possible investigation will be based on the effects of the metallic frames instead of dielectric frames. The effect of metallic frames on the SAR of mobile terminals has been previously investigated in [19-23], showing the possibility of significant effects. For this reason, simulation and measurements will be repeated with metallic frames to compare the general antenna characteristics (with dielectric frame) as well as SAR levels.

CONCLUSION

Several different antenna designs have been proposed in this thesis, for mobile terminals operating in the 4G frequency bands, i.e 700-960MHz and 1.7-2.7GHz. A variety of strategies have been evaluated like single/multi-feed and also passive/active antennas. Antenna alternatives for different mobile communication devices (like electronic eyewear) operating in 4G standards have also been mentioned.

Tunable components have been evaluated in circuits placed at the feed of mobile terminal antennas to achieve frequency band reconfigurability in Chapter II. MEMS switches and BST tunable capacitors were used as the tunable components, which are under development in the scope of the Artemos project by partners. Two antennas exploiting the MEMS switches were proposed and the main aim was to obtain a band switching behavior, to select either LB (700-960MHz) or HB (1.7-2.7GHz) operation. Two such antenna designs were proposed, where one of the design uses two SPDT MEMS switches to select between one of the two MN branches and the other uses only one switch to select one of the two driven strips. Due to components' reliability difficulties, S-Parameter measurements could be performed for only one of these prototypes. For the measurement of the other prototype, passive antennas were manufactured and band-switching performance was verified this way. The target bands could be covered comfortably with a reflection coefficient below -6dB (observed as generally below -7dB or -8dB) in the measurements. The passive prototypes were also used for the total efficiency measurements, which are on average 50% in the LB and 65% in the HB. It should be noted that these values will for sure be subject to a slight decrease taking into account the insertion losses of the MEMS switches. Another antenna design was also proposed using a BST capacitor to tune the input impedance of the antenna in the 700-960MHz frequency range. The coverage of the HB was achieved with a separately fed antenna composing a dual-feed system. The measurement results of this antenna is planned to be done as soon as the integration of the BST capacitor to the antenna PCB is done.

The main advantage of the antennas with tunable components is the relatively lower reflection coefficient obtained especially in the LB (around -8dB), when compared to other passive prototypes. This would result in higher total efficiency than passive prototypes however considering also the insertion losses of the tunable elements and also the effect of the bias lines, a similar level in terms of total efficiency can be foreseen. On the other hand, the main drawback was the reliability of the tunable elements. The main reason is the continuing design & optimization phase for these components by their manufacturers (in Artemos project). More reliability and repeatability is foreseen after the finalization of the optimization phase of the components. Another disadvantage when compared to passive prototypes is the additional losses due to internal resistances of the tunable elements, which will in return cause decrease in the total efficiency. There is also the disadvantage about the carrier aggregation for LTE-A standards. For example for the band-switching topologies (with MEMS switches), it is not possible to use inter-band carrier aggregation since either the LB or HB is matched at a time.

In Chapter II, a study about the circuit model representation of a driven strip with a grounded parasitic strip was also carried out. The accordance of the circuit model was verified through electromagnetic simulations. Another issue addressed in this chapter was the radiation efficiency drop, that occurs in the HB for the antennas using parasitic strips. Solution techniques have been proposed using some modified topologies.

A summary of the tunable antennas mentioned in Chapter II can be seen in Table 10. The green shaded results in the table indicate measurement results with passive prototypes, blue shaded results indicate active measurements and yellow fields indicate simulations.

Table 10 Summary of the Performance of Tunable Antennas

	S11(dB) in LB		S11(dB) in HB		Eff(dB) in LB		Eff(dB) in HB		PCB Length	GND Length	Height
	Max	Min	Max	Min	Min	Max	Min	Max			
MEMS-1	-7	-16.2	-3.8	-30	- 3.7	-1.5	-3.5	-1.1	120mm	107mm	-
MEMS-2	-5.7	-17	-11.3	-33.7	-4.9	-1.7	-2.5	-1.1	115mm	100mm	-
BST	-3.2	-27.3	-4.9	-32	-	-	-	-	120mm	105mm	-

Dual-feed antenna structures using coupling elements were proposed in Chapter III, again covering the 4G standard frequencies. In these designs, the plain CE which was used extensively in the literature for mobile terminal antennas was modified, making it hollow. The coverage of the LB was achieved using these hollow CEs, with appropriate matching networks. Separately-fed monopole type antennas were used for the HB coverage, obtaining high isolation levels thanks to both antenna placement and band-stop characteristics of the matching networks. Measured total efficiency levels of 40-50% and 50% (on average) were obtained in the LB and HB respectively, which are over the 50% level generally expected in free space for mobile terminal antennas. These antennas had the advantage of being appropriate for both intra-band and inter-band carrier aggregation. A further advantage of the dual-feed topology is the opportunity to get rid of a diplexer in the RF front-end for inter-band carrier aggregation, which is definitely needed in a single feed antenna. An application example of the hollow CEs was further proposed in the same chapter, by placing two CEs on the corners of the PCB, to achieve MIMO operation in the LB (between 740-960MHz). The isolation between the two elements in lower LTE band was enhanced using a neutralization line between the antennas.

In Chapter IV, single-feed antenna designs manufactured using LDS technology were presented. Both antennas consist of a driven strip which capacitively excites a grounded parasitic strip for bandwidth enhancement. One of these antennas covers the low LTE/GSM/UMTS bands, whereas the other covers all the 4G bands. The main challenge for these antennas was the short ground plane (75mm, considered because of the 3.5 inch touchscreens common in most of modern smartphones), which makes it difficult to cover down to 700MHz. The total efficiencies of the antennas with 75mm ground plane were on average 35% in LB and 50% in HB. When the ground plane length was increased to 90mm, the LB efficiency was increased by approximately 10%, without any significant change in the HB. The effect of the user's hand and head was investigated on these antennas through measurements, to form a basis for future studies. The first results of this study were also presented at the end of the chapter, proposing an antenna topology resistant to detuning due to the hand of the user (in simulations only).

A comparison of passive antenna prototypes from Chapter III and Chapter IV is presented in Table 11, in terms of dimensions, reflection coefficient and efficiency. All the values presented in the table are measured results.

Table 11 Summary of the Performance of Passive Antennas

	S11(dB) in LB		S11(dB) in HB		Eff(dB) in LB		Eff(dB) in HB		PCB Length	GND Length	Height
	Max	Min	Max	Min	Min	Max	Min	Max			
HollowCE	-4.7	-9.1	-2.8	-27.5	-6	-1.9	-4.3	-1	114mm	100mm	3mm
PrintedCE	-3.1	-9	-3.8	-15	-5.1	-1.5	-4.3	-1.2	114mm	100mm	-
UMTS LDS	-5	-22	-5.2	-19	-7.7	-3	-3.9	-2	114mm	75mm	5mm
LTE LDS	-3.8	-15.9	-3.5	-16.3	-14	-3.1	-5.5	-1.7	114mm	75mm	5mm

Finally in Chapter V, antennas using coupling elements were proposed for 4G operation in an eyewear antenna. First, a feasibility study was presented by evaluating three different positions for the CE on the PCB of the electronic eyewear device, considering the bandwidth potential and SAR. Afterwards, three antennas were proposed with appropriate matching networks. The behavior of these three antennas was evaluated in different use cases like free-space, with the head and with head and hand (to stand for the user changing applications or settings by putting his finger on the touchpad).

To sum up, it can be told that the desired performances in terms of reflection coefficient (below -6dB) and total efficiency (higher than 50% in free space) have been achieved with the novel antenna designs in this thesis. A final note can be made be on the utilization of active tunable elements, comparing the tunable/passive antenna designs in this thesis. As presented, the passive antennas can reach the target performance without any tunable components in free space condition. This way, the additional losses, complexity (like biasing circuit) and reliability concerns from the tunable elements can be avoided. However, the utilization of the tunable components can be very useful for minimizing the effect of the user and increasing the total efficiency of the antenna for instance in a tunable matching unit at the antenna feed .

FUTURE PERSPECTIVES

A possible improvement for the antennas presented in this thesis can be to minimize the effect of the user on the reflection coefficient and by this way increase the total efficiency taking into account the user's hand, head or both. The user effect (hand and head) have been investigated for the single-feed antennas in Chapter IV (antennas on LDS) and it was seen through measurements that the antennas (placed on the bottom of PCB) get detuned (towards lower frequencies) when the hand of the user is taken into account.

A different antenna design technique was recently proposed in [1-3], considering in the design phase the matching performance of the antenna in the presence of the user. This technique relies on combining the antenna design with circuit design concepts to cover 700-960MHz, 1.7-2.2GHz and 3.3-3.8GHz frequency bands [1]. The novelty of the design is to transfer the complexity of the antenna design to the complexity of the circuit before the antenna (at the antenna feed). The main aim is to get a very wideband antenna so the detuning effect due to the user (which unavoidably exists) is minimized by this way. In these designs, multiple simple IFA type radiators are used. The first and second order resonances of these radiators are selected and combined together to get a wideband response using diplexers and power divider/combiners resulting in a single-feed topology. These circuitries are composed of lumped SMD inductors/capacitors with up to 27 lumped elements.

This approach proves to be very robust to detuning due to user effects in cases like right/left hand and with head (in right/left hand configurations). When this methodology is compared with the results of the antennas in Chapter IV of this thesis, it is evident that the total efficiency is considerably lower (on average) in this methodology for free space condition (between 5-40% in LB and 15-55% in HB). This relatively low efficiency may cause a problem for the mobile phone manufacturers during the manufacturing tests in free space condition. Although robust to detuning, the measured efficiency with the user hand in [1] (5% in LB, 10% in HB on average) is also lower by approximately 3dB when compared to the antennas in this thesis. The results are approximately the same for the measurement with the head. However, one good advantage of this approach is that the designs can be integrated to any mobile phones by changing the values of the components in the circuitry.

Keeping this in mind, the main focus for the future studies on the user effects of the antennas in this thesis should be to minimize the detuning. For this purpose, some rule of thumbs were deduced in Chapter IV, from the measurements with hand/head to foresee the possible changes in the input impedance with user effects. Using this background, the first results from a dual-feed antenna design was presented with both simulations and measurements.

Another study was also started to design a wideband antenna as to cover 700MHz-2700MHz continuously, both to minimize the detuning due to user effects and also to enable the coverage of possible other standards (like GPS). The main target is to obtain a very high bandwidth potential around 1700MHz (which is the center frequency in this case) and thus obtain a very wideband antenna. For this purpose, the first simulation results of the antenna given in Figure 179 can be seen in Figure 180. The antenna consists of a driven strip printed under the plastic piece (same as the plastic pieces in antennas manufactured with LDS technology), which capacitively excites a loop antenna connected to the system ground plane at both ends. To increase the electrical length of the loop, two lumped inductors (each 25nH) are modeled in series with the loop, located at the

grounding points. A two element matching network consisting of a shunt capacitor (0.6pF) and series inductor (5.6nH) is used at the feed.

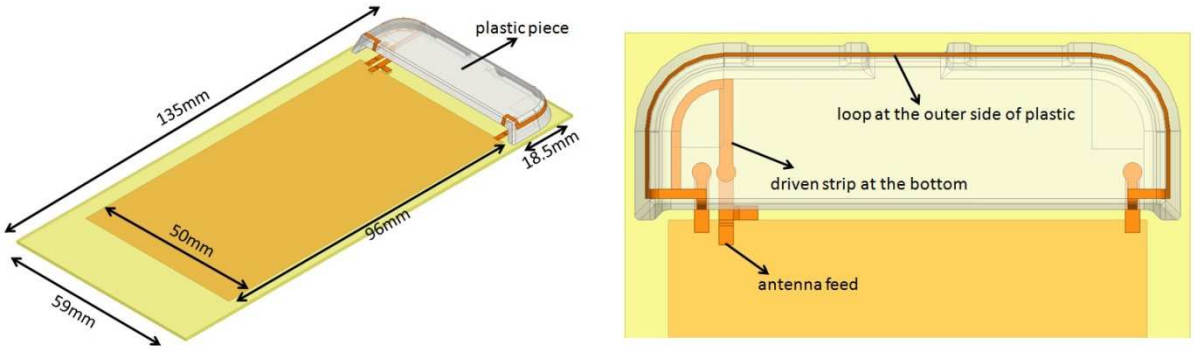

Figure 179 Parasitic Loop Antenna Model

As seen in Figure 180, the antenna can cover the interval of 700-2700MHz continuously with a reflection coefficient below -6dB. The simulated radiation efficiency of the antenna is given in Figure 181. A relatively low radiation efficiency is seen around 700MHz (30%) whose main reason is the high loss resistance values of the 25nH inductors modeled in simulations. It is foreseen that the efficiency can be increased by using lower value inductors (hence lower losses), by increasing the physical length of the loop by meandering.

ABSTRACT

With the introduction of the fourth generation (4G) of cellular mobile communications, there has been an increase in the frequency bands that a generic mobile phone should be able to operate. This requirement poses some challenges in the design of the transceiver modules of the device as well as the RF front-end and the antenna.

From the antenna design point of view, the newly added frequency bands especially LTE bands 12-13-17 which goes down to 700MHz creates the main design challenge: covering 700-960MHz (30% bandwidth) in the low-band, considering also backward compatibility with the former technologies like GSM850/900. Since the space reserved for the antenna is electrically small in this frequency range, special design techniques are necessary to obtain the required bandwidth for a generic mobile terminal antenna.

It should also be taken into account in the design phase, that the antenna needs to be appropriate for operation in the data-rate enhancement techniques like MIMO (multiple input multiple output) and carrier aggregation in LTE-Advanced. Furthermore, considering the real use cases of the mobile terminal, the effect of the user (hand, head and both) on the antenna performance should also be investigated.

In this thesis, several antenna designs for 4G coverage in mobile terminals are proposed. Different antenna topologies are evaluated consisting of tunable/passive antennas as well as single/multi-feed structures.

RÉSUMÉ

Avec l'introduction des standards de communication de quatrième génération (4G) dans la téléphonie mobile, les bandes de fréquence dans lesquelles un téléphone mobile générique doit fonctionner ont naturellement augmenté. Ces évolutions ont induit de nouveaux challenges techniques notamment en ce qui concerne la conception des modules d'émission-réception, du frontal RF mais surtout des antennes.

Les bandes de fréquences nouvellement ajoutées, en particulier les bandes LTE 12/13/17 qui descendent jusqu'à 700 MHz, constituent le défi antennaire majeur: couvrir la bande basse des 700-960MHz (30%) notamment en incluant la bande GSM850/900 compte tenu de la rétrocompatibilité avec les standards 3G. Etant donné que l'espace réservé pour l'antenne dans un terminal portatif est électriquement petit (dans cette gamme de fréquences basses), des techniques de conception spécifiques doivent être mises en œuvre pour pouvoir couvrir toute la bande de fréquence basse.

Dans la phase de conception, il doit également être pris en compte le fait que l'antenne ou les antennes puissent incorporer des techniques d'amélioration de débit de données telles que le MIMO (Multiple Input Multiple Output) et l'agrégation de porteuse (Carrier Aggregation) pour le LTE-Advanced. De plus, si l'on considère des cas d'utilisation réalistes, les effets de l'utilisateur (main, tête) sur les performances globales du terminal doivent aussi être examinés.

Dans cette thèse, plusieurs concepts d'antennes 4G pour les futurs terminaux mobiles sont proposés. Différentes topologies antennaires sont évaluées notamment des antennes reconfigurables / passives ainsi que des structures à alimentation simples et multiples.

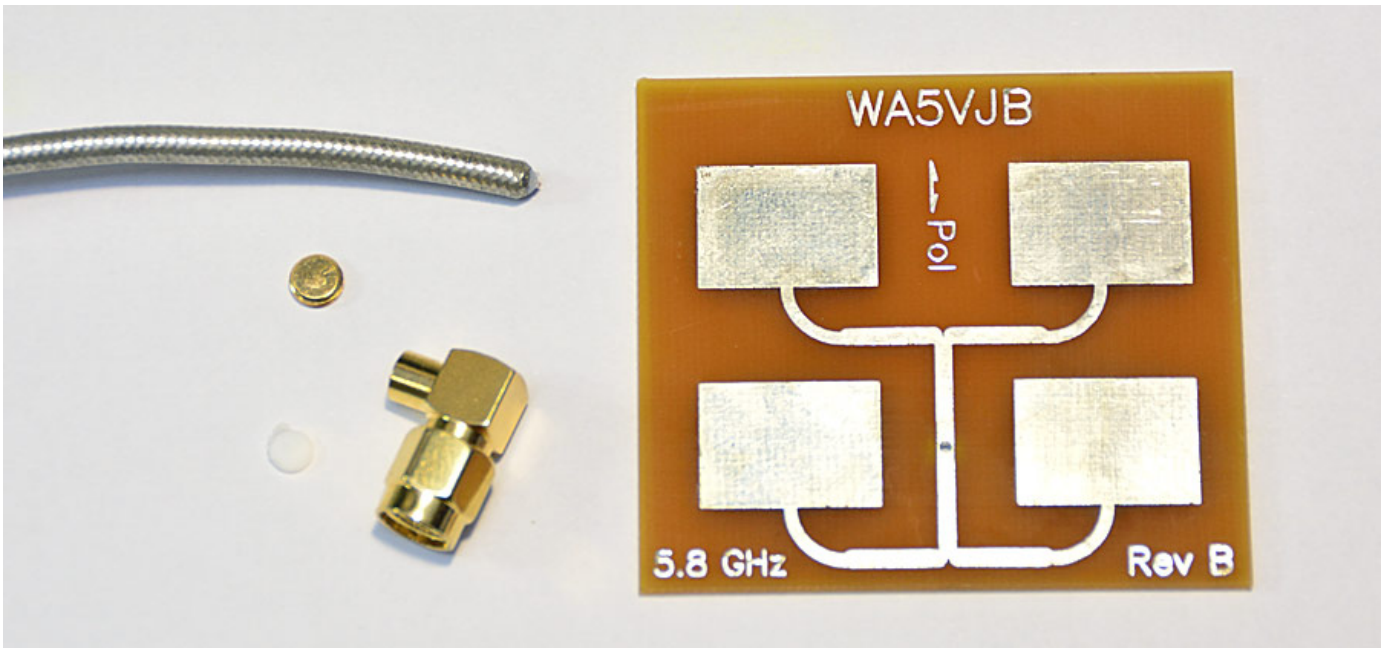
Homebrew 5.8 GHz patch FPV antenna

Posted on September 26, 2014 (http://vk4ghz.com/homebrew-5-8-ghz-patch-fpv-antenna/) Posted in FPV (http://vk4ghz.com/category/multirotors/fpv/), Multirotors (http://vk4ghz.com/category/multirotors/)

Like Share 35 people like this. Be the first of your friends.

These 5.8 GHz PCB patch antennas come from Kent Electronics (http://www.wa5vjb.com/) in Texas, USA.

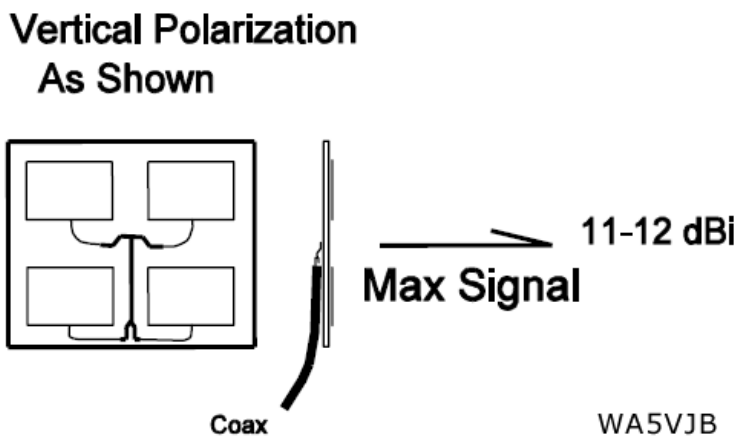


You can download the product PDF from here (http://www.wa5vjb.com/pcb-pdfs/5800MHzPatchArrays.pdf).

The quad patch array (pictured above) offers 11 – 12dBi gain, or 8.8 – 9.8 dB gain over a (unity gain) dipole.

To put that into a simplistic terms, is almost 10 times better than your dipole.

Along with some UT141 semi-rigid hardline coaxial cable, and a right-angle SMA (m) connector, both from RF Supplier (http://www.rfsupplier.com/) in Shenzhen, China, a low-cost patch antenna can be made for multirotor FPV use.



Another handy store for connectors and coax in Brisbane is The RF Shop (http://rfshop.com.au/), located in Oxley.
RF Shop is more expensive than a Chinese online store, (and most of their product is better quality, from Taiwan), and operates out of a home, but give them a call first, as they don't mind if you drop in and pay & pick up.

First step, prepare one end of the 141 to be soldered to the SMA (m) connector.

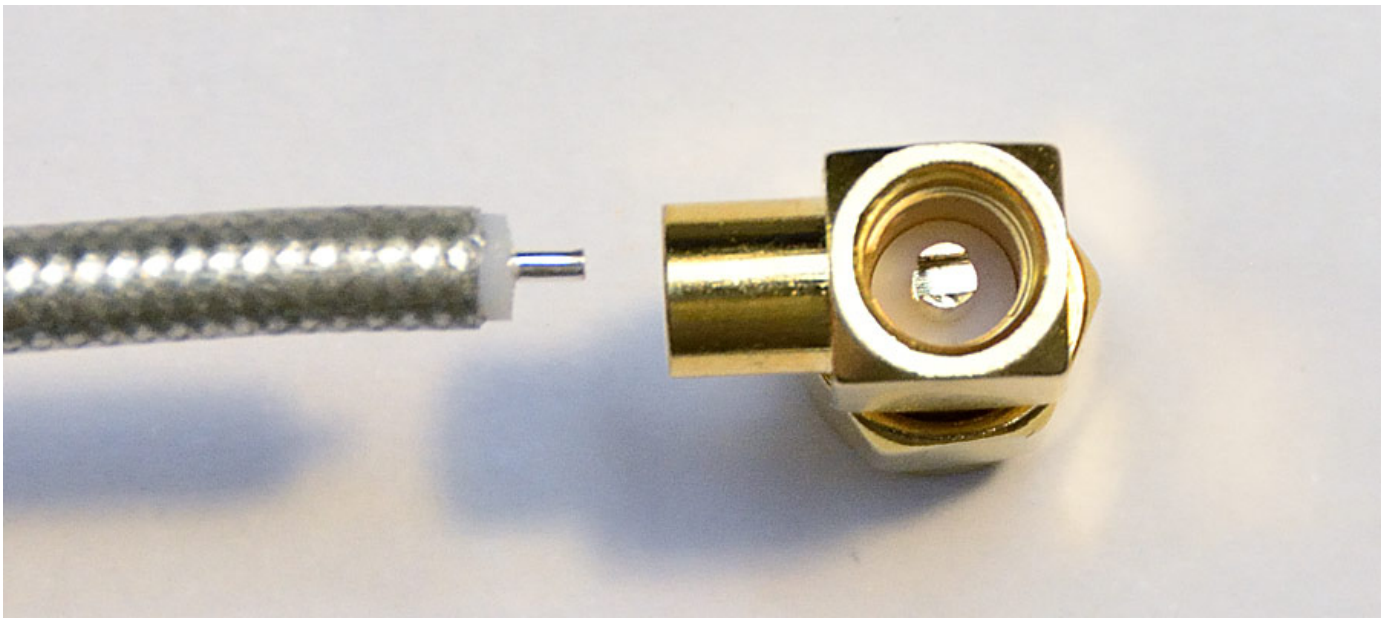
Working with 141 and SMAs is almost idiot proof.
141 has a teflon dielectric, so unlike RG58 type cable for CB or ham use, won't deform/melt with abuse from a soldering iron!

Start by preparing one end to suit soldering to the SMA (m) R/A connector.,

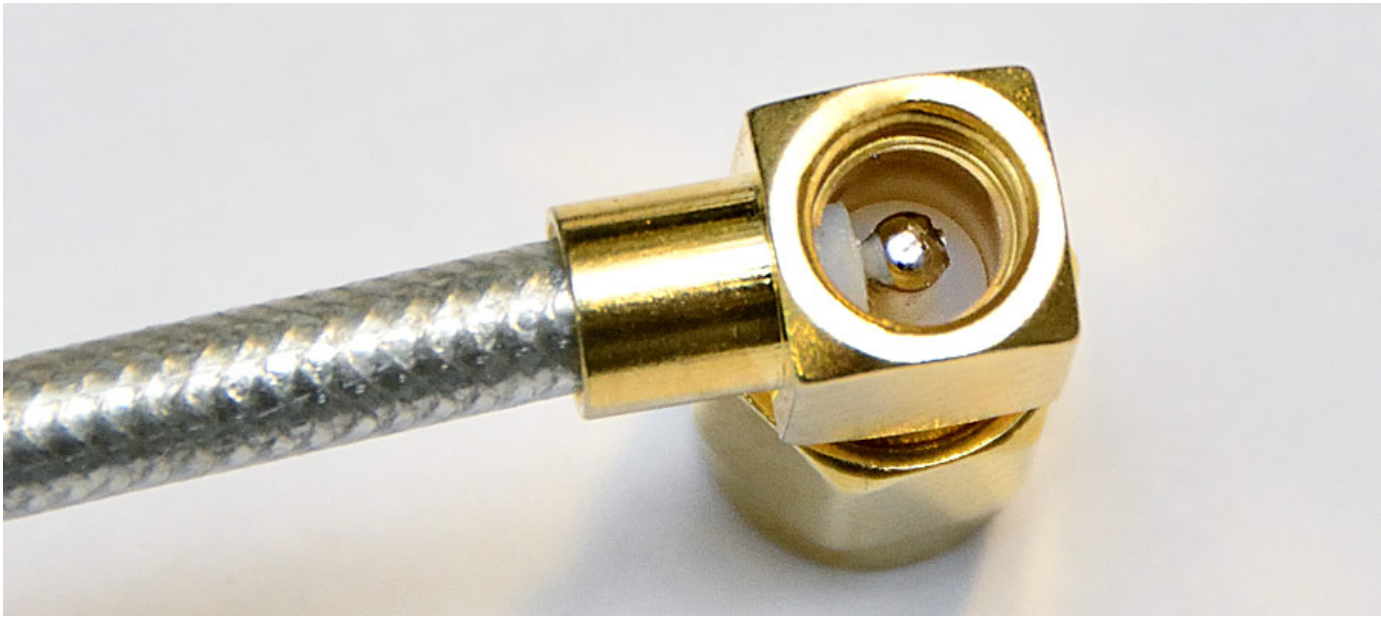
Score the outer sheath with a blade, as you rotate the coax (being careful not to cut into the dielectric):

Using pliers, twist and pull off the outer sheath, like so:
(I'm cheating, using a picture from further down)

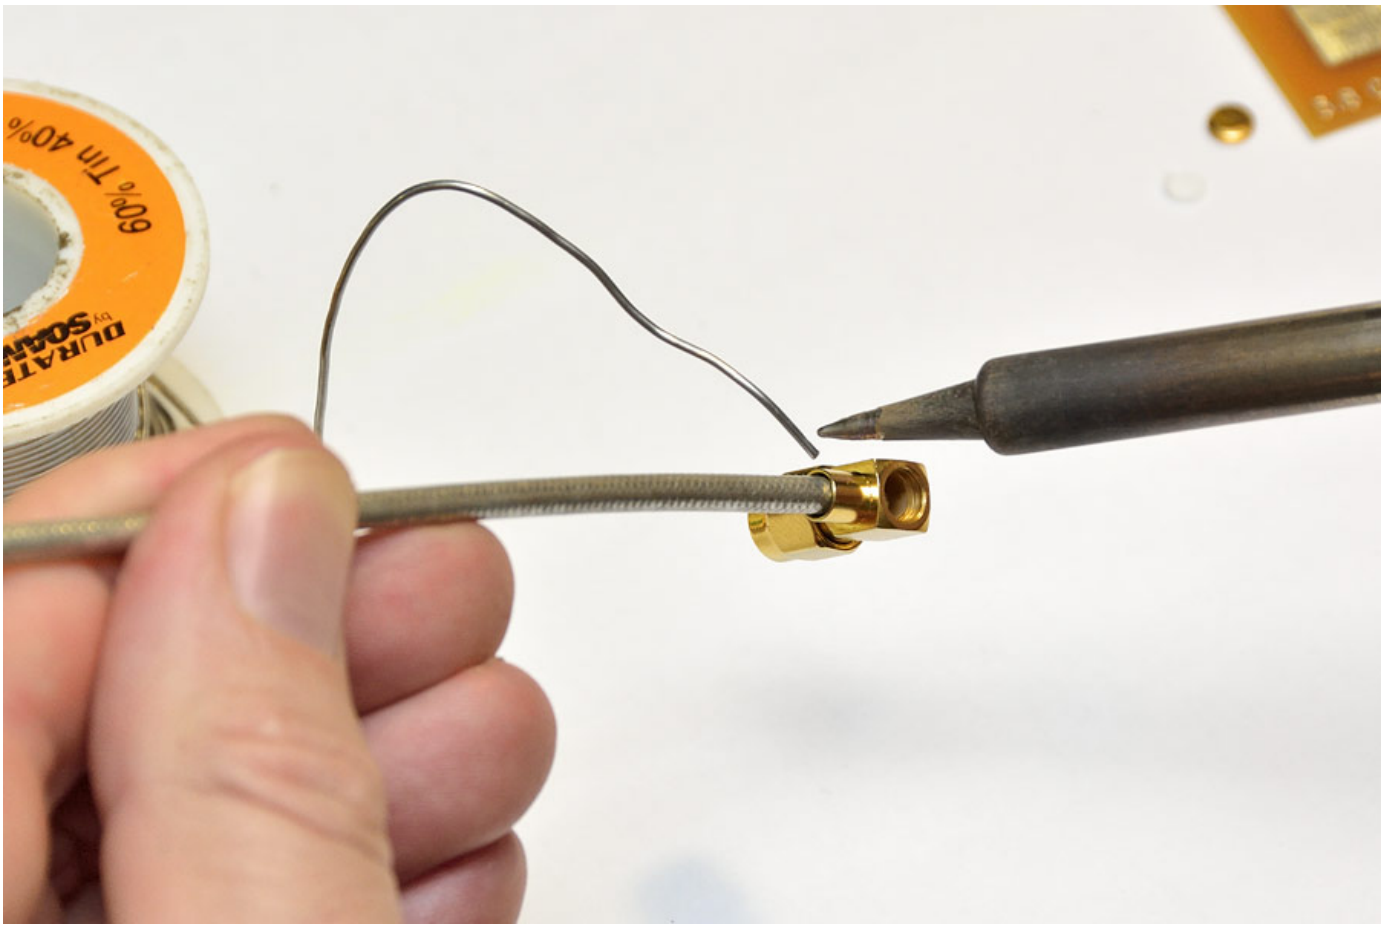
Coax end prepared, ready to solder to R/A SMA (m) connector:



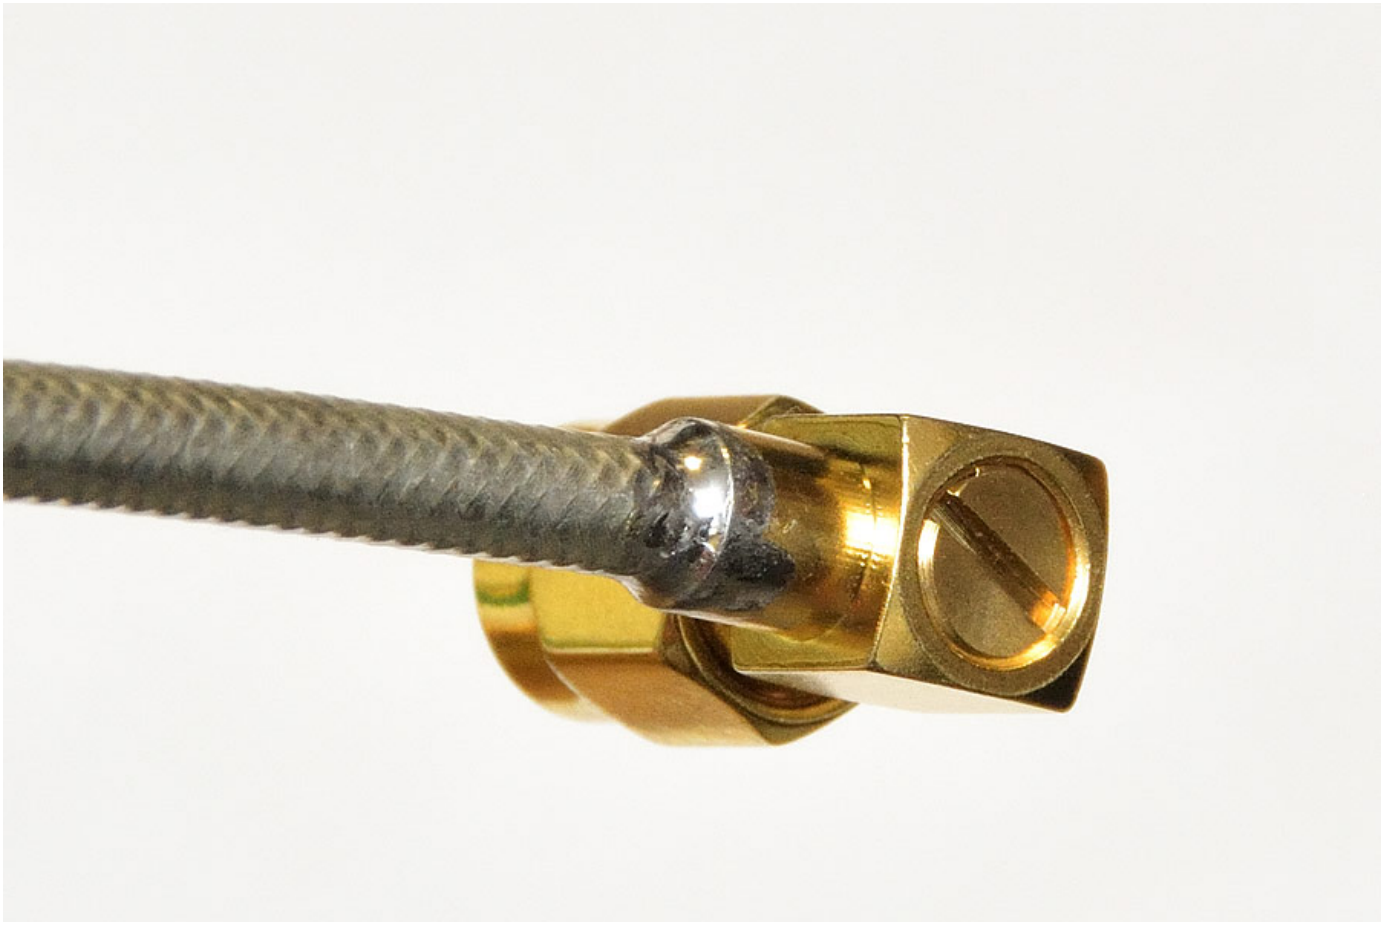
Coax inner soldered to centre pin:



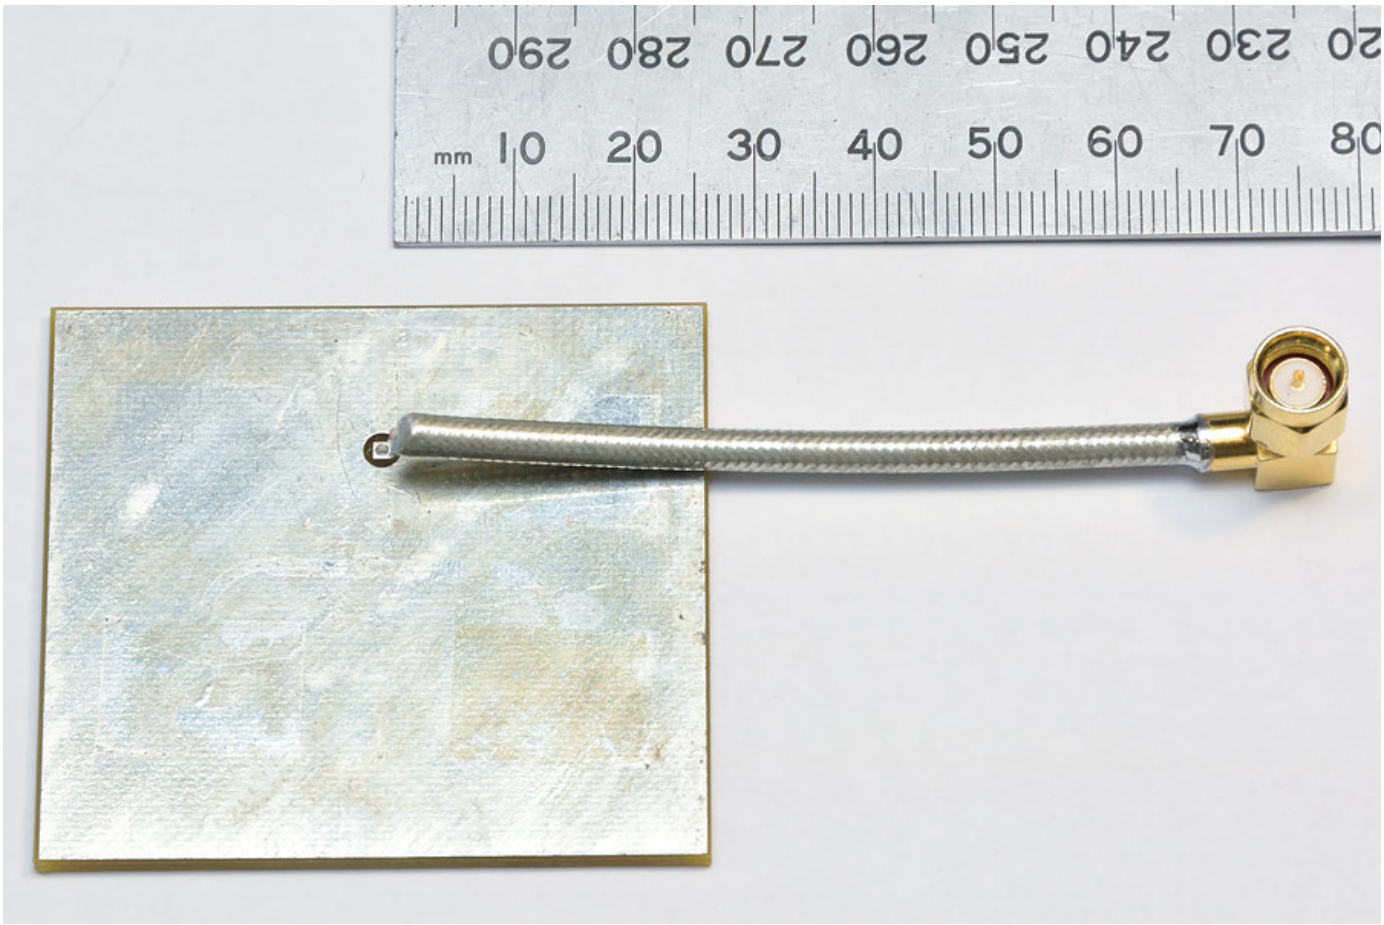
Add fillet of solder around outer sheath/connector body:



End cap screwed on:
Terminated!



A nominal length of coax is chosen:

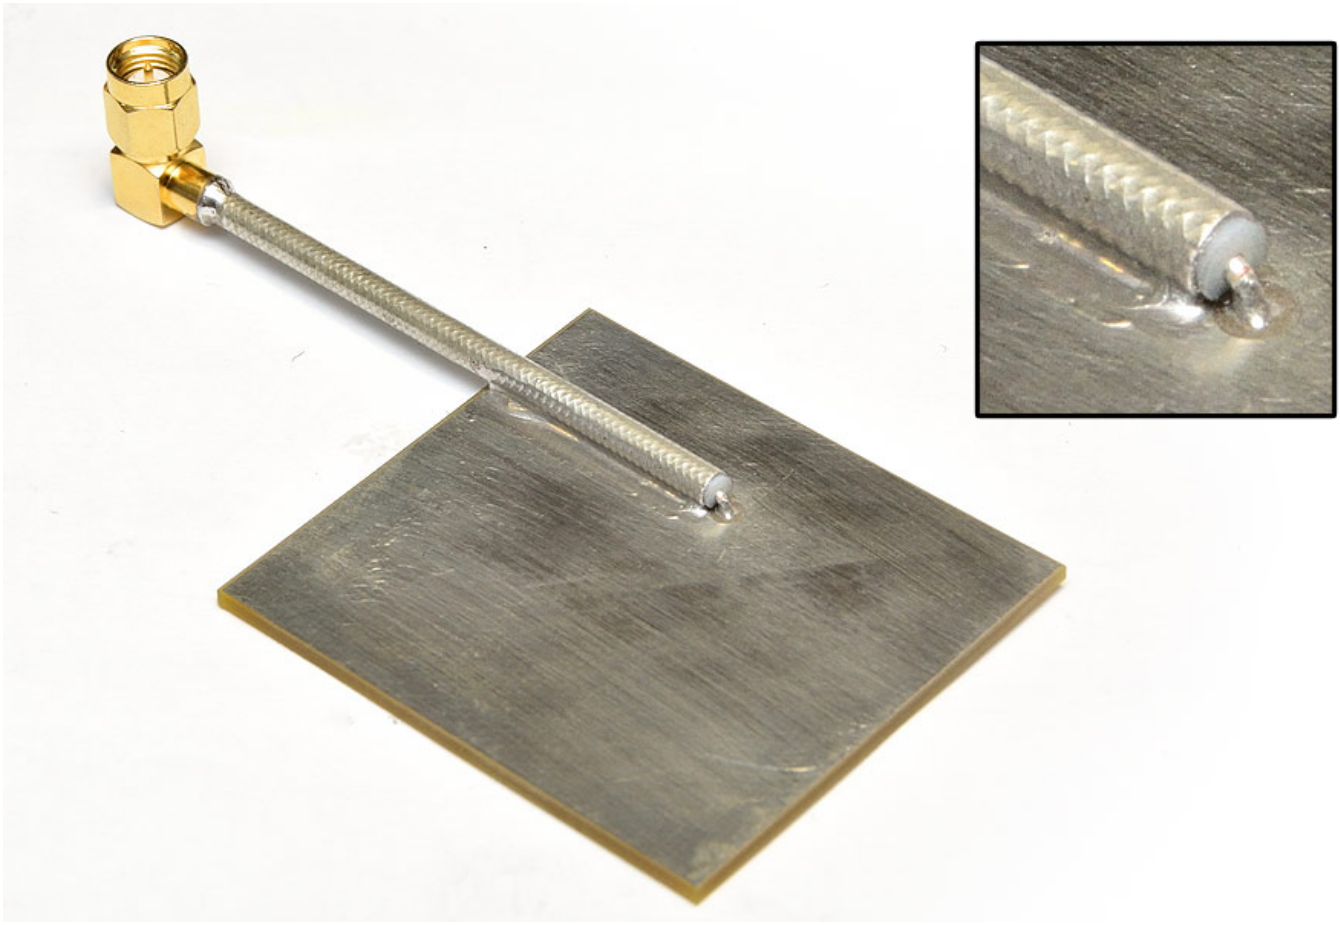


Sorry Americans, in millimetres… about time you adopted the metric system, like everywhere else! 😉

By the way, nothing fancy in the soldering department… just a bog standard Weller:

Coax end prepared, ready to solder to PCB:

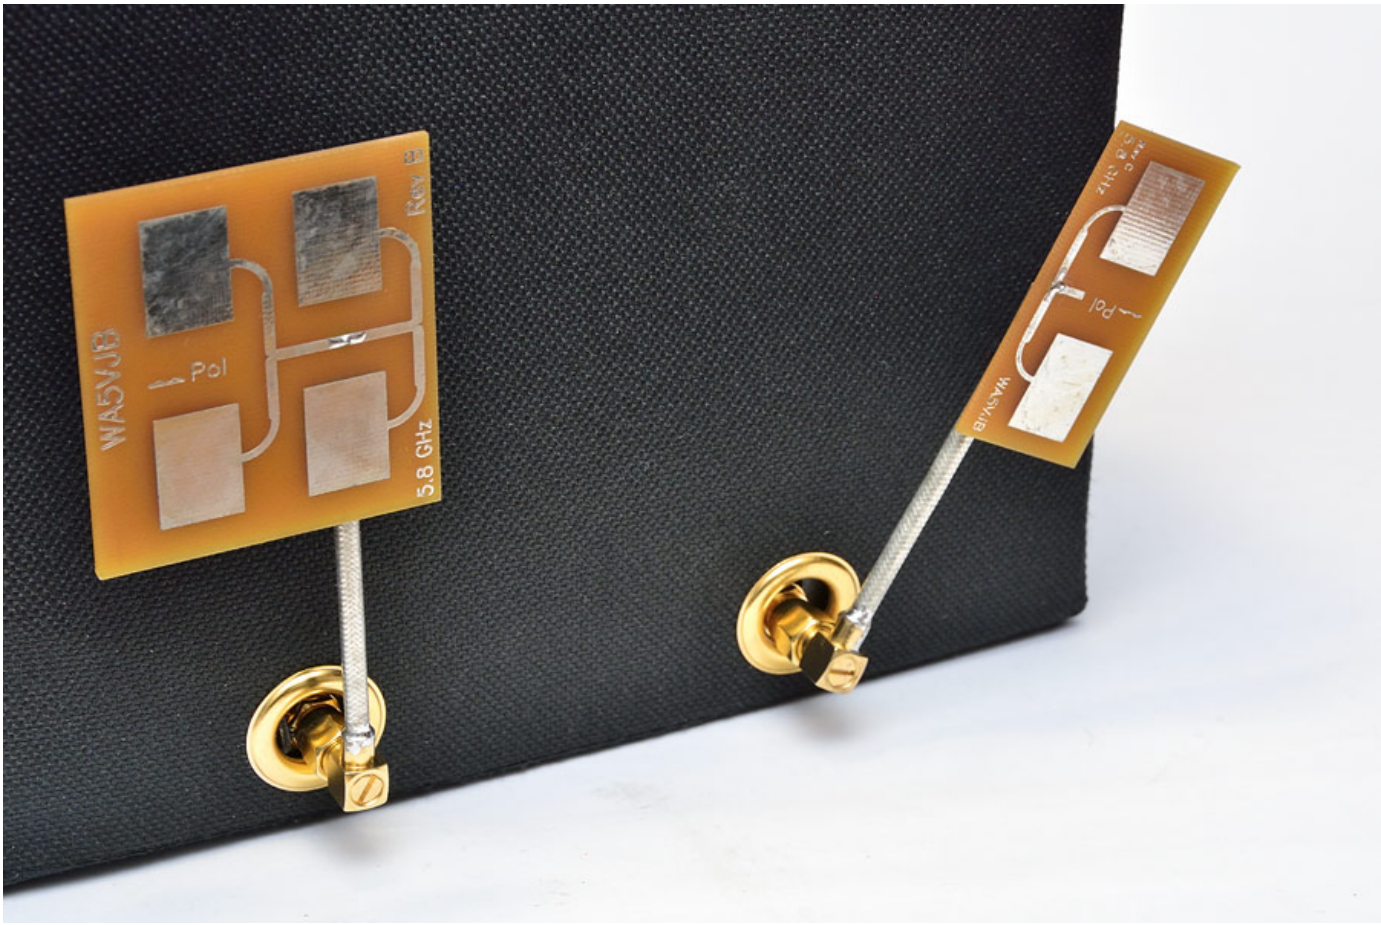
Coax soldered to the PCB antenna:

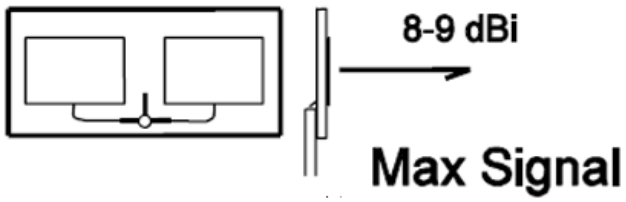


Note the fillet of solder that runs along the coax (on both sides), fastening the outer sheath to the ground plane of the PCB.

Installed on the rear of the 5.8 GHz diversity receiver/monitor, set up for horizontal polarisation:

A dual patch antenna was constructed as well.
Same procedure:





WA5VJB

Also on hand is a short in-line flexible “adapter”, with a male SMA at one end, a 30mm length of 141, and a female SMA, should a small angle be required:

As all hams operating on the microwave bands know, when dealing with SMAs, a 5/16″ spanner is always a handy tool to have:

Super Cheap Auto often have a bargain $1 bin on various size spanners.
Have a look for a 5/16″ next time you're in SCA.

A Feed Network for a Novel E-H Shaped Microstrip Patch Antenna Array

N. Misran, M. Tariqul Islam and K.J. Ng

ABSTRACT

This research presents a beamforming feed network for a novel E-H shaped microstrip patch antenna array. The broadband microstrip antenna array was developed based on the novel L-probe fed inverted hybrid E-H (LIEH) shaped element design arranged into 4x1 uniform linear array antenna, fed by a feed network. The corporate 4-ways Wilkinson power divider which was fabricated in-house covering the frequency range from 1.83-2.29 GHz (460 MHZ) were integrated to form the beamforming feed network. The beamforming feed network comprises of commercial variable attenuators (KAT1D04SA002), variable phase shifters (KPH35OSC000) and the corporate 4-ways Wilkinson power divider which was developed in-house. The developed 4-ways Wilkinson power divider achieves bandwidth of 22.33% at VSWR 1.25. The measured isolation and insertion loss are 30.72 and 0.32 dB correspondingly. The feed network developed and fabricated in-house has been shown to function well within its design ability.

INTRODUCTION

The evolution of **wireless communication**s has a deep impact on the field of antenna design. One essential component of the antenna array is its feeding technique. In an antenna array multiple radiating elements are assembled in an electrical and geometrical configuration. The antenna array provides beamforming capability to extract the desired signal and simultaneously filtering out the unwanted interference signal and environmental noise.

In designing array antenna, dipole, horn, waveguide slot or microstrip antenna can be used as radiating elements. However such radiating elements are unable to meet the requirements to be aesthetic and light weighted if implemented on the cell sites. To be aesthetic, the radiating element of the antenna array is desired to be small in size, low profile, conformal and compatible with integrated circuit and etc. Therefore, the radiating elements are preferred to be fabricated by microstrip technology that offers its non-electrical characteristic advantages (Pozar and Schaubert, 1995). Microstrip antennas are low profile and light weight. They can also be made conformable and well suited to be integrated with microwave integrated circuit (Lau *et al*., 2006; Zhang and Wang, 2006). In terms of fabrication, such system offers simplicity, which allows mass production and cost-effective manufacturing as well as high performance.

A combination of X- and C-band slots and patches were investigated and it was concluded that C-band patch/X-band slot concept had the greatest merit. In that design, the C-band feed network was on the same plane with the patches while the X-band feed was behind the ground plane. A combination of stacked perforated L-band patch overlaid over an array of C-band patches to achieve shared-aperture L/C-

Translate was reported in Shafai *et al*. (2000). Employing similar feeding principles, the C-band feed network behind the ground plane was aperture-coupled to the patches. The L-band feed network was on the same plane with the lower L-band perforated patch. This idea was further developed and applied to L- and X-band array in Pozar and Targonski (2001).

In their studies, Targonski and Pozar (1998) noted that it was impossible to accommodate two linear polarizations for two separate frequencies on a single feed layer. Maci and Gentili (1997), adding that single feed network for two frequencies was the most critical problem to solve for a dual-band array. Current dual-band shared-aperture technology suggests employing the higher- frequency feed network behind the ground plane (aperture-couple) and the lower-frequency feed network above the ground plane (coplanar feed). This may be because higher frequency feed produces higher spurious radiation, due to shorter wavelength and longer layout length. In a small array, feed layout above the ground plane may not produce excessive spurious radiation. However, in a larger array, feed line radiation may not be ignored.

In this research, the beamforming feed network was constructed using a four-way Wilkinson power divider of corporate structure type and a phase shifter-attenuator networks, connected in series to the ports to examine the scanning capability of the array. Due to the high cost and complexity of the design for planar and high resolution array, the design focuses on the development of a four-element (4x1) array antenna.

BEAMFORMING FEED NETWORK

A feed network is integrated with the antenna array. The radiating element of the antenna array is based on the LIEH shaped Microstrip Patch Antenna (MPA) that is arranged in a 4x1 linear array configuration which is termed as Broadband Microstrip Patch Antenna Array (BMPAA). The antenna array is constructed using two dielectric layer arrangement where a thick air-filled substrate was sandwiched between top-loaded dielectric substrate or superstrate with inverting radiating patch and an aluminium ground plane. The antenna array is used contemporary design techniques namely, the L-probe feeding, inverted patch and slotted patch techniques to meet the design requirement.

The difference in amplitude and phase of the array is fed to each element by feed network. This causes the radiating field of each element combines constructively in the intended direction and cancel out each other at other undesired directions in the far field (Balanis, 1997). Thus higher power gain and more flexibility in controlling the shape of the beamwidth and sidelobe levels can be achieved from this method. Moreover, the feed network allows the radiation pattern to be varied for beam scanning without any physical antenna motion.

Arrays can be fed in many ways, but the two general types of feed arrangement for microstrip patch arrays are series feed and corporate feed. Microstrip patch array in a series feed network is fed by a single transmission line, whereas patch array in a corporate feed network is fed by multiple transmission lines. Series feed network is much easier to design and fabricate compared to the corporate feed network. However this method will result in progressive phase delay between elements thus making unsuitable for phase scanning. Another problem with series feed arrangement is the high VSWR that is caused by the additive mismatches at the various junctions between the elements (Zurcher and Gardiol, 1995).

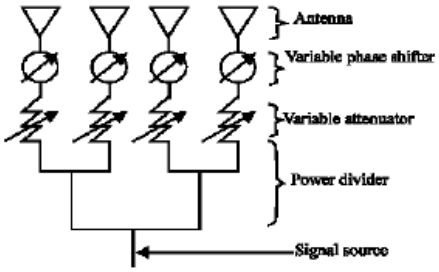

Fig. 1: Schematic diagram of a beamforming feed network

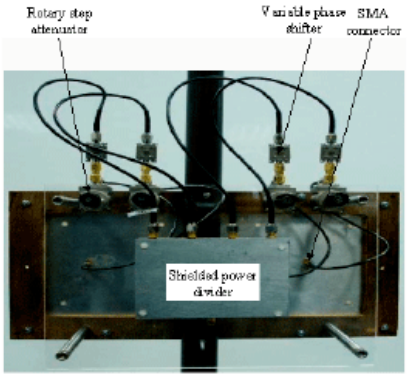

Fig. 2: Rear view of the 4x1 LIEH shaped BMPAA with a beamforming network

Corporate feed network is more flexible and offers better phase control over the performance of each array element. It is best suited for scanning phased array, multi beam arrays or shaped beam arrays. However, the use of corporate feed network is more preferable over

Translate

s work as it is less affected by frequency scan. A corporate feed network supplies excitation individually to each array element and use equal line lengths and power dividers for each element.

The beamforming feed network for the BMPAA consists of a 4-ways corporate structure Wilkinson power divider and a network of phase shifter-attenuator as shown in Fig. 1.

The phase shifter-attenuator network comprises of a commercial off-the-shelf (COTS) variable phase shifter KPH350SC00 and step-rotary attenuator KATID04SA002, both are from KMW Inc. The 4-way Wilkinson power divider was developed and fabricated in-house by using Taconic RF-35 with the dielectric permittivity, ε_{r1} of 3.5, thickness h = 0.76 mm and with the dimension 25x20 mm. Table 1 gives the summary of the beamforming feed network design and its electrical parameters.

Figure 2 shows the fabricated beamforming feed network connected to the antenna array. As shown in the Fig. 2, the power divider is covered by an aluminium shield and the antenna array is behind the power divider.

Table 1: Summary of the beamforming feed network

Parameters	Values
A. Wilkinson Power Divider	
Substrate	Taconic RF -35 (ε_{r1} = 3.5, h = 0.76 mm)
B. Phase shifter	
Insertion loss	0.25 dB (1-2 GHz)
0.35dB (2-3GHz)	
VSWR	1.25
Phase shift	35° @ 2 GHz
C. Attenuator	
Frequency range	DC~3 GHz
Insertion loss	0.2 dB
VSWR	1.15
Attenuation step	10 attenuation step of 1 dB

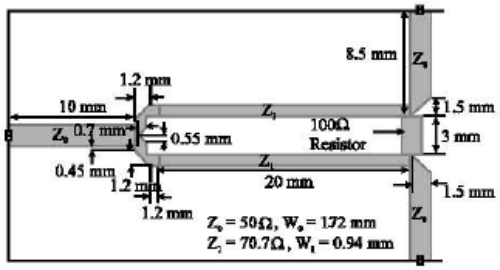

Fig. 3: The layout of 2-ways Wilkinson power divider on substrate Taconic RF 35 (ε_{r1} of 3.5, h = 0.76 mm and δ = 0.0018)

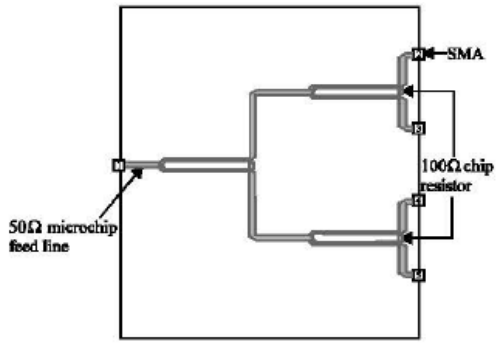

Fig. 4: The layout of 4-ways Wilkinson power divider

A 4-ways power divider is designed as a corporate feed network to feed the radiating elements with equal amplitude and phase. This power divider is based on Wilkinson power divider which offers good matching in all ports with good isolation between the output ports. The Wilkinson power divider has a useful property of being lossless when the output ports are matched, that is, only reflected power is dissipated (Pozar, 1990). The design schematic for the 2-ways Wilkinson power divider layout is shown in Fig. 3 and the layout of a 4-ways Wilkinson (3 dB) power divider is shown in Fig. 4.

Translate

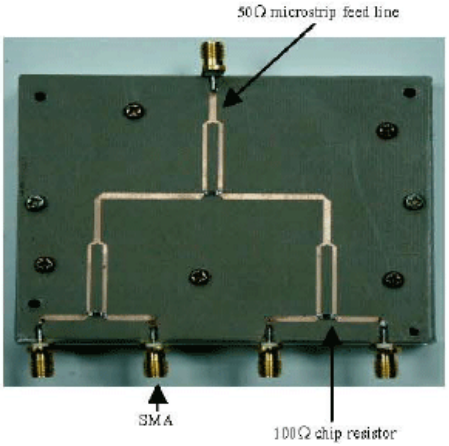

Fig. 5: Fabricated 4-ways Wilkinson power divider

Figure 5 shows the fabricated 4-ways Wilkinson power divider which is fabricated on Taconic RF-35.

RESULTS AND DISCUSSION

The antenna array and the power divider are simulated by *Sonnet® Suite em* simulator. The fabricated antennas and power divider are measured using the Agilent PNA E8358A network analyzer, Agilent ESG-DP Series E4436B signal generator, Advantest R3131A spectrum analyzer and the standard gain LPDA-0803 log periodic dipole antenna. SMA connector calibration kit, SMA male to male cable and automatic controlled rotator are also required for the measurement. Measurement is conducted in the UKM microwave lab and the UKM open field. The return loss measurement of 4-ways Wilkinson power divider is taken by using the Agilent PNA E8358A network analyzer. Return loss of every terminal is measured by terminating other element with 50 Ω load. Figure 6 shows the return loss at 1st terminal in 4-ways Wilkinson power divider. The measurement result shows higher value than the simulation results. This is due to the effect from SMA connector of every terminal. The aluminium ground plane is used to support SMA connector that is not been grounded properly. This installation problem causes the higher value of measurement; besides the used SMA connector, probe pin is not tapered. Simulated and measured return loss results are in good agreement in all terminals. The operating range for power divider is from 1.83-2.29 GHz (460 MHz) with bandwidth 22.33% at VSWR 1.25 considering all terminals.

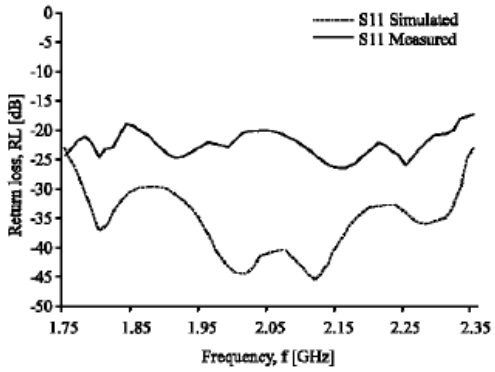

Fig. 6: Measured and simulated return loss of port 1 of the 4-ways Wilkinson power divider

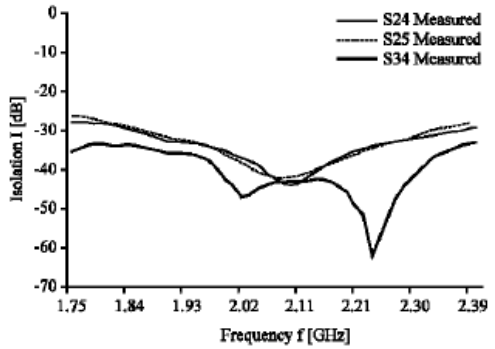

Fig. 7: Measured isolation of the 4-ways Wilkinson power divider

Table 2: Summarized result of power divider

Translate

Properties	Measurement results
Bandwidth	460 MHz (1.83-2.29 GHz at VSWR = 1.25)
Isolation	30.72 dB
Insertion loss	0.32 dB
Amplitude balance	0.70 dB
Phase balance	5.40°

Isolation of 4-ways Wilkinson power divider is shown in Fig. 7. The maximum value of isolation in the operating frequency range is at 30.72 dB. The measurement results of power divider are shown in Table 2.

Figure 8 and 9 show the E-plane and H-plane radiation patterns of the antenna array at 1.91 and 2.14 GHz (resonance frequencies) by using feed network. Chebyshev amplitude distribution is used to have narrow beamwidth and low equal side lobe level (-20 dB). Chebyshev distributions value is shown in Table 3 as normalized in dB.

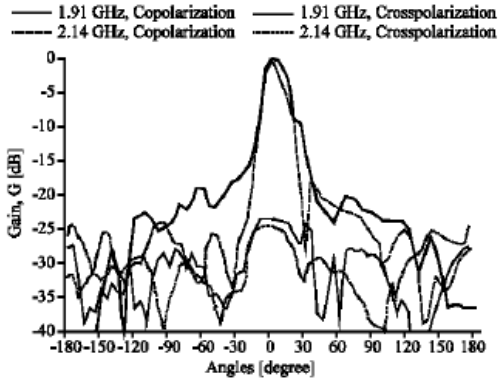

Fig. 8: Measured E-plane radiation patterns for the LIEH shaped BMPAA at 1.91 and 2.14 GHz

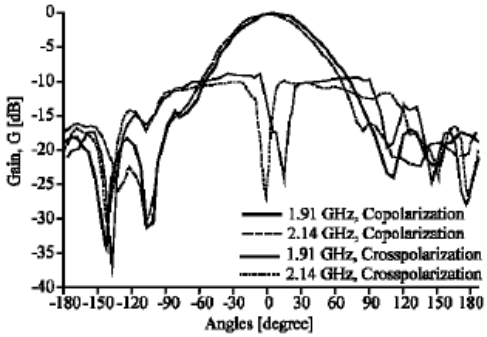

Fig. 9: Measured H-plane radiation patterns for the LIEH shaped BMPAA at 1.91 and 2.14 GHz

Table 3: Chebyshev distributions for each element of 4x1 BMPAA

Element-1	Element-2	Element-3	Element-4
0.48312 (3.1594 dB)	1(0 dB)	1(0 dB)	0.48312 (3.1594 dB)

Table 4: Amplitude and phase value for measurements

0° Scanning Element-1	Element-2	Element-3	Element-4
-10.06 dB	-6.5 dB	-7.5 dB	-9.65 dB
100.0°	-50.85°	149.3°	2.55°

However, the exact amplitude and phase distribution were unable to obtain due to the limitation of the available variable attenuator and phase shifter. Therefore, the antenna radiation pattern result is expected to be distorted from the desired performance.

Scanning pattern is measured for 0°.Amplitude and phase values are chosen by considering the following initial phase angle and by employing progressive phase shift equations. Amplitude and phase values for measurement are shown in Table 4.

Initial phase angle: Port 1: 100°
Port 2: 105°
Port 3: 101°
Port 4: 105°

The phase in each element of the array is progressively shifted by $\alpha = -\beta d\cos\theta$, where β is the phase shift factor and d is the inter-element spacing.

Translate

patterns show some fluctuations due to the reflection from some obstacles in the field, however, they have good beam patterns and crosspolarization level, which is shown in Fig. 8 and 9. The 3 dB beamwidth is closed to 25° for the E-plane while the 3 dB beamwidth is about 65° for the H-plane. The H-plane radiation pattern is virtually symmetrical, while the E-plane radiation pattern exhibits some asymmetries, which is similar in the report by Huynh and Lee (1995) using a thick substrate. As shown in Fig. 8, the sidelobe levels are unequally distributed. The first side lobe levels at 1.91 and 2.14 GHz are -18.9 dB (at -60°) and -20.47 dB (at 45°), respectively. This result is due to the amplitude/phase unbalances in the beamforming feed network. The maximum crosspolarization of the array is in the order of -23.47 and -10 dB for E-plane and H-plane, respectively.

CONCLUSION

The beamforming feed network was constructed using a four-way Wilkinson power divider of corporate structure type and off the shelf variable phase shifter (KPH350SC00@ KMW Inc) attenuator (KATID04SA002@ KMW Inc) networks to measure the beamforming capability of the array antenna. Due to the high cost and complexity of the design for planar and high resolution array, the design focused on the development of a uniform four-element (4x1) array antenna. The array designed by employing novel hybrid E-H shaped design, inverted patch, slotted patch and L-probe. The developed 4-ways Wilkinson power divider enjoys the bandwidth of 22.33% at VSWR 1.25. The measured isolation and insertion loss are 30.72 and 0.32 dB correspondingly.

Abstract

This thesis focuses on mobile phones antenna design with brief description about the historical development, basic parameters and the types of antennas which are used in mobile phones. Mobile phones antenna design section consists of two proposed PIFA antennas. The first design concerns a single band antenna with resonant frequency at GPS frequency (1.575GHz). The first model is designed with main consideration that is to have the lower possible PIFA single band dimensions with reasonable return loss (S11) and the *efficiencies. Second design concerns in a wideband PIFA antenna which cover the range from 1800MHz to 2600MHz. This range covers certain important bands: GSM (1800MHz & 1900MHz), UMTS (2100MHz), Bluetooth & Wi-Fi (2.4GHz) and LTE system (2.3GHz, 2.5GHz, and 2.6GHz). The wideband PIFA design is achieved by using slotted ground plane technique. The simulations for both models are performed in COMSOL Multiphysics.*

The last two parts of the thesis present the problems of mobile phones antenna. Starting with Specific absorption rate (SAR) problem, efficiency of Mobile phones antenna, and hand-held environment.

Acknowledgements

The work of the thesis has been carried out of Blekinge Institute of Technology (BTH), Karlskrona, Sweden under the supervision Dr. Benny Lövström.

Firstly, thanks to Allah who give us the ability and the strength to be managed to complete our thesis work and we really thank the people who support us and guide as to success this thesis work.

We would like to gratitude our thesis supervisor Dr. Benny Lövström for his encourages and his comment he was behind this success and we extend our thanks for Prof. Ansel Berghuvud.

We would like to thank Dr. Sven Johansson.

Chapter1

1.1 Introduction

The huge development of the mobile phones have grown up rapidly in the last years, frequency bands have come up and the market is asking for smaller mobile phones with more services which give the user the ability to use the mobile phone with good signal performance and helps to use the mobile phone around the all world. On top of that it is important to reduce the risks affecting in the human body because of the antenna radiation.

In the past the mobile phone was so heavy, big and had external antenna on the top of the phone which effect badly on the human head and most of the signal radiate is reflected and absorbed by the human head which lead to bad efficiency.

Nowadays the internal antenna has been using instead of the external antenna the main reason of that is the internal antenna has a good relation with SAR rate, on the other hand the size of the phone became smaller.

Recently there are many types of the internal antennas for example PIFA antenna (Planar Inverted- F Antenna), fractal antenna and monopole antenna. Those kinds of antennas can cover a single band, dual band, wideband and multiband based on the design of the antenna.

PIFA antennas are used widely in mobile phone antennas design due to its advantages such as SAR rate and less interaction with hand-held environment, but one of the significant problems of PIFA antennas that's PIFA antennas have a narrow bandwidth. Wideband and multiband PIFA antenna can be a solution of that problem. By designing multiband antenna or wideband antenna

it's possible to have one antenna can cover more frequency such as using one antenna that can cover the very important bands which are in use in most countries GSM, UMTS, Wi-Fi and LTE.

1.2 Thesis Motivation

The work in this thesis is motivated by the necessity to investigate antenna structures which can be integrated in today is mobile phones which have a small available space for antennas inside. Nowadays the demand on low profile antennas increases rapidly that's in response to the huge developments of mobile phone devices either in functions or in size.

The other motivation is to investigate and design a wideband PIFA antenna. In general PIFA antennas have a disadvantage that's PIFA antennas have a narrow bandwidth, but on other hand PIFA antennas have many advantages such as best SAR rate, low profile and easy to be integrated inside mobile phones which make PIFA antennas the best candidate for mobile phones antennas. There are many papers published which study and discuss the narrow bandwidth of PIFA antennas, but most of those papers give the solution of the problem in dual band PIFA or in multiband design which in both cases do not solve the problem totally. Since there are some bands remain without covering, consequently the need of several antennas appears for covering low and high frequency bands.
So this thesis presents a study of a proposed wideband PIFA antenna with bandwidth more than 30% and the bandwidth cover an important range which could cover GSM, UMTS, and some bands of LTE system.

1.3 The Development of Mobile Phone Antennas

In the first generation 1G of mobile system, the system was operating at 800 MHz and as known it was analog. The first antenna handset for one quarter of wavelength has length about 9.4 cm, and it was one antenna only. The first mobile phone was Motorola DynaTAC8000X[1] with type

antenna is sleeve dipole as shown in the figure 1.3.1 which is not use any more in modern design of mobile phones antennas, however it still is used in different wireless LAN access points.

Sleeve dipole antenna has an efficient performance; the length of it is about half the wave length at its frequency. So at 850 MHz the antenna should be 176mm.

With the improvement on mobile phone and due to the dramatic minimizing size of the mobile phone, there were no needs for a sleeve dipole to be proportional to the cellular phone.

Photo was loaded from http://mashable.com/2014/03/13/first-cellphone-on-sale/

Figure 1.3.1 Motorola DynaTAC8000X with Sleeve dipole antenna.

In 1990s 2G launched which offered new services such as text message, and it is operated at GSM 900 MHz, where later on at 1800 MHz unlikely 1G, the second generation handset antenna has two antennas monopole and helix with only single band supporting as shown below in figure 1.3.2 and 1.3.3.

http://tech-kid.com/nokia-phone.html

http://www.northstandchat.com/showthread.php?289468-Your-first-ever- Mobile -Phone-and-what-make-and-model-was-it-!/page3

Figure 1.3.2 Nokia 1011 supports only GSM900 single band band.

Figure1.3.3 Motorola m300 support only GSM1800 single

In 1997, Motorola produced a mobile device Motorola mr601 which was the first dual band GSM phone, it supported GSM900 and GSM1800 dual band and its antenna consists of two antennas helix antenna which has travelling wave in the shape of corkscrew with circularly polarized and whip antenna which can be consider as dipole antenna and it is Omni-directional radiation pattern. That's model phone offered the ability to access network in over 70 countries by the end 1997.

In the first dual band PIFA operating at GSM900 and GSM1800, invented by Prof. Peter Hall in 1996 U.K, the first dual band PIFA a slot with a certain geometric dimensions, lead to support two different bands.

The development timeline of mobile phone has several significant steps, one of them was in 1999, when Nokia launched Nokia3210 as shown in figure 1.3.4 the first mobile with fully internal antenna, support both GSM900 and GSM1800 dual band, and was one of the most popular handset with over 160 million being sold [2].

In 1999, Prof. Peter Hall comes back with the first Triple Band PIFA which operates at GSM800/1800/1900. He designed Triple Band PIFA with two slots in the ground plane of the PIFA antenna, that's let the antenna to transmit and receive different band of frequencies.

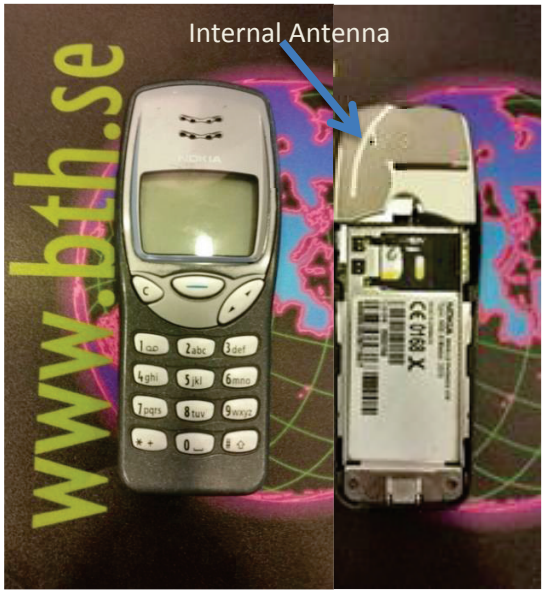

Figure 1.3.4 Nokia 3210 and its internal antenna which is installed to the top left of the back view of the mobile phone.

The first commercial 3G network was launched by Hutchison Telecommunications branded as 3G in June 2003, and in 2004 Nokia released Nokia6630,as showing in figure1.5 which was the first mobile phones allows truly global roaming, and first mobile with dual mode tri-band, GSM900/1800/1900 and UMTS 2100.

The photo to the left was loaded from http://www.mondomobileblog.com/2010/03/31/codici-segreti-nokia-6630/

Figure 1.3.5 Nokia6630 mobile and its internal antennas.

Table1.1 The timeline of development antenna use in mobile phones [1].

Year	1900	1950	1970	1990	2000	2010
Frequency	< 10 kHz	< 30 MHz	< 800 MHz	< 1.9 GHz	< 2 GHz	3 GHz 5 GHz
System	Telegraph / telephone for train, ship, police cars	Vehicle and portable systems for business, Pager	Mobile phones (analog), cordless phones, pagers, GPS	Mobile phones (digital),aircraft (voice and data) personal phone	Mobile phones (multimedia), Wireless access, Bluetooth	Mobile phones (high data rate), Ultra wideband,
Antenna	Monopole dipole, whip,	Blades, ferrite coil, helical antenna	Corner reflector, PIFA, helix	Meander line, normal mode helix, ceramic chip, adaptive array	Wideband, multiband built-in antennas, adaptive array, MIMO	Small compact functional antennas, implant antennas

Table 1.3.1 shows the time line of development in both sides' frequencies and antenna which are used for mobile phones systems. The frequencies are raised from 10 kHz till 3 or 6 GHz which is considered as a 4G system.

Cordless phones navigation systems and multichannel access systems have contributed dramatically to the development of antennas design, while the personalization of mobile terminals raised the needs of small antennas. Other needs for small antennas are hybrid systems, the handset of multiband GSM combined with DECT (Digital Enhanced Cordless Telecommunications) for example.

The specifications of the handset small antennas are low profile, compact and lightweight, which has led to modify and develop the antennas. One of the antennas is a modified PIFA, which has changed that it is difficult to recognize it as an original PIFA. The modified PIFA was first used in GSM handsets and has become more common in several different mobile terminals. Other modified antennas such as monopole were used in PDC (Personal Digital Cellular) with a normal mode helical antenna.

In modern mobile phone, we can conclude a summary of the considerations in design process as following:

- The requirement of multiband and built–in antenna.
- The requirement of small size antenna due to small size mobile terminals, for example RFID units (Radio-frequency identification).
- The requirement of function antennas such as adaptive antennas and MIMO for transmission high data rate.

Printed antenna has been used in mobile terminals; also Printed antennas have the smallest dimensions comparing with other installed small antennas. Chip antennas or a printed antenna consists of dielectric material and a ground plane which is a part of the antenna. Chip antennas offer a high gain, appropriate radiation pattern, and high efficiency.

Chapter 2

Basic Mobile Phone Antennas Principles

2.1 Parameters of Mobile Phone Antennas

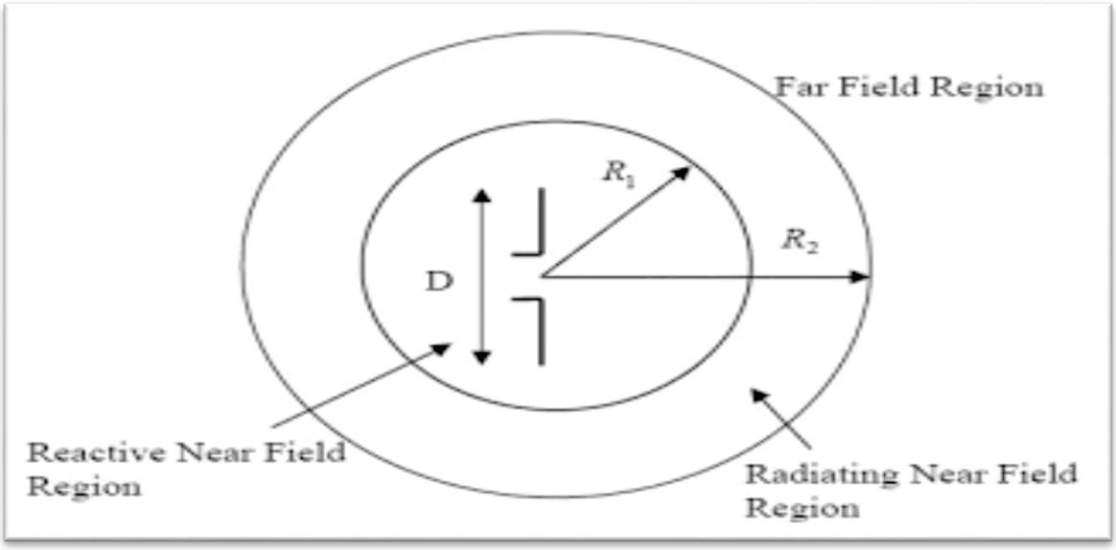
Radiation pattern

Radiation pattern can be describe by power radiated through the antenna, which depends on the direction, and it can be represented as graphical or mathematical function of the radiation properties.

There are two common types of antenna pattern , the first one is a power pattern and the second is field pattern , the first type is considering the power radiated and the position of the spherical coordinate and the second type which depend on the field if we have electrical field or magnetic field with the position of spherical coordinate.

The field region of the antenna pattern can be dived to three regions. The first region is Reactive Near Field Region which is the closest region to the antenna so it gives possibility to control the

energy and standing waves. The second region which is locate between the Reactive near field region and the far field region where control the radiation field, The last region is the far field region which has a far distance of the antenna , as showing in figure 2.1.1.



http://antenna-practices.blogspot.se/2008/11/antenna.html

Figure 2.1.1 The radiation pattern and the field regions.

There are many types of antenna pattern

1- Isotropic pattern the radiation of the isotropic is symmetric in all directions which is the ideal antenna but it is not found until these days.
2- Directional pattern which radiate more focusing with one direction.
3- Plane pattern which consist of two principles the electrical field plane (E-plane) and the magnetic field (H-plane).

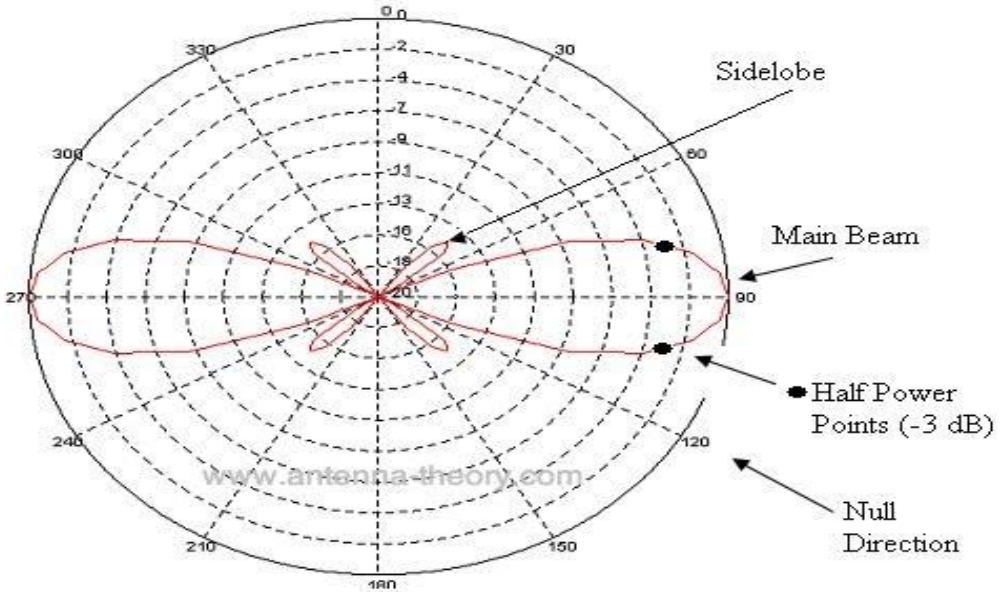
What is (E-plane) and (H-plane)?

E-plane consists of electrical field vector combined with the direction of maximum radiation.

H-plane consists of magnetic field vector combined with the direction of maximum radiation.

Parameters of antenna pattern

1- Main lobe is the radiation lobe going in the same direction of the maximum radiation.
2- Side Lobe is the radiation lobe of any directional lobe except the intended direction.
3- Back lope which has the opposite direction of the main lobe.
4- Half-Power Beam width (HPBW) the angular between two directions the half power point and the beam width which equal to -3db.
5- First Null Beam width (FNBW) - angular width between two directions the first zero and other side in the side lobe.



http://www.antenna-theory.com/basics/whyantennasradiate.php

Figure 2.1.2 A polar figure of an antenna with performance Parameters.

Directivity

Directivity is one of the antenna parameters that guide us to measure the direction of the radiation pattern, the directivity help us to determine the efficiency of the antenna, directivity of isotropic antenna equal to 1 (0 dB).

The directivity can be calculated by determining the maximum value of the magnitude of the radiation pattern which is defined by F(θ, ϕ) and the average power of all the direction which is equal to 1 so, the formula of calculating the directivity it can be written as:

$$\boldsymbol{D = \frac{1}{\frac{1}{4\pi}\int_0^{2\pi}\int_0^{\pi}|F(\theta,\phi)|^2 sin\theta d\theta d\phi}} \quad \textbf{(2.1.1)}$$

θ = The angle between the z-axis and the vector from the origin to the point

ϕ = The angle between the x-axis and the projection onto the x-y plane.

Mobile phone antenna should have a low directivity, because is not useful to use an antenna with high directivity, that is the received signal it can be from different directions. On the other hand the base station needs a high directivity.

Table 2.1.1 Directivity of different types of antennas [4].

Antenna Type	Typical Directivity	Typical Directivity (dB)
Short Dipole Antenna	1.5	1.76
Half-Wave Dipole Antenna	1.64	2.15
Patch (Microstrip) Antenna	3.2-6.3	5-8
Horn Antenna	10-100	10-20
Dish Antenna	10-10,000	10-40

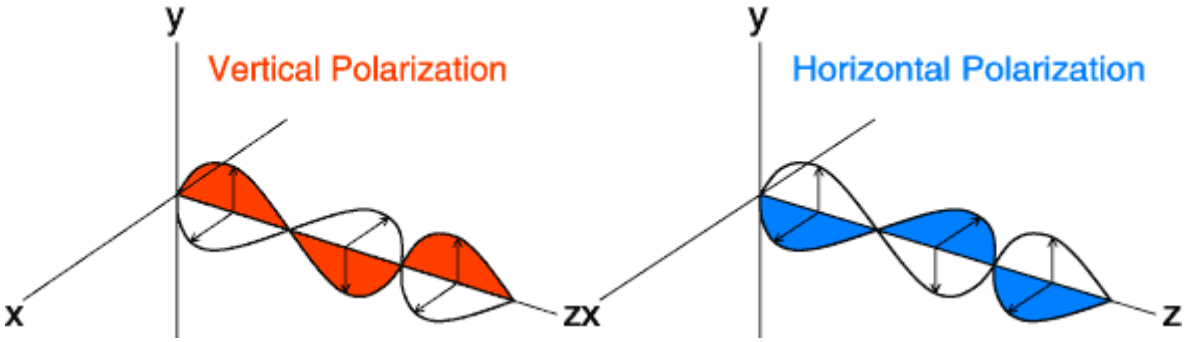
As showing in the table 2.1.1 above the directivity of different types of antenna so, the properties of the antenna have to be chosen regarding to what we need, as we have mentioned if you want to choose antenna for mobile station as cell phone, car or computer we will choose antenna with low directivity.

Polarization

One of the characteristics for any types of antennas is the direction of the electrical field vector of the electromagnetic wave. The polarizations of electromagnetic wave depend on the electrical field, which is perpendicular with the magnetic field.

The polarization of antennas can be classified in three different types based on electrical field

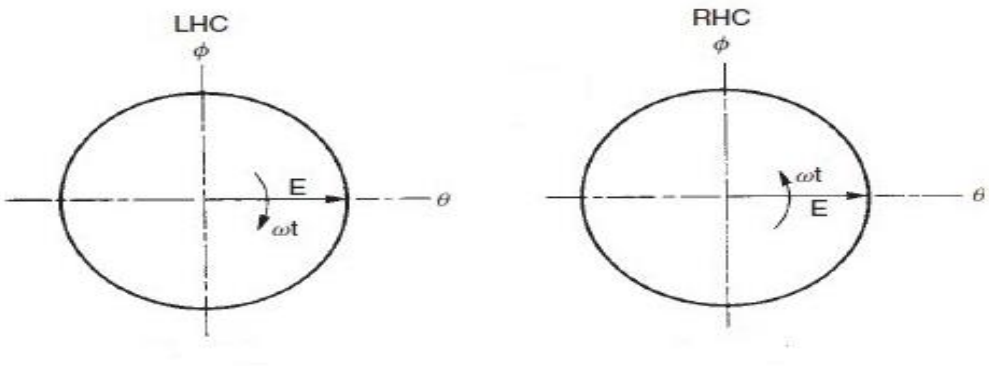
1- **Linear polarization:** as seen in the figure 2.1.3 the electrical field travels with the same direction of the plane wave. There are two types of linear polarization:
   - **Vertical polarization:** the electrical field travelling orthogonally to the y-axis and the magnetic field is travelling horizontally to x-axis.
   - **Horizontal polarization:** the electrical field is travelling horizontally to the x-axis and the magnetic field is travelling orthogonally to the y-axis.



http://www.srh.noaa.gov/hun/?n=dualpol

Figure 2.1.3 Vertical polarization and horizontal polarization.

2- **Circular polarization:** the electrical field travels circularly as seen in figure 2.1.4. It can be divided to two types regarding to direction of the circle:
   - Right Circular polarization: the direction of the circle is clockwise.
   - Left circular polarization: the direction of the circle is anti-clockwise.

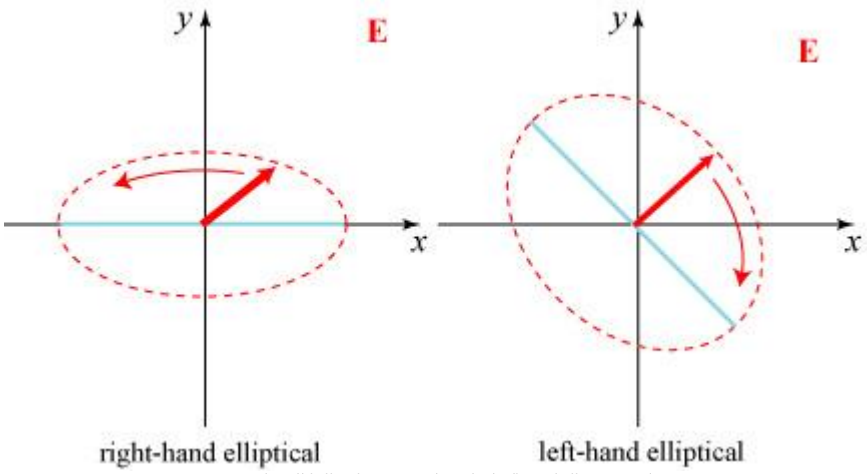


http://www.antetec.com/news/2010/01/27-371.html

Figure 2.1.4 Right circular polarization and left circular polarization.

3- **Elliptical polarization:** the electrical field travels with an elliptical shape based on the direction of the electrical field figure 2.1.5 it can be divided to two types:

- Right elliptical polarization which is has direction with clockwise.
- Left elliptical polarization which has direction anti-clockwise.



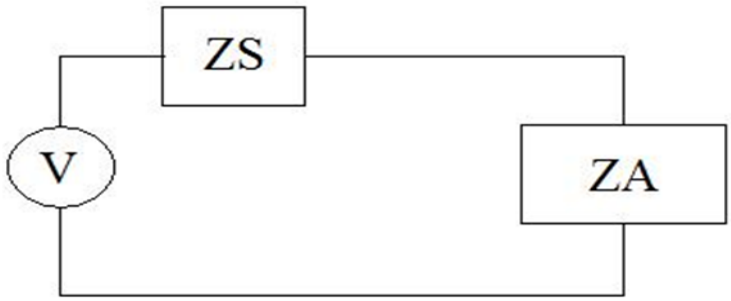
http://skullsinthestars.com/2012/09/23/hairy-balls-in-optics/

Figure 2.1.5 Right elliptical polarization and left elliptical polarization.

Impedance

The impedance of the antenna mainly depends on the input voltage and current for the power losses equal to the power transmission of the antenna. The benefits of knowing the input impedance it is lead you that to choose the suitable transmission line.

The impedance of an antenna ZA must be matched with its impedance transmission line ZS (feeder). Otherwise there will be amount of a reflection wave back to the signal source. To have maximum power at the antenna from source as shown in figure 2.1.6 ZS should be equal to ZA



http://www.antenna-theory.com/basics/whyantennasradiate.php

Figure 2.1.6 The equivalent circuit of an antenna and the transmission line.

Antenna gain

One of the antenna properties to describe the value of the power transmission to the peak radiation direction. The efficiency of the antenna always relate with the antenna gain so if the efficiency is perfect 100% that's mean the gain and the directivity are equal to each other, it can be describe by the following formula:

$$G = \varepsilon_R D \qquad (2.1.2)$$

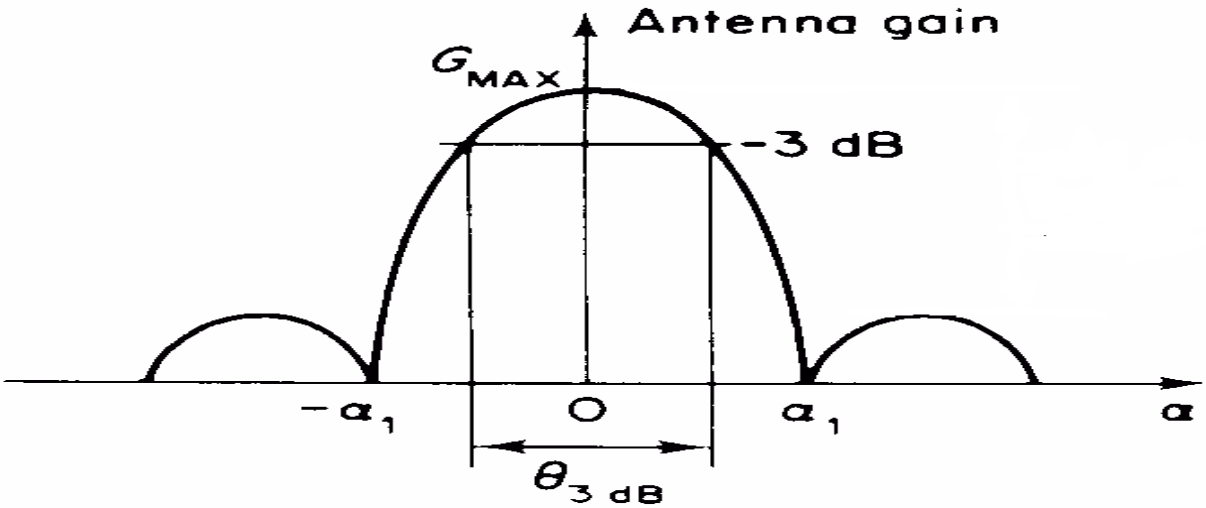
Antenna efficiency

The relation between the input power to the antenna and the dissipated power which is the losses power within antenna, regarding to the relation between the power radiate and the power input the efficiency of the antenna can be written by the following formula:

$$\varepsilon_R = \frac{P_r}{P_{in}} \qquad \textbf{(2.1.3)}$$

Antenna Beamwidth (θ)

The angle between the two points of the half power of the radiation pattern, the beamwidh could be clarify as the half power, the directivity become high if the beamwitdh very small. The beamwidth is found by determining the two points with 3db as showing in figure 2.1.7.



http://happy.emu.id.au/lab/rep/rep/9510/txtspace/9510_010.htm

Figure 2.1.7 Half power Beamwidth.

Effective area

To calculate the transmission power (P_t) and determine how much power has been lost due to the plane wave, regarding to the relation between the power density (P) and the effective area (A_e) the following formula can be written as:

$$P_t = PA_e \qquad (2.1.4)$$

To calculate the effective area we should consider the relation between the effective area and the antenna gain the formula can be written as:

$$A_e = \frac{\lambda^2}{4\pi} G \qquad (2.1.5)$$

Bandwidth

One of the other important parameters is bandwidth which determines the range of the frequencies where the antenna is operating, table 2.1.2 shows different common types of antennas with frequency range of each antenna. The percentage of the bandwidth can be calculated as following:

$$Bandwidth\% = \frac{f_{max} - f_{min}}{f_{Center}} \times 100 \qquad (2.1.6)$$

Table 2.1.2 different common types of antennas with frequency range of each antenna [4].

Antenna	Center frequency	Frequency range	Percentage bandwidth
Patch	1000MHz	985-1015MHz	3%
Dipole	1000MHz	960-1040MHz	8%
Horn	1000MHz	154-1848MHz	169.40%
Spiral	1000MHz	95-1900MHz	180.50%

VSWR

Voltage standing wave ration or S_{11} which describe the reflection power coefficient or the return losses of the antenna, the VSWR can be defined by the following formula:

$$\boldsymbol{VSWR = \frac{1+|\Gamma|}{1-|\Gamma|}} \qquad \textbf{(2.1.7)}$$

Γ : the reflection coefficient

If the voltage standing wave has a small value that means the value of the power transmission will deliver to the antenna better but does not necessarily mean the power delivered sometimes also radiated. The value of the ideal VSWR is 1 and that's will happen if the voltage of the transmission wave matched in this situation we will not have a return losses on the other hand if the voltage in the transmission waves haven't matched with the antenna that's mean there is some losses.

VSWR is a measure of how much power is delivered by a voltage source to an antenna. Which means that's an antenna dose not radiate all the received power; there is always amount of reflection voltage due to mismatching network.

Based on the VSWR concept we find that an antenna with VSWR less than 2 that's good enough to have a good impedance matching, on the other hand the transmission of more power to the radio can be lead to damage the radio.

2.2 Antenna types

Dipole Antenna

One of the most common antennas today in radio communications is a dipole antenna due to its simplicity. Dipole antenna has two rods or wires (poles) which are identical conductive elements, and fed by a signal source or feed energy. As shown in figure 2.2.1 below the two elements, current, and the voltage causes electromagnetic wave.

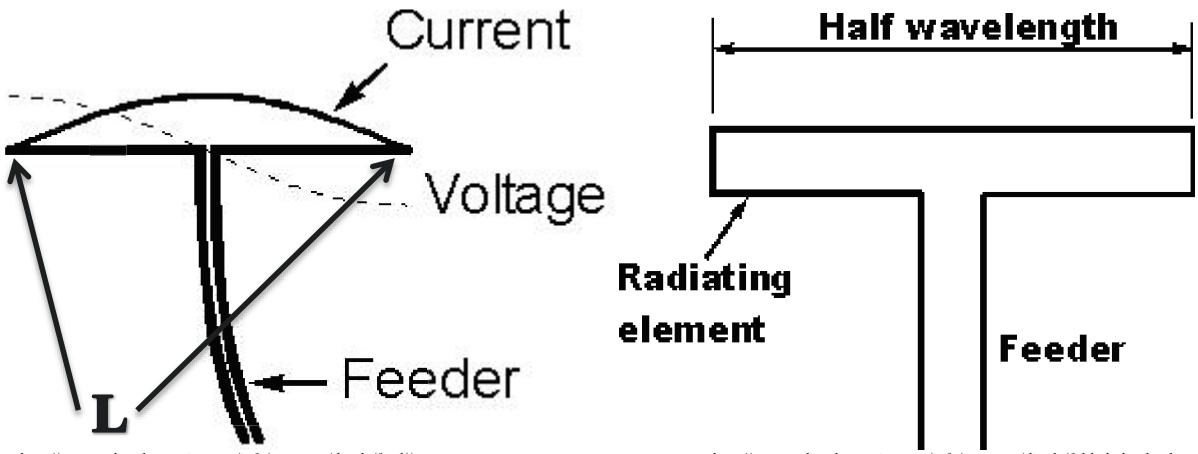


Figure 2.2.1 The half wave dipole antenna with center feed point, and to the right Half-wave folded dipole antenna.

Dipole antenna types

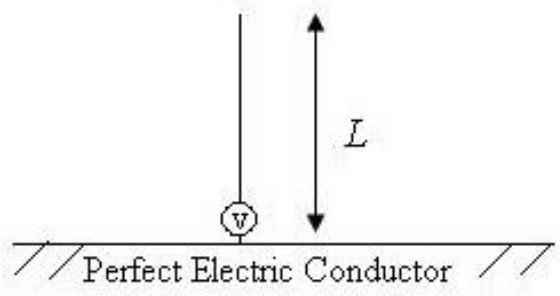
Half wave dipole antenna is the most popular type. But still there several types which could be used.

- **Short dipole**
  A dipole antenna is called a short dipole antenna if its rods or wires length (L) shorter than half of a wavelength (λ), for example if L< λ/10.
- **Half wave dipole antenna**
  As shown in figure # above a half wave dipole antenna consists of two wires each of them quarter of the wavelength, and the feeder is connecting to both wires.
- **Multiple half wave dipole antenna**
  A dipole antenna with odd multiple of half wavelength long.

- **Folded dipole antenna**
  A folded dipole antenna is half wavelength dipole but its wires are folded back as shown in figure 2.2.1.

Monopole antenna

Unlikely dipole antenna Monopole antenna is an antenna which consists of a one straight rod conductor, and is installed over a ground plane (conductive surface) as seen in figure 2.2.2. Monopole antennas are fed at lower end, near to ground plane which works as a reflector. In case the ground plane conductive and valid in size, the efficiency of the ground plane is as well as a vertically installed dipole.



http://www.antenna-theory.com/antennas/monopole.php

Figure 2.2.2 Monopole antenna with length L.

There are other common types of monopole antenna such as Whip, helical, T-antenna, and mast radiator. Monopole antenna like dipole antenna both have omnidirectional radiation pattern, for that the monopole it could be used in cell phones and other applications, for example indoor applications such as airplane, or shopping center.

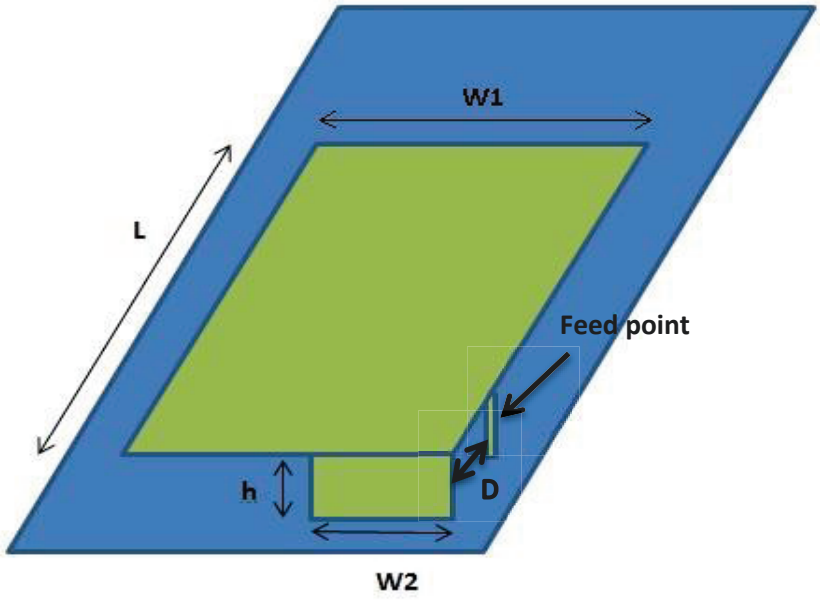
Monopole antennas are widely used in mobile communications, specially the quarter wave monopole -the length of the monopole L is approximately quarter of wavelength- which is a suitable for MIMO wireless communications systems, due to its low angle radiation and minimized ground losses [3].

For better efficiency of monopole antennas, many methods are applied, one of them type of the ground plane; The ground plane can be infinite or finite with different geometric shape such as spherical, cylindrical, or rectangular sheet. That's affect characteristics monopole specially radiation pattern, and less effects in monopole's impedance [4].

Based on fact that, monopole antennas are half the size (half length) of their dipole. So we can describe the directivity of monopole in term of its dipole, for example if the directivity of a dipole of length 2L has a directivity D1 [decibels], then the directivity of monopole with length L will be D1+3 [decibels], this because there is no radiation happens below the ground plane [4].

PIFA antenna

PIFA is the short name of Planar inverted-F antennas which is the most common type of cellular phone antenna nowadays, it has the same structure of microstrip antenna but it shorted with the ground because of this short pin the PIFA produce a quarter wave length. The main reason of name PIFA because has change of using wire to use ground plane. The PIFA structure consist of a rectangular planar which is installed on the ground plane, it is always parallel to reduce the height. Figure 2.2.3 is showing the geometric dimensions of the PIFA antenna the length which is L, The width which symbolized by W1, The short pin is W2, for height is h and the distance between the short pin and the feed point is D.



http://www.raymaps.com/index.php/planar-inverted-f-antenna-pifa/

Figure 2.2.3 PIFA antenna and its geometric dimensions.

The structure of the PIFA can deal with different frequency band

- Single band
- Multiband
- Reconfigurable

The main advantages of using PIFA antenna

1- Due to the small size of PIFA antenna it gives the availability to insert the antenna inside the cellular phone.
2- PIFA has availability to get high gain for both polarization states vertically and horizontally there for it can receive the reflection wave easily from different directions.
3- The backward radiation of the PIFA has be reduced that's mean the electromagnetic waves power has reduced which lead us to get a good deal to less damage of the human health.
4- The design and the material of the PIFA are not costly on top of that it has a very high efficiency also It is easy to fabricate.

As we know the development of communication always come up with a new evaluation but until now there are no antennas can work without disadvantages, So there is a problem in PIFA antenna could not be solved until now which is the sensitivity of the bandwidth but in general PIFA prove that is the best cellar phone antenna have been used regarding to the comparing between the advantage and the disadvantage of the antenna.

There are a few di-electrical material can be used in PIFA, and when the air is the one which is used, the gain will be better comparing with other material.

Fractal antenna

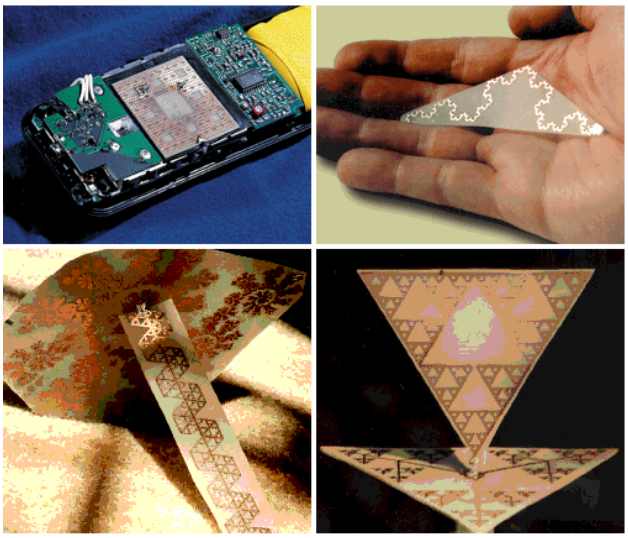


Photo was loaded from http://www.antenna-theory.com/antennas/fractal.php

Figure 2.2.4 Triangle Fractal Geometry. Upper Left: Patch Antenna Fractal. Lower Left: Monopole Fractal. Lower Right: Bowtie Monopole Fractal Antenna.

One of the problems of popular designs of antenna, that's the antenna which is smaller than a quarter of the wavelength, is very sensitive to a narrow band of frequencies. This problem is a significant issue for mobile phone, where the requirements are always to minimize the size of the mobile phone which leads to the problem of sensitive narrow band frequencies.

As shown in figure 2.2.4 the fractal antenna has a complex shape which offers many electric current modes to exist, that's causes, the increasing in radiation, consequently very wide bandwidth.

Fractal antenna designs can solve sensitive narrow band frequencies problem. Experiments have shown that antennas built with only a small number of iterations of a fractal process can exhibit sensitivity at several frequencies, and it is worthy to mention that's fractal antenna can work efficiently more at one quarter of the wavelength than other antennas types [5].

Geometry of fractals

The shape of a fractal can be formed by iterative mathematical process called Iterative Function Systems (IFS) [6] and by using affine transformations as following:

W(x, y) = (ax+by+e, cx+dy+f)

a,b,c,d control rotation and scaling e , f control linear translation by repeating the upper calculations, we get the IFS sequence that converges to the final image.

Chapter 3

Mobile phones antenna design

Mobile phones consist of several antennas for several purposes such as Wi-Fi antenna, GPS antenna, low and high frequencies antennas. Each type of antennas is designed according to certain considerations, of course, the small sizes the main issue.

As it is mentioned in the previous sections of this thesis. Dipole antenna is a useful type of antennas; easy to be constructed, and integrated in cell phones

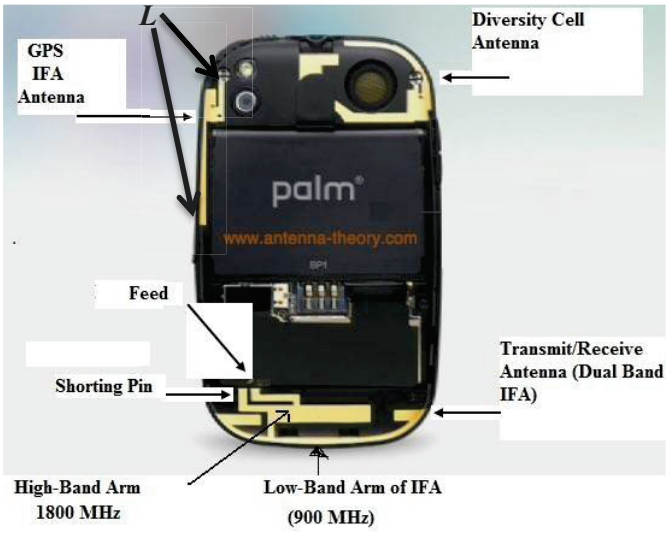
3.1 Mobile phone GPS antenna design

GPS antenna is an omnidirectional small antenna with only receive mode that can be one of main design's considerations. The GPS frequency is 1.575 GHz, with practically no bandwidth, and the GPS satellites are RHCP (table 3.1.1) to avoid Faraday rotation problems, and there is one other benefit, that's circular polarization does not need rotational alignment of a circularly polarized antenna at mobile phone.

For a maximum received power the user terminal's antenna must be RHCP. User terminal's antenna which is linearly polarized will have a loss 3dB in received power due to polarization issue. By looking at the power density of the GPS received wave. We find that it is extremely low level which equals to -160dB. Therefore, we need an efficient antenna at the receiver.

Table 3.1.1 Cell phone GPS antenna specifications and goals [4].

Transmit and receive frequency	Receive only 1.575 GHz
Efficiency	-3 dB to -9 dB
Polarization	RHCP
Quarter wavelength(L)	About 4.75cm or 1.87 inches



http://www.antenna-theory.com/antennas/aperture/ifa.php

Figure 3.1.1 Palm Pre Antennas viewable by Removing Back Cover.

As shown in figure 3.1.1 in this design, quarter wavelength IFA antenna is used. The ground plane (the chassis) of the mobile phone is considered as one arm of dipole antenna and the feeder is placed on opposite side at a point which helps for matching impedance. The GPS antenna is placed on the top of the mobile phone to guarantee best performance; that's because the users hold the mobile phone vertically when they want check current location for example, and in that case their hands will be on lower part of mobile phone, far from GPS antenna.

As obvious in figure 3.1.1 IFA antenna is designed with its geometric dimensions to get the better efficiency, and of course to take into account the available low profile for the antenna in mobile phone.

To obtain circularly polarized dipole antenna, we use two crossed dipoles to provide the two orthogonal field components, and if the two dipoles are fed with a 90° time-phase difference the polarization will be circular along zenith [28].

Single band PIFA Antenna design

GPS antennas are received mode antennas. So we do not have to worry about SAR measurements. In this section we will design a single band antenna for GPS use and simulate the model by COMSOL.

Model descriptions

The desired bandwidth is a single frequency 1.575 GHz (table 3.1.1). Thus we try to make the resonant frequency of the PIFA antenna close to 1.575 GHz to provide high receiving efficiency as much as possible. The gain of the antenna should be between -3dB to 0dB.

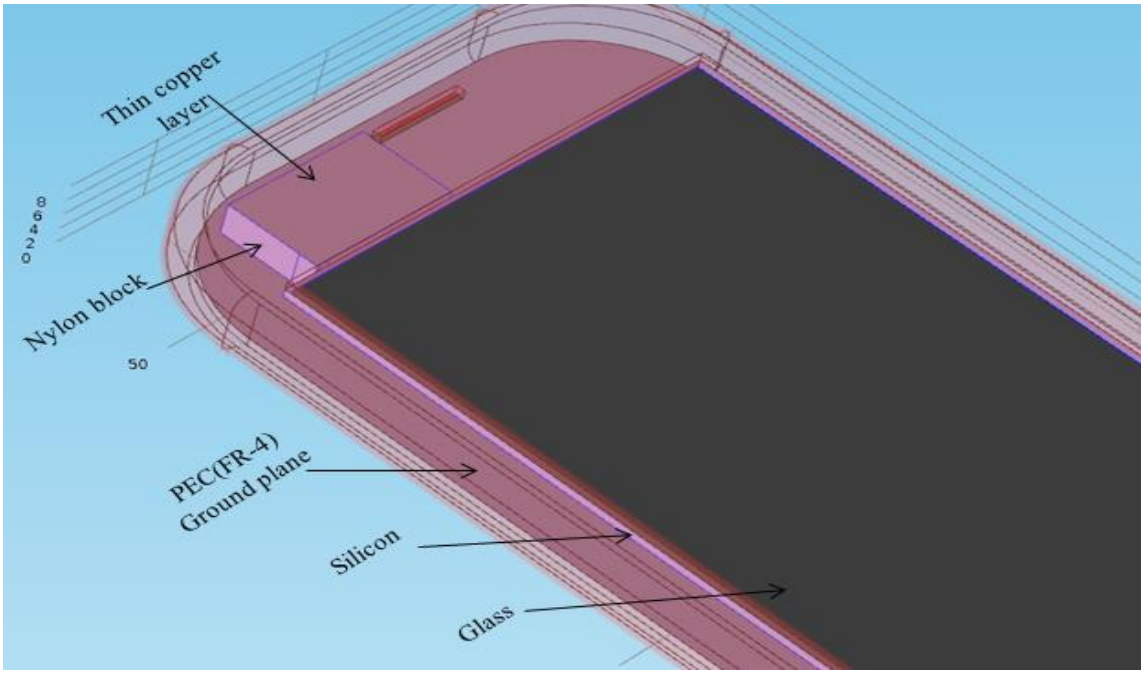


Figure 3.1.2 Zoom view of PIFA antenna block. It consists of Nylon block and the radiating part and the materials which are used in design.

Calculations

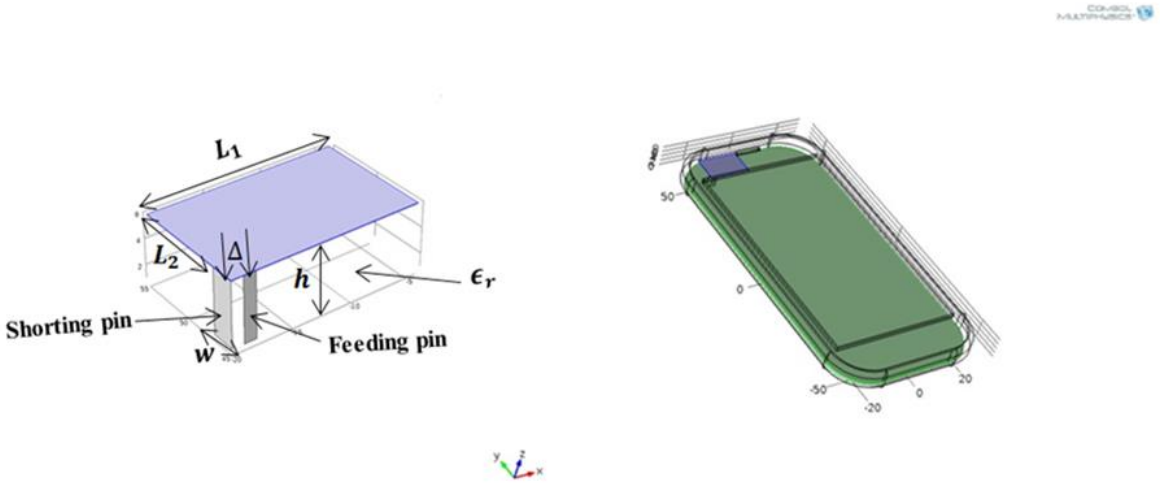

Figure 3.1.3 The antenna to the left and its dimensions $L_1 = 20mm, L_2 = 10mm, w = 2mm, h = 4mm$ $\epsilon_r = 3.8$, $\Delta = 0.2mm$ *to the right the casing's dimensions have length =119mm, width =60mm.*

The resonant wavelength of a PIFA antenna can be calculated as following:

$$\boldsymbol{L_1 + L_2 - W = \frac{\lambda_0}{4}} \qquad \textbf{(3.1.1)}$$

And the relation between the resonant wavelength and the resonant frequency can be determined by the equation:

$$\boldsymbol{\lambda_0 = \frac{c_0}{f_0\sqrt{\epsilon_r}}} \qquad \textbf{(3.1.2)}$$

λ_0: Resonant wavelength of PIFA.

c_0: The speed of light in space.

f_0: Resonant frequency.

ϵ_r: Relative permittivity.

Mathematically, PIFA antenna's size can be reduced by using factor $\sqrt{\epsilon_r}$ (equation 3.1.2)

Therefore if we use a material with higher ϵ_r ,that reduces the size of the PIFA which is a useful way to get a low profile antenna but that could affect the gain of the antenna as well. It is a big challenge to keep the efficiency without any effects when the small size is required, so the PIFA dimensions which are used in this design were chosen after many simulations, and based on the best efficiency, lowest value in return loss S11, and the smallest size. We determined the dimensions.

By applying equation 3.1.1 we find that:

$20 + 10 - 2 = \frac{\lambda_0}{4}$, $\lambda_0 = 112$ mm

Hence,

$$f_0 = \frac{3 \times 10^8}{112 \times 10^{-3}\sqrt{3.8}} = 1.374 \text{ GHz}$$

The calculated resonant frequency is not very close too much to the desired frequency 1.575 GHz. But by increasing and decreasing the gap impedance change, the resonant frequency will shift to upper or lower than the calculated resonant frequency. Increasing and decreasing of the impedance gap affects the input impedance, consequently effects at VSWR for the resonant frequency.

Simulations

In simulation, first we installed the antenna to left of the casing figure 3.1.3 and inserted the materials as shown in figure 3.1.2 and with dielectric constant as table 3.1.2 in addition the outer shell of the casing is simulated with Polytetrafluoroethylene (PTFE). We use whole chassis as a ground plane for better efficiency.

A 50 Ω lumped port is used to excite the antenna and determine the input impedance. The lumped port is mounted between two metallic boundaries: the vertical feeding and the ground plane of FR4 board as seen in figure 3.1.2. The distance Δ, the impedance matching gap affects significantly the matching impedance. So another strip shorted to the ground plane is added. The dielectrically material which will be used for the antenna block is Nylon.

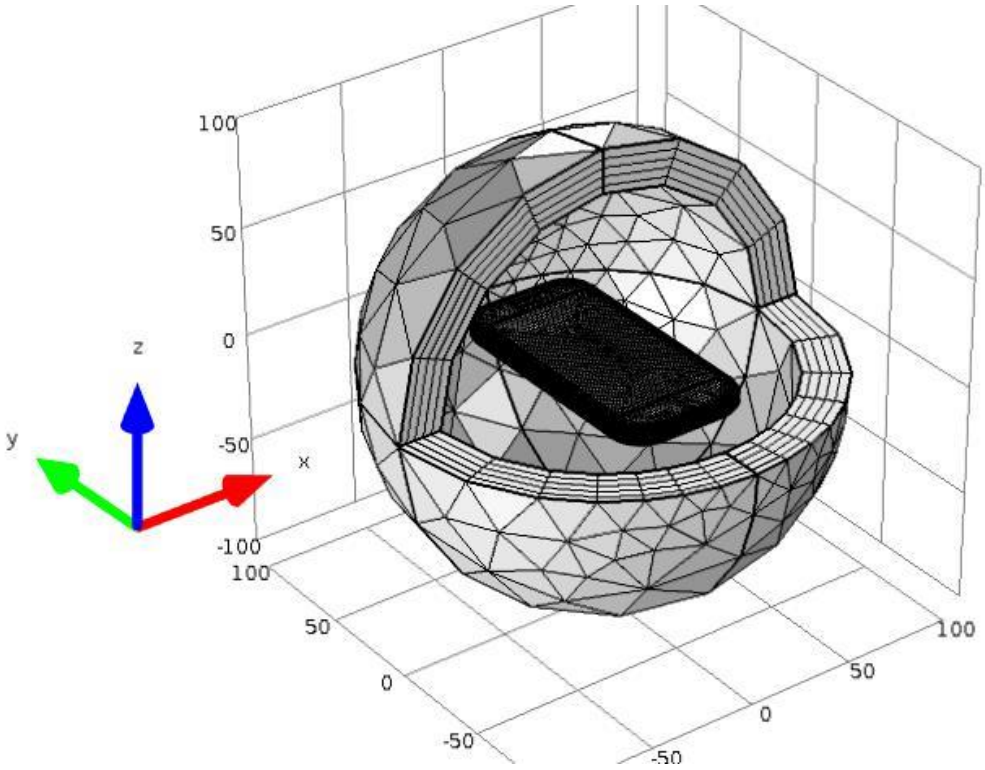

Figure 3.1.4 Mesh model for the whole simulated model: PIFA antenna, casing of the mobile phone and the surrounded perfect matched layers.

The model consists of several domains; every domain has a certain material figure 3.1.2. In addition there is one more domain encloses the casing. This domain is simulated as a sphere with radius 100mm, material air, and has five perfect matched layers in order for the radiation to be able to travel anywhere as shown in figure 3.1.2. The metal part of the antenna element at frequency 1.575 GHz can be modeled using perfect electric conductor boundaries.

Table 3.1.2 the materials of the simulated model and its Dielectric constant according COMSOL's materials libraries except Nylon.

Material	Dielectric constant (ϵ_r)
Air	1
FR-4	4.5
Nylon	3.8*
Glass (quartz)	4.2
Silicon	11.7
PTEF	2.1

* The Dielectric constant of Nylon accordinghttp://www.professionalplastics.com/professionalplastics/ElectricalPropertiesofPlastics.pdf

Results and Analysis

E-field norm on the xy-plane slice is shown below in figure 3.1.5. The plot shows that the electric field is strong at one of the top metallic surface shell far from the feeding point. This looks alike the E-field distribution of a quarter wavelength monopole antenna, which the PIFA derived from.

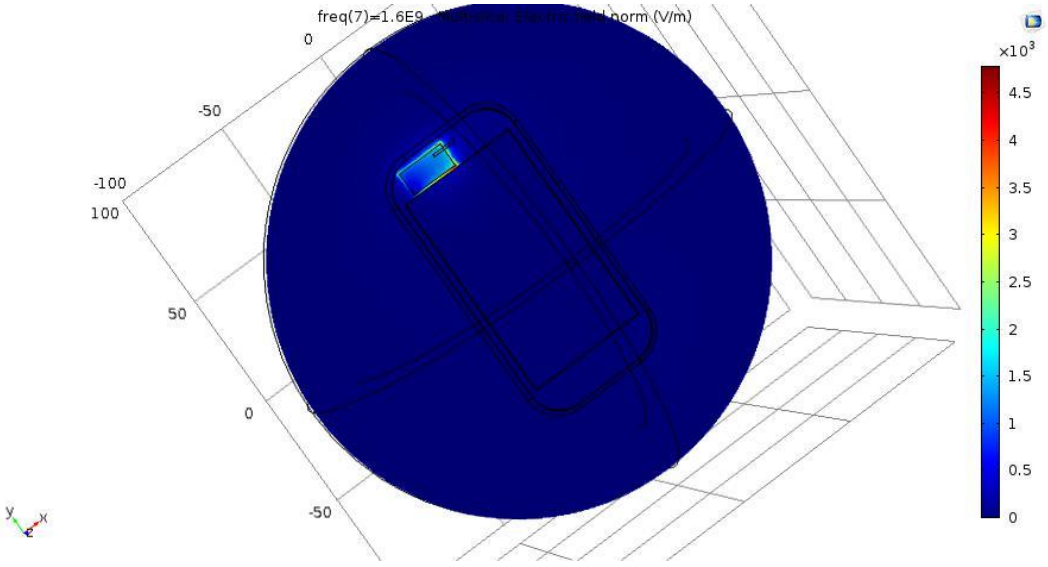

Figure 3.1.5 E-field norm distribution on the top of the PIFA.

The polar plot of the far field radiation pattern of the antenna is shown in figure 3.1.6 As obvious the antenna gain on xy-plane varies from about -6dBi to 1.5dBi. The azimuthal radiation pattern is not Omni-directional any more, since the antenna is mounted on the ground plane and miniaturized.

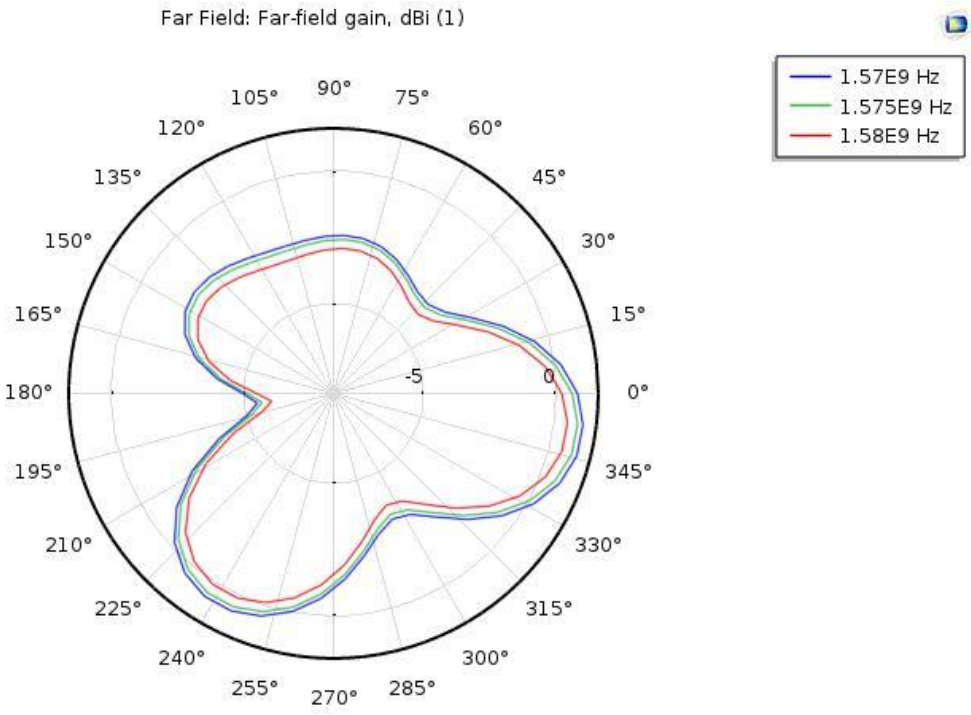

Figure 3.1.6 Antenna gain pattern on the xy-plane.

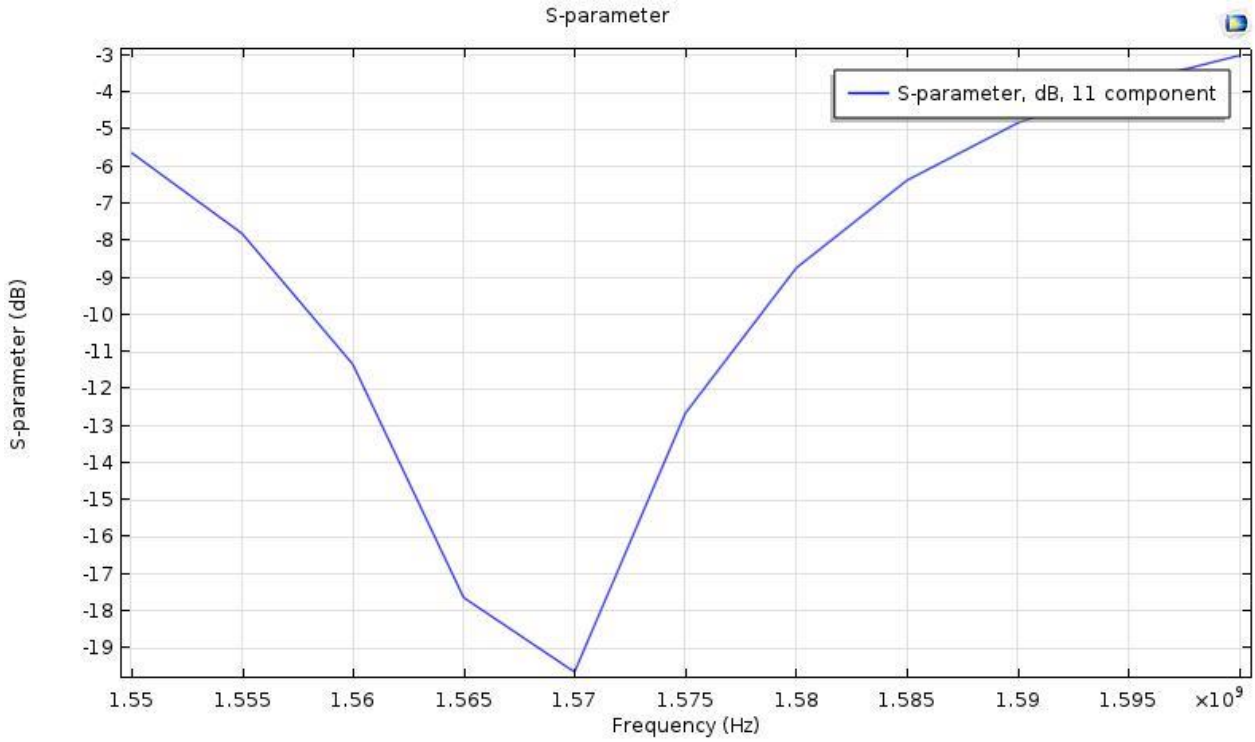

Figure 3.1.7 Return loss S-parameters (S11) for the antenna by simulation.

S-parameters (S11) measurements indicate that at 1.575GHz is -13dB which means that the reflected power is 5%. This describes how well the antenna input impedance is matched to the 50 Ω reference impedance.

Antenna's bandwidth regarding figure 3.1.7 is a narrow bandwidth:

$$Bandwidth \approx \frac{1.577 - 1.557}{1.570} \times 100 = 1.2\%$$

The wide bandwidth for GPS antenna is not required. So the bandwidth above is sufficient.

Keeping the feeding point near to the shorting pin as much as possible reduces the antenna size but that causes a narrow bandwidth. The electrical characteristics of PIFA are affected by the size of ground plane. By varying the size of ground plane, the efficiency and the bandwidth are changed; to increase the bandwidth we need the whole possible free space in the chassis. In simulation we use the whole chassis as ground plane in order to get a better efficiency.

The effective of the PIFA antenna geometric dimensions on the resonant frequency can be summarized by the following table 3.1.3

Table 3.1.3 Effect of geometric dimensions on resonant frequency.

	L_1	L_2	W	H
f_0 ↑	↓	↓	↑	↓

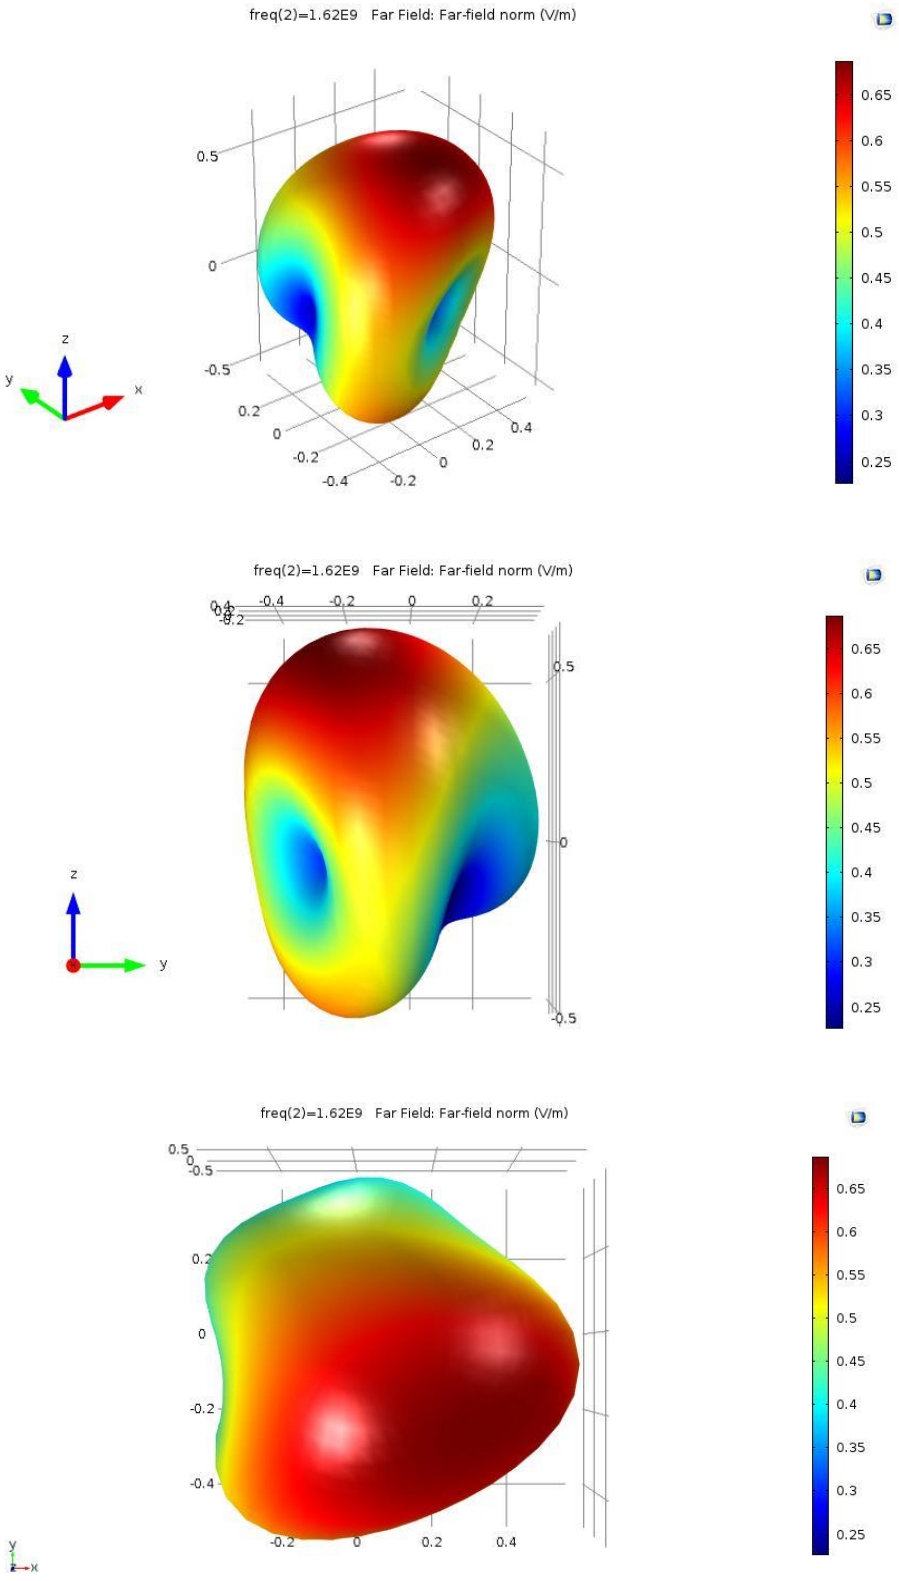

Figure 3.1.8 3D far-field radiation pattern shown from three different angles.

3.2 Wideband PIFA Antenna Design

PIFA antenna is used widely in mobile phones today as shown in the table 3.1.3, that's due to many advantages of PIFA which are mentioned in chapter 2 Antennas types. Hence in this section PIFA antenna will be used to design a wideband antenna and simulate the model in COMSOL.

Model descriptions

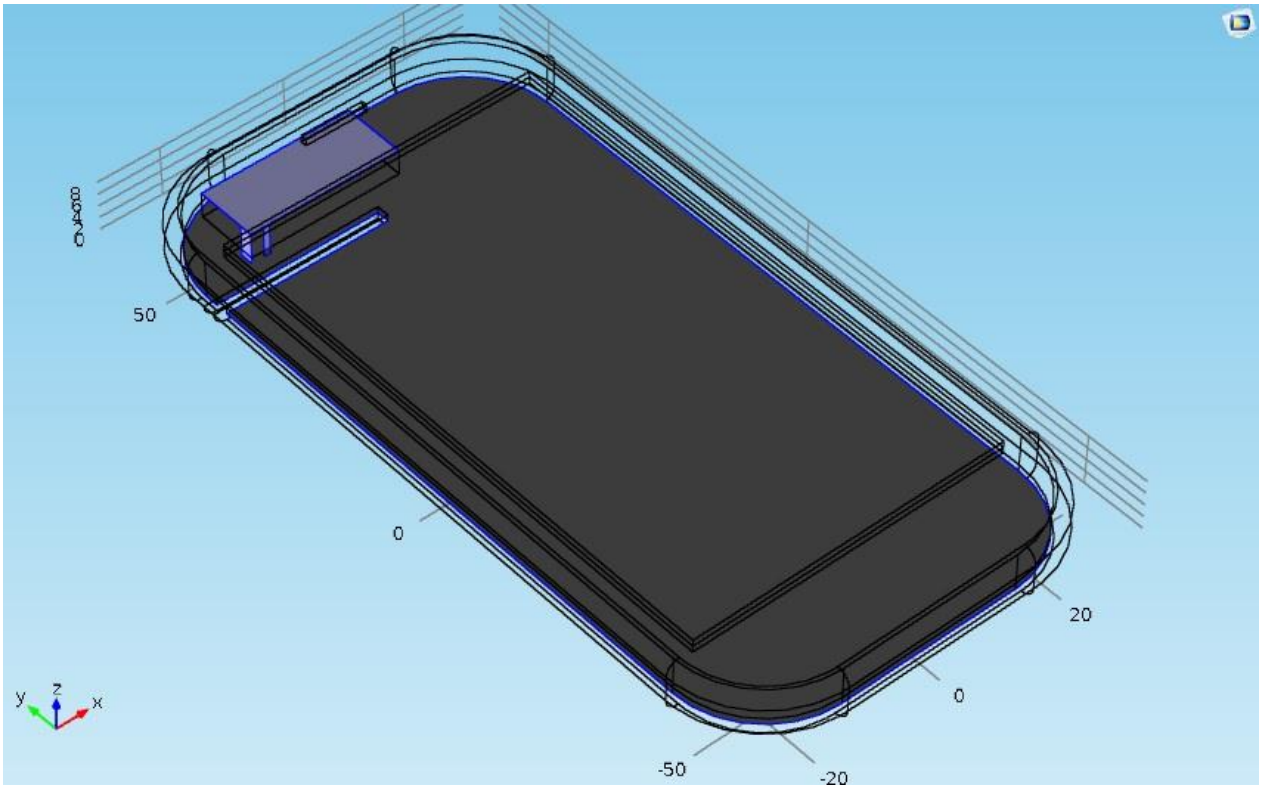

Figure 3.2.1 the wideband PIFA antenna is mounted to left top of the slotted ground plane.

PIFA antenna design using slot technique, with desired range of frequency from 1800MHz to 2600MHz. This important range cover GSM (1800MHz & 1900MHz), UMTS (2100MHz), Bluetooth and Wi-Fi (2.4GHz), and LTE system (2.3GHz, 2.5GHz, and 2.6GHz).

The wideband PIFA antenna design using slot technique model consists of the same materials which are used in previous design table 3.1.2, except the dielectric material between the PIFA and the ground plane which is air with dielectric constant (ϵ_r) equals to 1 to have a better efficiency and a wider bandwidth.

Calculations

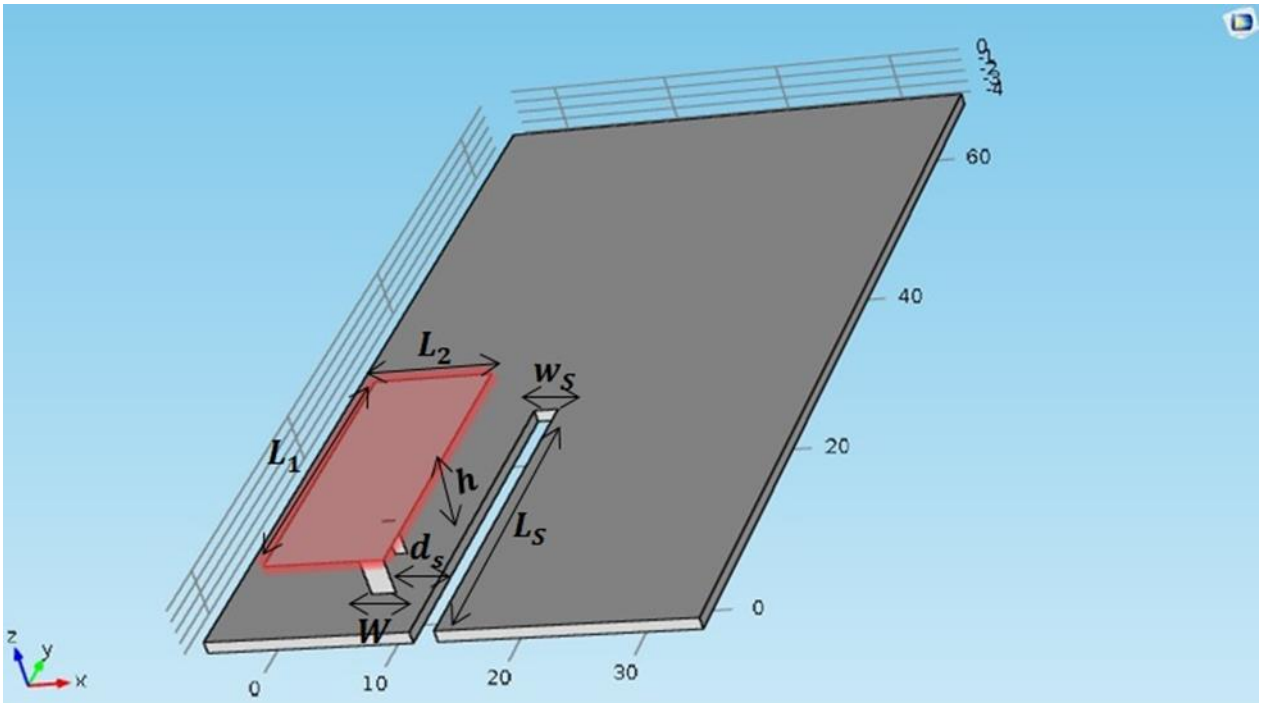

Figure 3.2.2 The illustration dimensions of the PIFA $L_1 = 24mm$, $L_2 = 10mm$, $h = 4mm$, $W = 2mm$ *and the ground plane with its slot dimension* $d_s = 5m, Ls = 28mm$, $W_s = 2mm$.

The resonant frequency of the PIFA antenna can be calculated using 3.1.1 and 3.1.2 formulas respectively.

$24 + 10 - 2 = \frac{\lambda_0}{4}$, $\lambda_0 =$ 128mm

$f_0 = \frac{3\times10^8}{128\times10^{-3}\times\sqrt{1}} = 2.343GHz$

The desired bandwidth percentage:

$f_{center} = \frac{2600+1800}{2} = 2200MHz$

$Bandwidth\% = \frac{2600-1800}{2200} \times 100 = 36.36\%$

If the bandwidth percentage higher than 20%, that's bandwidth is considered as a wide bandwidth.

Simulations

In this design we use a slotted ground plane in order to improve PIFA bandwidth. A slot in a ground plane creates different paths of current flow which leads to kind of diversity in electric field, consequently a wider bandwidth. The length of the slot should be proportional with the desired resonant frequency. The simulations are performed for two cases, one without the slot and other with slot, for different positions of the slot on the ground plane and for different dimensions of PIFA except the width of the planar which is fixed at 10mm and width of the short pin is 2mm.

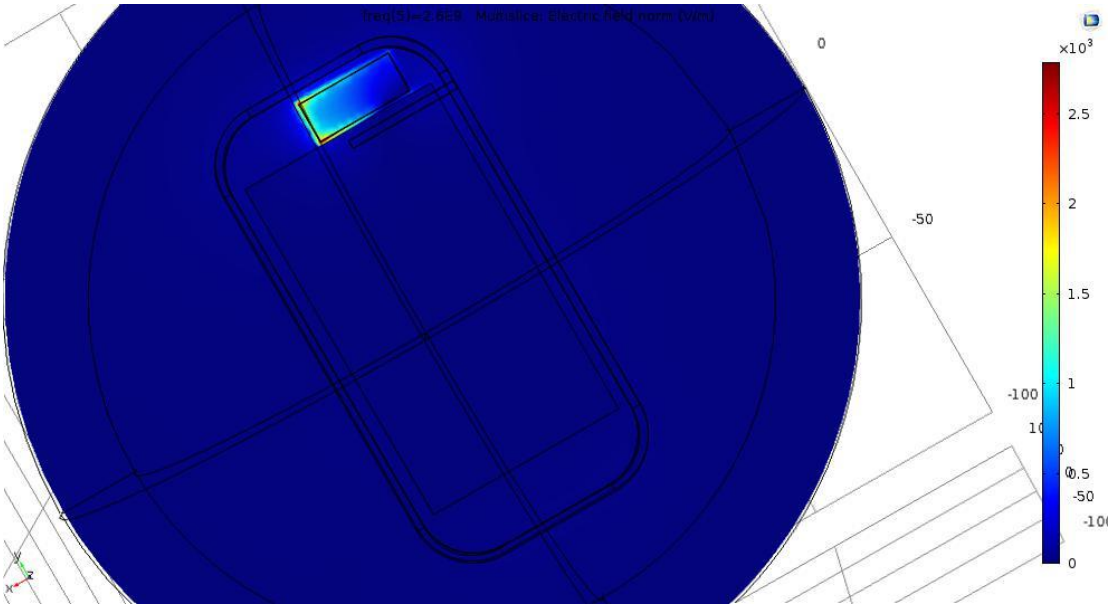

Figure 3.2.3 Back view of E-field norm distribution on the top of the wideband PIFA.

In figure 3.2.3 the plot of the E-field shows that the electric field is strong at one of the top metallic surface shell far from the feeding point on both corners of the planar which similar to E-field plot in previous design.

Figure 3.2.4 shows the far-field gain in dBi for every frequency center of the desired bands and in figure 3.2.5 the 3D far-field radiation pattern of wideband PIFA shown from three different angles.

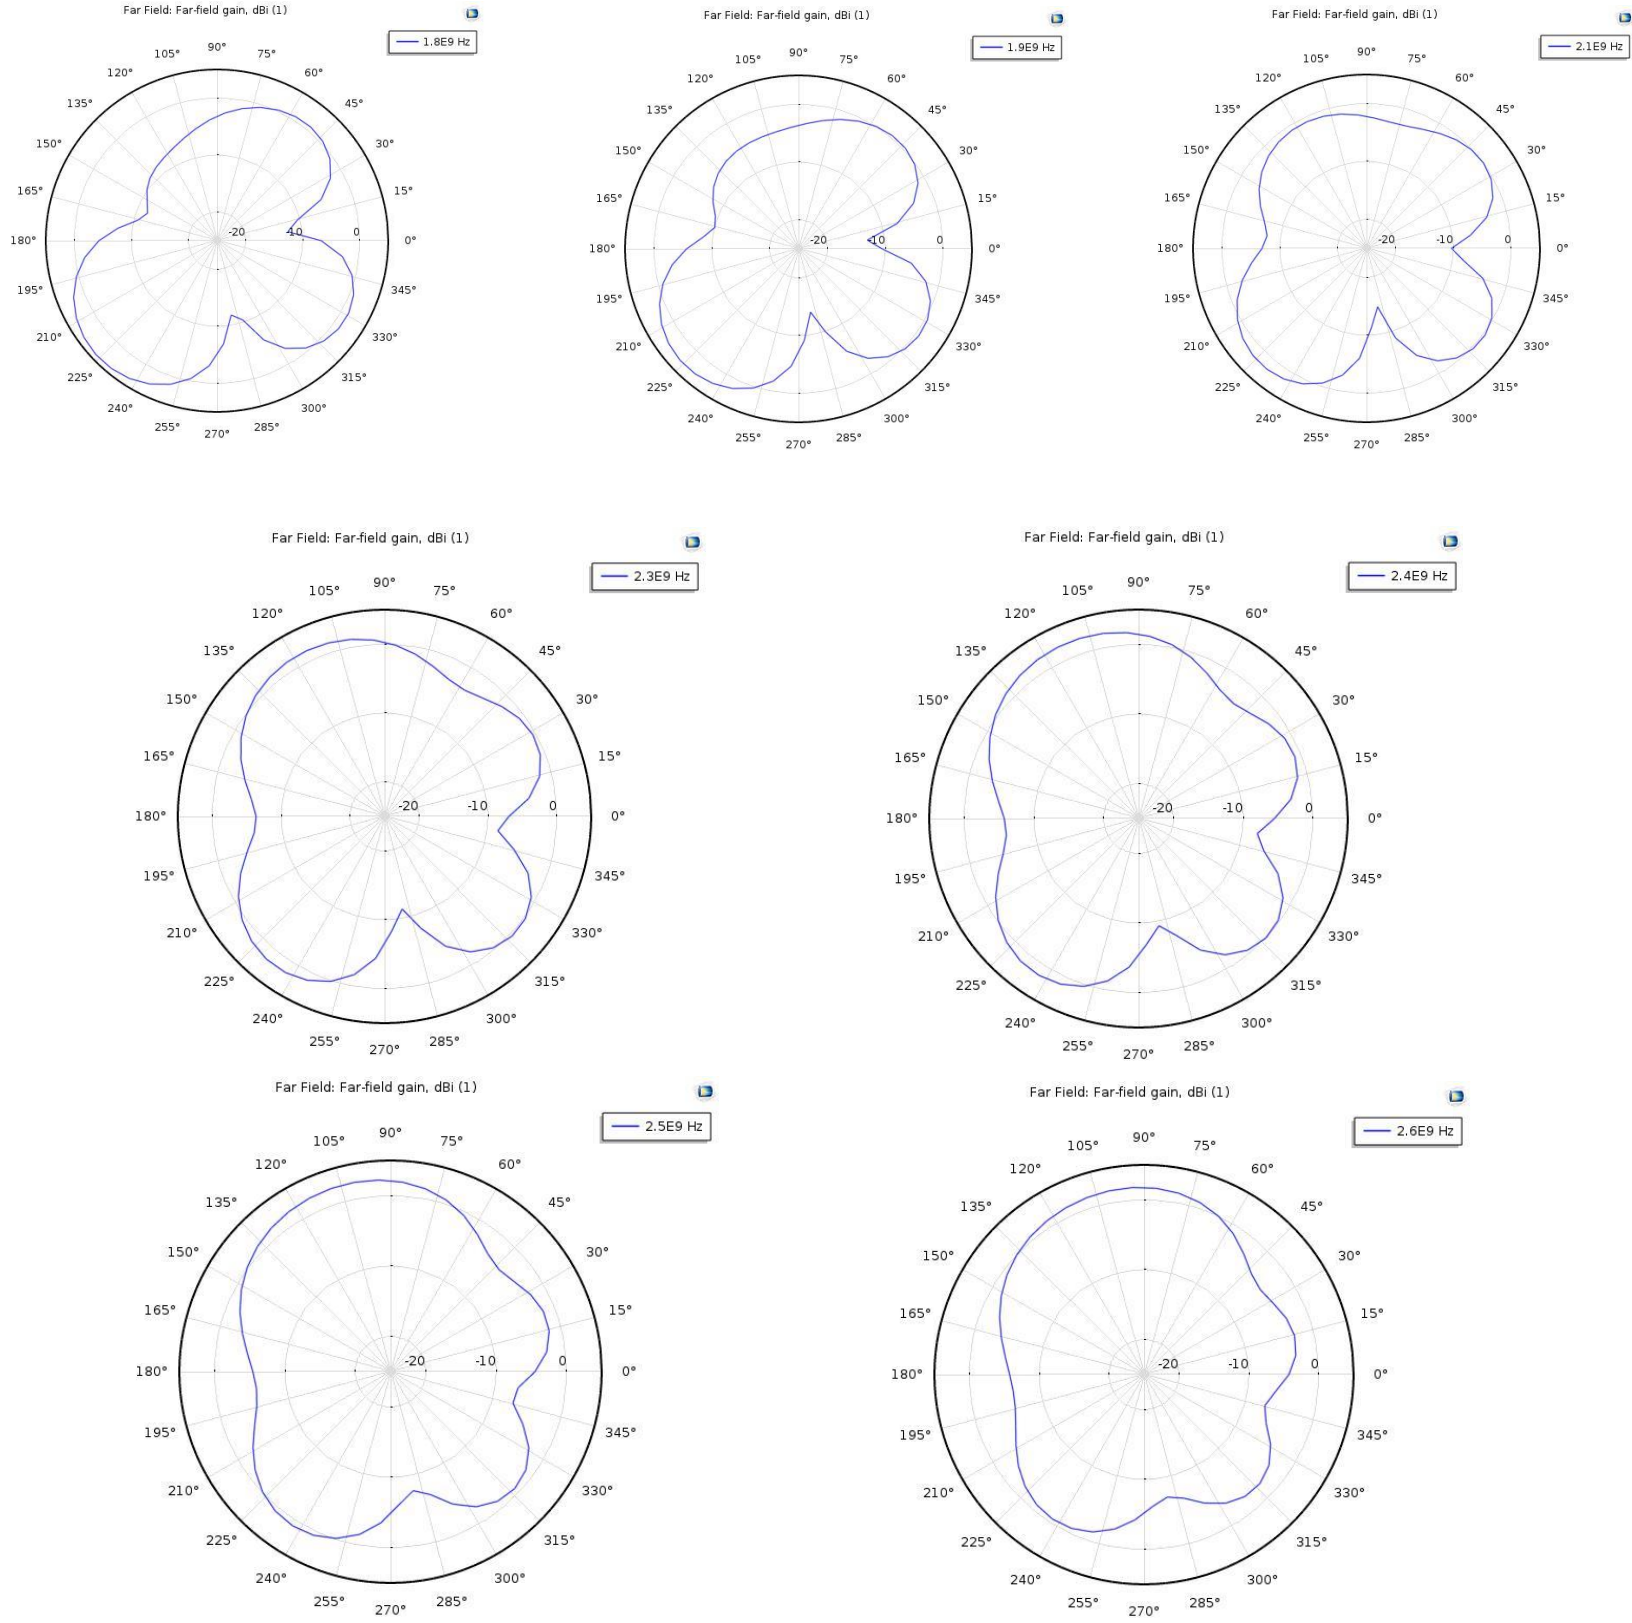

Figure 3.2.4 Antenna gain pattern on the xy-plane for each frequency band.

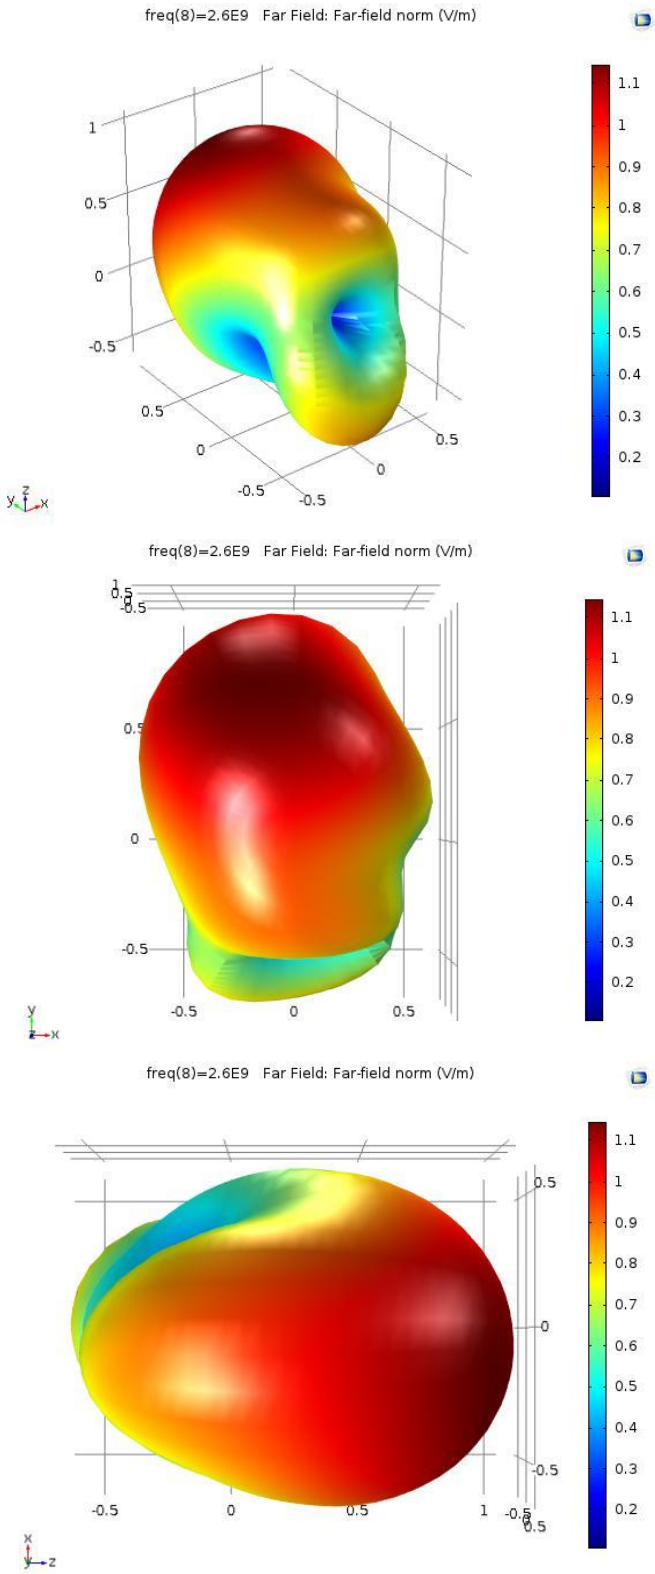

Figure 3.2.5 3D far-field radiation pattern of wideband PIFA shown from three different angles.

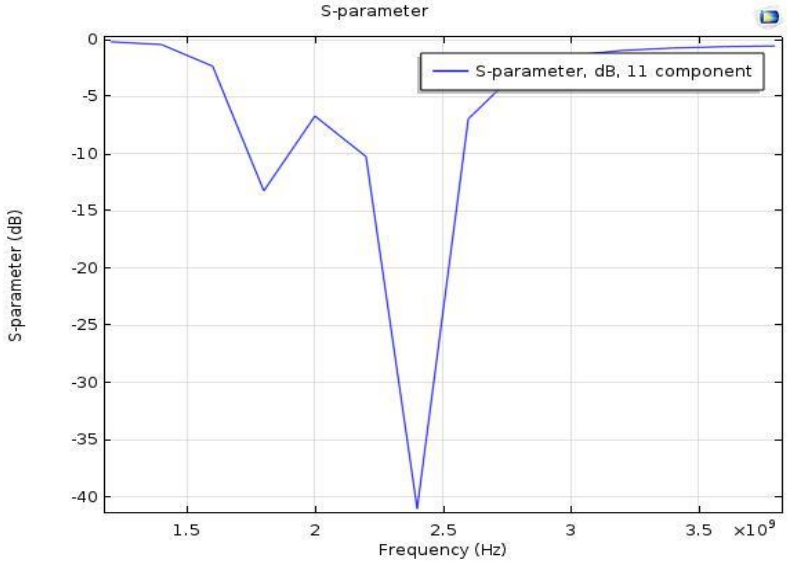
Results and Analysis



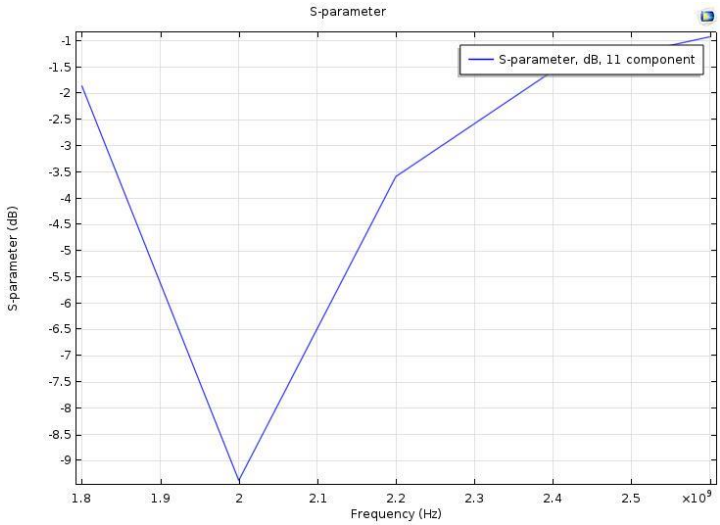


Figure 3.2.5 (a) Return loss (S11) for the wideband PIFA using slotted ground plane by simulation.

(b) Return loss (S11) for PIFA without slot.

As shown in figure 3.2.5 (a) the resonant frequency is 2.4GHz with -40dB and return loss of the frequencies 1800MHz,1900MHz,2300MHz,2400MHz and 2500MHz is $\leq -10dB$. At 2600MHz is -8dB and at 2100MHz is -9dB which it's still reasonable. With considering 2600MHz has a sufficient low return loss, the bandwidth will be 36.36%.

Figure 3.2.5 (b) shows the PIFA antenna without using a slot on ground plane with resonant frequency at 2GHz, return loss -10dB and the bandwidth can be calculated as following:

$$Bandwidth\% \approx \frac{2.01-1.99}{2} = 1\%$$

Based on what is mentioned above, we can conclude that's the slot has a big significant effect on either bandwidth or on better matching impedance network. In bandwidth there is a huge difference; without using slot the bandwidth is 1% and with slot is 36.36%. Even if we exclude the band 2600MHz the bandwidth 32.36% which is still much wider rather, comparison is nonessential. On other hand the effect of the slot on return loss (S11) is clear as well. Where PIFA with slotted ground plane resonate at 2.4GHz with -40dB, and without slot resonate at 2GHz with poor return loss -10dB.

As seen in figure 3.2.4 it's obvious that all frequencies bands have an Omni-directional behavior with reasonable gain table 3.2.1 summary the maximum and minimum gain.

Table 3.2.1 Simulated gain of the frequencies which shown in figure 3.2.4.

Frequency	Maximum gain	Minimum gain
1800MHz	4.95dB	-12.48dB
1900MHz	3.97dB	-13.86dB
2.1GHz	2.89dB	-14.72dB
2.3GHz	2.54dB	-11.31dB
2.4GHz	2.78dB	-9.33dB
2.5GHz	2.89dB	-7.79dB
2.6GHz	2.25dB	-7.1dB

In this design several methods are followed in order to improve the Bandwidth and the gain, where the relation between the Bandwidth and the gain is not linear. Using dielectric material with high dielectric constant causes a degraded gain; on other hand the effects on Bandwidth could be neglected.

Techniques which are used to increase the Bandwidth for proposed PIFA:

- Bandwidth depends very much on the size of the ground plane. So for better performance, the whole available size of the chassis should be used as a ground plane. Reducing the ground plane can effectively limit the bandwidth of the PIFA antenna.
- Using slotted ground plane: using a slot with proper length to get other resonant frequencies.
- Using Air as a dielectric material between the PIFA element and the ground plane this technique improves the Bandwidth and enhances the gain.

A wideband PIFA antenna has been designed and presented. The proposed PIFA antenna occupies a compact envelope dimension of $24 \times 10 \times 4mm^3$ while covering the required wide band with a sufficient impedance matching (S11 ≤ -10 dB) covering GSM (1800MHz &1900MHz), Bluetooth & Wi-Fi (2.4GHz), and LTE system (2.3GHz, 2.5GHz) except UMTS (2.1GHz) and LTE (2.6GHz) which has acceptable return loses.

3.3 Wi-Fi and Bluetooth Antenna

Wi-Fi and Bluetooth antennas work by transmitting and receiving the electromagnetic waves from the antenna to the receiver. They are one of the most useful services in the new smart phones, Wi-Fi antenna is the smallest antenna could be finding in the mobile phones because it works with the highest frequencies.

One of the best advantages of the Wi-Fi antenna that can support dual-band, the first band is from 2400 MHz to 2484MHz and also can support 5150-5850MHz; therefore the Wi-Fi antenna can cover the band of the Bluetooth too.

Nowadays, the most useful Wi-Fi antenna in mobile phone that's is connect to small chip which work for the Wi-Fi and the Bluetooth antennas in the same time, also we can have two antennas one for the Wi-Fi antenna which cover 5GHz and the other one for the Bluetooth which cover 2.4GHz but it is not common to use two types of antennas it will need more space and it will be costly than use one antenna.

As we mentioned Wi-Fi antenna is the smallest antenna in the mobile phones, the antenna half wavelength which covering the Bluetooth 2.4 GHz supposed to be 6.25 cm and at 5GHz which is mostly dipole antenna the half wavelength for sure will be smaller, it is 3 cm. also the quarter wavelength could be used which mean that the size of the antenna will be much smaller which is usually PIFA or PMA.

The quality of the Wi-Fi and Bluetooth antenna connection depend mainly on the gain of the antenna as we have mentioned in the second chapter, by determining the antenna power gain we can identify the efficiency and the directivity of the antenna, the order of the Wi-Fi mobile phone antenna efficiency from -6 dB to -2dB.

In case the primary antenna of the mobile phone does not cover the Bluetooth and Wi-Fi frequencies the Wi-Fi and Bluetooth antenna integrated on the top of the phone close to the GPS antenna due to the hand held of the user.

Chapter 4

Specification Absorption Rate (SAR)

As the world care about the development of wireless communication and with the really huge goals they have achieved on the other hand we should consider the human health and the risk which is effect negatively in the human health.

The meaning of SAR is a short name of specification absorption rate which is the measurement of the energy has absorbed by the human body during transmit the radio frequency electromagnetic field. The human body absorbed the energy that's mean we will lose some energy the second problem that's mean will affect the human body badly.

SAR can be calculated by integrating or averaging over 1 gram or 10 gram:

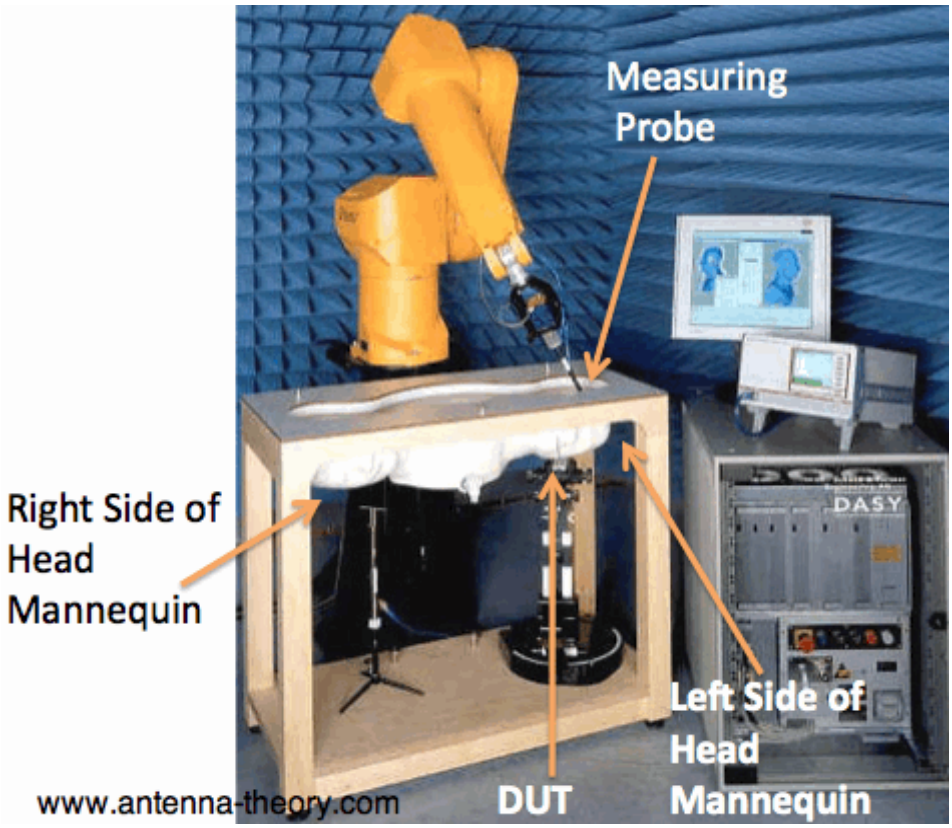
$$\boldsymbol{SAR = \int \frac{\sigma(r)|E(r)|^2}{\rho(r)} dr} \qquad \textbf{(4.1)}$$

Regarding to the equation 4.1 it explains that SAR is a function of the induced electrical field which is from the radiated energy E it can be measured by $volts\ /\ meter$, the electrical conductivity σ which can measured in $Siemens\ /\ meter$ and the mass density ρ can be measured in $g\ /\ (cubic\ meter)$, finally the unit of the SAR is $W\ /\ kg$.

The SAR have different values regarding to the design of the mobile phone and the location of the antenna in the mobile phone, therefore always, the mobile phone antenna located on the bottom of the phone to keep the radiate as far as much of the user. Low SAR means that it is safer than the high SAR while all the mobile phones has radio frequencies. On the other hand we don't forget to mention that the SAR will effect on the quality of the power by reducing the power level because of the absorption.

4.1 How To Measure The SAR?

Measuring the SAR by the DASY measurement system as shown in figure 4.1.1



http://www.antenna-theory.com/definitions/sar.php

Figure 4.1.1 The DASY SAR measurement system.

If we look at the figure 4.1.1 it shows different equipment which gives us availability for picturing the same situation of using the mobile phone in the real life.

The hollow tub in the figure 4.1.1 has the same shape of the right side and the left side of the human head, also there is a yellow robot with long arm which has in the end of the arm a measuring probe, the measuring probe moves around the all the region of the right side of human head and the left side too to lead us the measuring the SAR. But to get the correct measuring of the SAR we should have the correct conductivity and correct density therefore the tub must be filled with special fluid which has almost the same properties of the human tissue.

It is really worth to mention that the fluid has to change the standardized of the human tissue regarding to the frequency we are dealing with.

The DUT which has a long arm, it is located under the hollow tub and close to the head shape due to our need to place the mobile phone in the edge of the head as it must be in the reality.

Finally, the measurement shouldn't be in one side of the human head and we should consider that the measurement of the SAR very sensitive so we can get a very big different result because of the complex nature of the near field.

4.2 The Techniques Of Reducing SAR

Reducing the electrical magnetic field of the antenna will effect to reduce the value of SAR in human head that can be made by using the RF shield to the front side of the phone. The RF shield which has been made of ferromagnetic material so it can help to reducing the value of the SAR because of the suppression of the surface current on the front of the mobile phone box as shown in figure 4.2.1.

During the travelling of the electrical magnetic wave through the free space the wave will be divided to three parts, the first part of the wave going to transmitted, other parts will reflect and absorbed, the function of the electrical magnetic wave material absorbed the energy of the wave as magnetic loss then convert it to energy which it can be feel as heat.

The main materials that are used for making electromagnetic shield are sheet metal, metal foam and material, the holes in the shield should be smaller than the wave length to keep it away.

The value of the reduction depends mainly on the material that have been used, the hickness of the shield, the frequency of the field, the shape, the directivity of the aperture to indicate the electromagnetic field and the size of the shield.

http://en.wikipedia.org/wiki/Electromagnetic_shielding

Figure 4.2.1 The RF shield in mobile phone.

The identification of the RF shield can be determined by determining the value of the SAR reducing factor (SRF) so if the value of SRF is very large that's mean its need to greater RF shield.

SRF can be calculating by the following formula:

$$\boldsymbol{SRF_{Total}}(\%) = \frac{\boldsymbol{P_{abs} - P_s}}{\boldsymbol{P_{abs}}} \times \mathbf{100} \qquad \textbf{(4.2.1)}$$

$$\boldsymbol{SRF_{1g}}(\%) = \frac{\boldsymbol{SAR_{1g} - SAR_{1g,s}}}{\boldsymbol{SAR_{1g}}} \times \mathbf{100} \qquad \textbf{(4.2.2)}$$

$$\boldsymbol{SRF_{10g}}(\%) = \frac{\boldsymbol{SAR_{10g} - SAR_{10g,s}}}{\boldsymbol{SAR_{10g}}} \times \mathbf{100} \qquad \textbf{(4.2.3)}$$

- (SRF) is the total SRF
- (P_{abs}) is the power absorbed in the head model, (P_s) is the power in the RF shield.

- (SRF_{1g}, SRF_{10g}) is the SRF for 1g and 10g peak SAR
- (SAR_{1g}, SAR_{10g}) is 1g and 10g peak SAR (without RF shielding)
- ($SAR_{1g,s}, SAR_{10g,s}$) is 1g and 10g peak SAR (with RF shielding)

Headset vs SAR

Based on the study of UK consumers association reported that the headset can reduce the value of SAR, because of the wire that's connect the headset to mobile phone therefore the wire is working as channeled unshielded radiation and antenna to the human head. The SARtest discovered that can reduce the absorbed radiation until 70%.

4.3 The Limit of SAR in Different Countries

TABLE 4.3.1 The limit of the SAR in different countries [13].

Country/Region	SAR measurement protocol	Reference to SAR limit	Limit
Europe	European Specification ES 59005 (1998)	ICNIRP Guidelines 1998 (ICNIRP 1998)	2.0 W / kg in 10g of tissue
Australia	Australian Communication Authority (ACA) standard (ACA RS 1999)	Australian standard AS/NZS 2772.1	1.6 W / kg in 1g of tissue
US	Federal Communications commission(FCC) Guidelines(FCC1987)	American Standard ANSI C95.1 (ANSI 1992)	1.6 W / kg in 1g of tissue

Regarding to the table 4.3.1 the average limit of European countries is 2.0 W / kg in 10g of tissue is absorbing the most signal, Australia and US has the same limitation 1.6 W / kg in 1g of tissue.

In India they were following the same limitation as Europe until 2012 then they have switched to follow the same limitation as US, and the test of India in SAR is done by Telecommunication engineering center. There are many countries have been following the same limitation of US such as Korea, Bolivia and Canada 1.6 W / kg in 1g of tissue.

4.4 SAR With Different Types Of Antenna

There are some types of antenna that have a really good deal with SAR, the table 4.1.3 shows the dealing between the level of SAR with different types of antenna.

Table 4.4.1 The level of SAR in different types of antenna.

Type of antenna	Level of SAR
Helix	High SAR
Slot	LOW SAR
PIFA	LOW SAR
PMA	High SAR

As showing in figure 4.4.1 first shape show the human head with Helix external antenna which used since 1995 to 1999 with thickness 20 mm and the value of SAR 1.68 mW/g , we notice in the second shape it had used the same type of antenna but the thickness have changed from 20mm to 10mm because of this change of the thickness the value has increased to 2.26 mW/g, the used of PIFA from 1997 to 2009 which has a really good deal with SAR as we mentioned in table 4.4.1 and PMA which used above 2009 with SAR value 2.0 mW/g.

Figure 4.4.2 Comparing between the radiation of Helix, PIFA and PMA.

We can notice from the previous figure 4.4.2 that he radiation of Helix and PMA are like a dipole antenna but PIFA has different characteristics of radiation which guide us to notice that it is a type of microstrip antenna. So we can mention that the dipole antenna hasn't a good relation with SAR.

Table 4.4.1 The highest SAR values in different well known mobile phone manufacture companies [12].

Manufacture company	Model	SAR in W / kg
Apple	IPhone 5	1.25
Nokia	Lumia 630	1.52
Sony Ericsson	Z1010	1.41
Samsung	P400	1.18
Blackberry	Curve 9320	1.56

Table 4.4.2 The lowest SAR values in different well known mobile phone manufacture companies [12].

Manufacture company	Model	SAR in W / kg
Apple	IPhone 4,5c,4s,6	1.18
Nokia	9300	0.07
Sony Ericsson	Tz600	0.16
Samsung	X830	1.18
Blackberry	Curve 8900	1.01

Chapter 5

Problems of Mobile Phone Antennas Design

Mobile phones antenna design is a complicated process. There are a lot critical considerations, the place where the antennas will be installed in mobile phone chassis for example, and regulatory requirements, what are the possible bands of frequencies could be used. In addition, nowadays, mobile phones have multiple antenna for different functions.

5.1 The Radiation Efficiency of the Mobile Phone Antennas

The performance of an antenna depends on the antenna element itself and the ground plane of the mobile phone. That leads to the small size antenna problem, which means that there are limitations for how much the antenna can be minimized, in term of available space in mobile phone or in the expectable good performance. Mobile phone antennas have low efficiencies, and low input resistance and high input reactance, that's create a difficult for matching impedance between the antenna element and the transmission line.

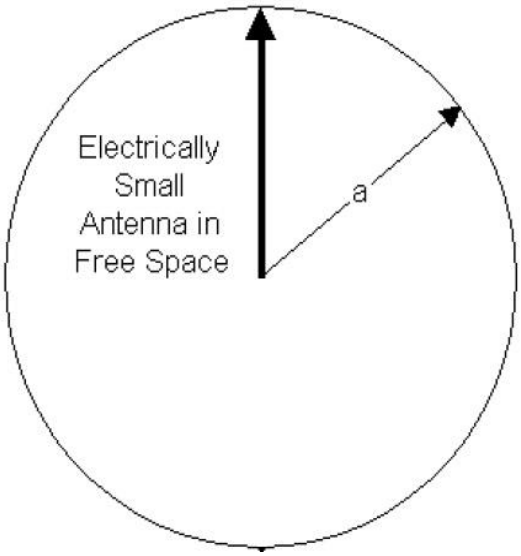

Figure 5.1.1 Imaginary Sphere encloses an antenna in free space with radius a.

At the beginning Wheeler introduced a method to define the maximum volume radiation for electrically small antenna by two measurements, first one in free space and the other within an imaginary closed sphere with radius $a = \frac{\lambda}{2\pi}$ as shown in figure 5.1.1 [18]. Wheeler considers that the antenna resonance frequency can be described as two series resistances; radiation resistance R_{rad} and loss resistance R_L (of used material) [18]. The radiation efficiency of a small antenna can be determined by the following formula:

$$\boldsymbol{\eta_{rad} = \frac{R_{rad}}{R_L + R_{rad}}} \qquad \textbf{(5.1.1)}$$

The current distribution in the small electrically antennas has small space to flow as it's obvious, that's make the antenna to behave as a capacitor, and consequently the current will be zero, that means there is no radiation power. In that case we must satisfy a proper matching impedance network in term to get radiation power by the small antenna. Radiation resistance for small antennas becomes very small due to weak radiation [26].

Efficiency of a system- which consists of antenna and matching network- can be expressed with help of the radiation efficiency which described in equation 5.1.2 by:

$$\boldsymbol{\eta_s = \eta_{rad}\eta_m} \qquad \textbf{(5.1.2)}$$

η_s: Efficiency of the system.

η_m: Efficiency of the matching network.

Based on the equations 5.1.1 and 5.1.2 we can conclude that in order to get higher efficiency of a system, we have to take in account several parameters:

1. Maximum Radiation resistance.
2. The lowest value of loss resistance.
3. The lower mismatch network as possible (lower |Γ|).

In addition, the mobile phone case's material type, and the surrounding environment (such as hand-held, which it will be discussed later) have an additional effect on the radiation efficiency. Antennas with bigger size have better efficiencies than small antennas. On other hand the space which is available for antenna in chassis of mobile phones is very restricted. Thus there is always tradeoff between size and performance.

5.2 Bandwidth

We can determine the bandwidth of an antenna by determining the impedance for all frequencies in that desired range. But in small antennas case the bandwidth depends on others factors. Small antennas such as PIFA have less real input resistance (it approaches to zero) and highly reactive input impedance, which leads to mismatching network problem. To match the impedance of a small antenna with its feeder's impedance is a quite critical issue. The bandwidth depends on the reflection coefficient and matching networks.

The quality factor Q is a limit of the accessible impedance bandwidth at certain efficiency. Sometimes the small antenna is defined by Q.

As it's mentioned in the previous chapters, we can define the bandwidth by the following formula:

$$\boldsymbol{Bw} = \frac{\boldsymbol{f_{max} - f_{min}}}{\boldsymbol{f_0}} = \frac{\mathbf{1}}{\boldsymbol{Q}} \qquad \textit{Valid for } Q >> 1 \qquad \textbf{(5.2.1)}$$

For obtaining wide bandwidth we need to have the most possible minimum value of Q that's a hard challenge to solve. In 1947 Wheeler started to define radiation power factor, and the work on that issue is continued until nowadays. The most famous paper was published by Mclean 1996 [90] which describe the Q factor for a linearly polarized in free space based on Wheeler's concept as following:

$$\boldsymbol{Q_{LP} = \frac{1}{k^3 a^3} + \frac{1}{ka}} \qquad \textbf{(5.2.2)}$$

Where, $k = \frac{2\pi}{\lambda}$

For circularly polarized antenna Q has slightly different requirement:

$$\boldsymbol{Q_{CP} = \frac{1}{2}\left[\frac{1}{k^3 a^3} + \frac{1}{ka}\right]} \qquad \textbf{(5.2.3)}$$

The small antennas with higher values of Q have narrow bandwidth and that due to the low radiation resistance and high reactance. The Q factor for a small antenna is defined as following:

$$\boldsymbol{Q_{minimum} = \frac{2\omega max(W_e, W_m)}{P_{rad}}} \qquad \textbf{(5.2.4)}$$

ω: The angular frequency.

W_e: The stored electric energy.

W_m: The stored magnetic energy.

P_{rad}: Radiation power.

With assuming that's there is no stored energy (W_e, W_m) inside the sphere (figure 5.1.1) which means reactive fielded equal to zero.

Based on equation 5.2.4 we note that's, mathematically to get the lowest value of Q the power radiation should be maximized, that's lead us to the efficiency problem. The mobile phones antenna design's problems are related with each other. Consequently more challenges are added to design process.

Multiband antenna can be used in order to solve the bandwidth limitations problem partially, since there is no small multiband antennas can cover all desired bands. As obvious from the discussion above, the wide bandwidth is a hard challenge to achieve by an ESA due to low profile (small size). In modern mobile phones, there are several antennas for different functions as mentioned in mobile phones antennas design's chapter. Each antenna operates with certain band; for example one antenna for higher band frequency, and one for GPS etc. Then all desired bands can be covered by that method. On other hand we have to take care on matching network, since we have several antennas to deal with, mutual coupling antenna to antenna loss, and the available space in mobile phone's chassis.

5.3 Mutual Coupling Antenna to Antenna Loss

The mutual coupling is the amount of the absorbed energy by an antenna when another nearby antenna is operating [4]. This interaction between near antennas is unwanted because that's amount of the absorbed energy should be radiated instead. Thus the mutual coupling reduces the efficiency of the antenna on both receiving and transmitting mode.

Mobile phones consist of several antennas, and with mobile phones geometrical dimensions, we find that the antennas near to each other in such way make the mutual coupling loss inevitably exists. So a good isolation is required to keep the antennas in mobile phone's chassis far from each other as possible. For that the antennas are generally distributed on top and bottom of the chassis which reduce the coupling loss. The coupling loss can be 1-2dB for antenna efficiency. Isolation values for smartphones which have same ground plane at the low band are about 10 dB, and can be 20 dB for the high band [28]. The coupling loss is not constant, it's varying; the coupling loss at low frequencies and at high frequencies are different.

The isolation can be increased by:

- Minimizing the correlation coefficient between the antennas.
- Increasing the separation space between antennas as much as possible.
- Using different polarizations for the antennas.

- Using proper filters with the antennas to decrease the effects of opposite antennas frequencies.
- Using dielectric walls between the antennas.

The isolation between two antennas is measured by connecting both of them to a Vector Network Analyzer and measuring of S12.

5.4 The Hand-Held Environment Problem

Table 5.4.1 Dipole performance at different locations of simulated distance from human head [24].

Distance from Head	**cm**	**Free space**	**5**	**4**	**3**	**2**	**1**
Input Impedance	Ω	75+j1.3	64+j27	60+j28	62+j35	52+j17	60+j23
Radiation Efficiency	**%**	100	72.3	63.4	50.5	42.7	29.1
Max. Directive Gain	**dB**	2.15	4	2.15	0	-1	-2
Min. Directive Gain	**dB**	2.15	-7	-7.5	-8	-9	-12

As shown in table 5.4.1, when the antenna is closer to the human head, the input impedance decreases, consequently the resonant frequency of the antenna decreases also. The absorption which occurs by human head reduces the radiation efficiency to 29% when the distance 1cm as shown above.

Other effect of handheld is in the directivity of the antenna. The difference between two positions at free space and 5cm far from the head, shows that the directivity increases from 2.15 dB to 4 dB, that's because the sum of radiation fields and fields scattered by the head which somehow compensate the loss in radiation of efficiency[24].

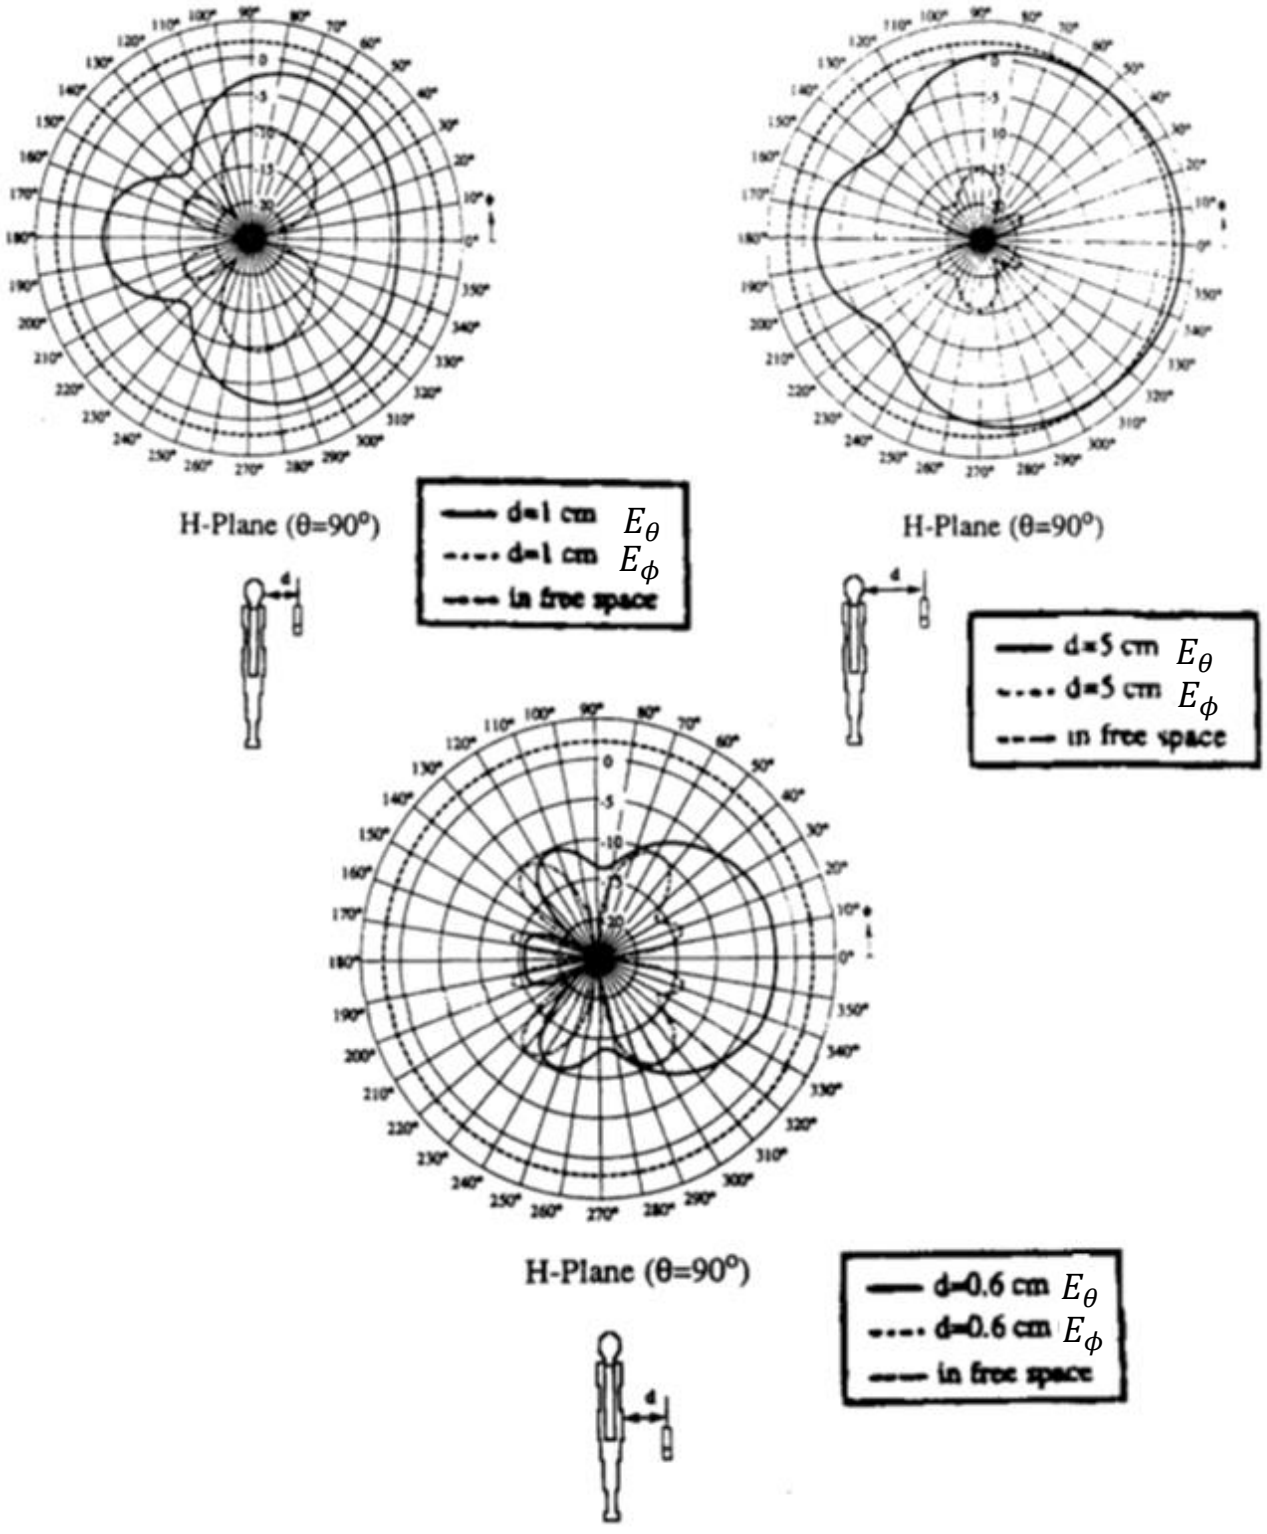
In general we can conclude that when the mobile phone is closer to the head the gain will fall quickly and the directivity is lost due to polarized fields.

Another model of a dipole antenna with a simulated distance is 0.6 cm from human head, and by applying the method of moments (***MoM***). The input impedance is 65 + j13 Ω, directional properties are same as 1cm and 15% radiation efficiency [25].

In figure 5.4.1 we can note that all three of the patterns radiation show -10dB nulls directly behind the user because absorption of energy by the modeled tissue, the attenuation increases as distance from the body decreases, and is worst for operation near the human torso [24].

Table 5.4.2 The effects of iPhone4 cases on antenna efficiency and absorption in the user's hand [17].

Case Type	Efficiency		Hand Peak SAR (mW/g)	
	GSM900	3G	GSM900	3G
No Case	14%	16%	19.3	27.0
Plastic Case (t = 1 mm)	16%	17%	11.6	12.6
Plastic Case (t = 2 mm)	18%	17%	7.1	8.0
Plastic Case (t = 4 mm)	18%	17%	2.3	5.4
Ring: Plastic (t = 1 mm)	16%	16%	12.7	11.3
Ring: Plastic (t = 2 mm)	18%	16%	7.9	8.5
Metal Case (t = 1 mm)	0%	1%	0.0	0.2
Ring Metal Case (t = 2 mm)	0%	3%	0.0	0.0
Chrome Plated Plastic (t = 2 mm)	4%	7%	9.2	11.7
Ring: Metal (0.3 mm) + Air (3 mm)	23%	15%	16.3	25.8
Ring: Metal (0.3 mm) + Air (1 mm)	11%	17%	3.6	21.5
Ring: Plastic (1 mm) + Air (3 mm)	24%	22%	7.4	9.8
Ring: Plastic (1 mm) + Air (1 mm)	22%	21%	7.9	9.6



Chuang, H. R. "Human Operator Coupling Effects on Radiation Characteristics of a Portable Communication Dipole Antenna"., IEEE Transactions on Antennas and Propagation, v. 42, n.4, April 1994, pp. 556-560.

Figure 5.4.1 .Free space dipole radiation pattern compared to the calculated (using MoM) radiation patterns for operation of a dipole antenna near the simulated human head and torso.

Coupling of energy to the hand of the user is another problem caused by hand-held environment. Figure 5.4.1 shows the experimental and measured results of the reflected power radio at different distance from the human hand for internal PIFA antenna by using an FDTD model for human hand. As seen below in figure 5.4.2 when the distance d becomes less more and more (the hand of the user gets closer to the antenna) the resonance frequency is shifted, and the reflected power radio becomes more, which means that's the antenna's efficiency is obviously degraded.

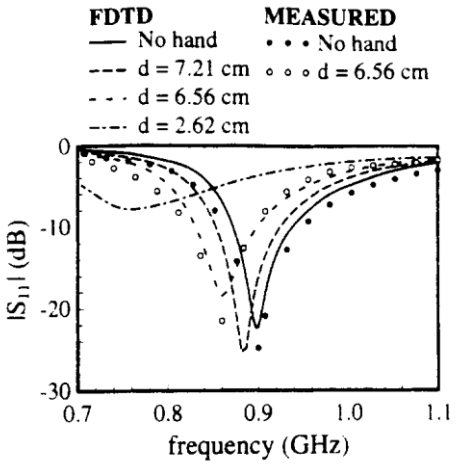


Photo was loaded from: Jensen, M., Rahmat-Samii, Y. "EM Interaction of Handset Antennas and a Human in Personal Communications".

Proceedings of the IEEE, v. 83, n. 1, Jan. 1995, pp. 7-17.

Figure 5.4.2 The experimental and measured results of the reflected power radio at different distance from the human hand.

The hand-held environment problems add more challenges in design process. Since it's so important to take in account the different scenarios. Some of that's issues can be solved by design and installed the antenna in the lower part of the mobile phone to keep the antenna far as possible from the hand of user. Another critical factor can play big role in this term is a good isolation for antenna.

IPhone 4 suffers from isolation antenna problem. Many users reported that signal strength of the phone was reduced when touching the lower left of the phone, which causes dropped calls in some areas [26]. On other hand Apple recommended the consumers to do not grip the phone at that corner.

On July 16, 2010, Steve Jobs advertised that Apple would offer a case for the consumers to help solve the antenna issue [26]. Table 5.4.2 shows an iPhone4 and the effects of different material of casing on efficiency and SAR. Metal cases with thickness equal to 1mm, and 2mm, keep the efficiency without any effects and SAR values at almost zero.

Summary and Conclusion

Mobile phone antennas have several critical parameters such as the geometric dimensions, dialectical materials which are used in design, and the ground plane of the antenna. All of that should be taken into account for optimizations process. The fast development of mobile phones devices add more demand on optimizations of the antennas.

In this thesis we investigate PIFA antenna type by design two models of it. The first model handles one single band with resonant frequency 1.575GHz which could be suitable at that frequency for GPS signal with reasonable gain from -6dBi to 1.5dBi and with return loss (S11) -13dB. The bandwidth 1% which is sufficient since there is no bandwidth practically.

The second proposed PIFA is a wideband antenna with dimensions $24 \times 10 \times 4mm^3$cover range from 1800MHz to 2600MHz. This important range covers GSM (1800MHz & 1900MHz), UMTS (2100MHz), Bluetooth & Wi-Fi (2.4GHz), and LTE system (2.3GHz, 2.5GHz, and 2.6GHz). The Bandwidth is 36.36% which is considered as a wide bandwidth. This wideband PIFA antenna is designed using slotted ground plane and air as a dielectric material between the planar element and the ground plane.

Mobile phone antennas design is a big challenge. Mobile phone antennas designs have lot problems. Low efficiencies can be the most critical problem which leads to tradeoff between size and performance.

1.0 Introduction and Summary of Findings

In 1995 MegaWave Corporation, under an NAB sponsored project, developed a broadband VHF/UHF set-top antenna using the continuously resistively loaded printed thin-film bow-tie shown in Figure 1-1. It featured a low VSWR (< 3:1) and a constant dipole-like azimuthal pattern across both the VHF and UHF television bands.

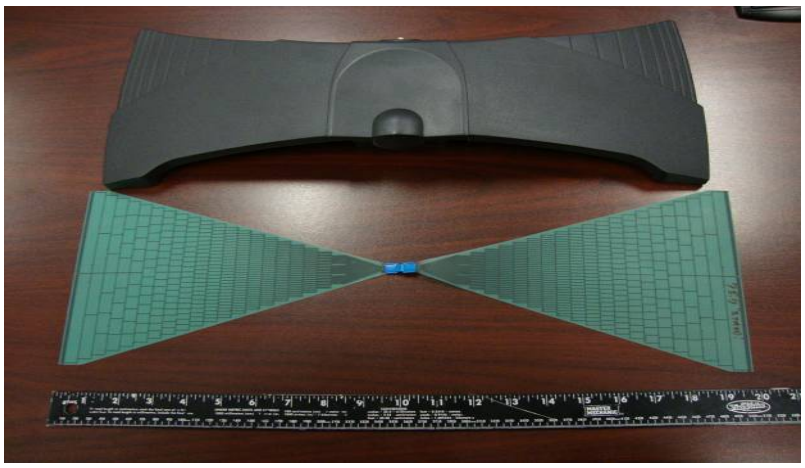

Figure 1-1: MegaWave 54-806 MHz Set Top TV Antenna, 1995

In the 15 years since then much technical progress has been made in the area of broadband and low-profile antenna design methods and actual designs. These improvements have been published in: technical textbooks, peer-reviewed articles, patents, government research and development reports, and seminar proceedings. As a developer of advanced antenna systems, primarily for the U.S. government, MegaWave constantly reviews these sources and acquires the latest computer based EM simulation tools in order preserve its competitive advantage. In this project, this knowledge was used to identify ten candidate design methods and technologies that have the potential to materially improve the performance of indoor VHF-UHF TV antennas. This report describes each candidate and its potential to improve indoor ”set-top” reception of DTV signals between 54 and 698 MHz.

Of course, it must be kept in mind that, while advanced design methods and actual physical designs exist, so do the laws of electromagnetics. Maxwell’s equations have resulted both in practical as well as, what Dr. R. C. Hansen humorously calls, “Pathological Antennas”. These pathological designs are described in his most recent textbook [1], especially in the area of electrically-small and broadband designs. It is instructive to apply these fundamental limitations to the problem at hand, the set-top TV antenna.

[1] Hansen, R.C., “Electrically Small, Superdirective, and Superconducting Antennas,” Wiley, 2006

Consider that a half-wavelength in the low VHF TV band varies between 9.2 and 5.6 feet; between 34 and 27 inches in the high VHF band and between 12.6 and 8.5 inches in the UHF (470-698 MHz) band. A dipole antenna whose physical length is less than its wavelength divided by pi (λ/π) is considered to be an electrically "small" antenna (ESA). ESAs unfortunately are characterized by narrow bandwidths and low gains. Assuming 2 to 3 feet as a maximum acceptable length for an indoor or set-top antenna, it definitely falls into the ESA category in the low VHF band. But, in addition to size constraints and the resulting difficulty in obtaining acceptable performance from a single antenna over the 54 to 698 MHz spectrum, there are other concerns. Indoor and set-top antennas are fundamentally disadvantaged due to building penetration losses and by proximity to sources of manmade radio noise. The former effect is more pronounced at UHF and the latter at low VHF channels. Both can have a significant deleterious effect on antenna performance. This brief discussion highlights the difficult problems inherent in designing efficient, high performance antennas for the indoor/set-op TV environment. Fortunately, emerging technologies may effectively address these concerns.

This report is organized as follows. Sections 2.1 through 2.10 contain summaries of each advanced method and hardware technology identified as a potential candidate for high-performance indoor VHF-UHF DTV antennas. Each section includes a list of references and, in many cases, photographs and performance data for multiple implementations of the technology that is described. Section 3 includes conclusions and a conceptual design for a practical indoor/set top VHF-UHF antenna system.

The authors evaluated each technology and arrived at the conclusions and design concept after sorting the nine hardware candidates into three categories as follows:

- Mature technologies that **do not** require any CE-909-A channel designator or signal quality information from the DTV receiver:
  - Fragmented Antennas (Section 2.2)
  - Non-Foster Impedance Matching (Section 2.3)
- Mature technologies that **do** require channel and quality data from the receiver:
  - Active RF Noise Cancelling (Section 2.4)
  - Automatic Antenna Matching Systems (Section 2.5)
  - Physically Reconfigurable Antenna Elements (Section 2.6)
- Emerging technologies that show promise, but are not sufficiently mature or practical at this time:
  - Metamaterials (Section 2.7)
  - Electromagnetic Band Gap (EBG) Materials (Section 2.8)
  - Fractal/Self Similar Antennas (Section 2.9)
  - Retrodirective Arrays (Section 2.10)

A common thread connects each of these technology areas: ***advanced computational methods***. Whether a particular technology is mature and immediately applicable or emerging and highly speculative, various schemes for antenna design optimization are universally applicable and described in Section 2.1. These methodologies apply to all of the candidate technologies discussed in Sections 2.2 through 2.10, and accordingly was placed at the beginning of Section 2. If even one of the optimization algorithms described had been available during the development of MegaWave's 1995 broadband set top antenna, it is likely that markedly better gain performance would have resulted, especially in the low and high VHF bands. Another attractive and potentially very significant capability offered by optimization algorithms is the possibility of discovering entirely new antenna geometries, rather than simply optimizing a pre-existing geometry.

Table 1-1 ***subjectively*** ranks the nine identified candidate hardware technologies (2.2 - 2.10). A score of 10 represents perfection. By maturity we mean how close to off-the-shelf a particular technology's hardware is and how well it basic principle of operation has been vetted in the literature. The term SWAP refers to size/weight and power.

	Method/ Technology	Active/ Passive	Requires CE-909-A Interface	Maturity	Vetted	Risk	Design Complexity	SWAP	Comments
2.1	Adv. Comp. Methods	N/A	N/A	9	9	Very Low	N/A	N/A	Applies to all Technologies
2.2	Fragmented	Passive	No	7	7	Low	Low	9	Planar
2.3	Non-Foster	Active	No	6	7	Low	Moderate	7	Limited Bandwidth
2.4	Active Noise Cancelling	Active	Yes	7	6	Low	High	3	Requires I&Q
2.5	Automated Antenna Matching	Active	Yes	7	7	Moderate	High	7	Requires complex TV interface
2.6	Reconfigurable Antennas	Active	Yes	6	7	Moderate	High	6	Control of MEMS w/DC
2.7	Metamaterials	Passive	No	3	4	High	High	8	Emerging/ Availability an issue
2.8	EBG	Passive	No	5	6	High	High	5	Inherently Narrow Band Maybe useful for shielding
2.9	Fractal/Self Similar	Passive	No	6	4	Moderate	Moderate	8	Controversial Performance Gain
2.10	Retrodirective	Active	Yes	4	5	Very High	Very High	2	Narrow - Band, Large

Table 1-1: Candidate Technologies Considered and Their Ranking

As an example of how advanced computational methods could be combined with an advanced hardware technique, that does not require a CE-909-A interface, is described at the end of Section 3 and summarized here.

Using the genetic algorithm described in Section 2.1.5 a fragmented antenna was designed and combined with a non-Foster-matching circuit to provide a planar 54-698 MHz dipole approximately 13 by 13 inches with significantly better gain, especially in the 54-88 and 174-216 MHz bands, than the 1995 MegaWave/NAB set top antenna. Figure 1 shows the broadband fragmented planar element's design obtained after approximately 24 hours of computational time on a PC. Details of the specific method used are in Section 2.2 of this report. It is well matched across the UHF DTV band, but requires some passive matching in the high VHF band (which would also serve as the band combiner) and the more robust matching capability of the active Non-Foster-Matching technique, described in Section 2.3, for the low-VHF band.

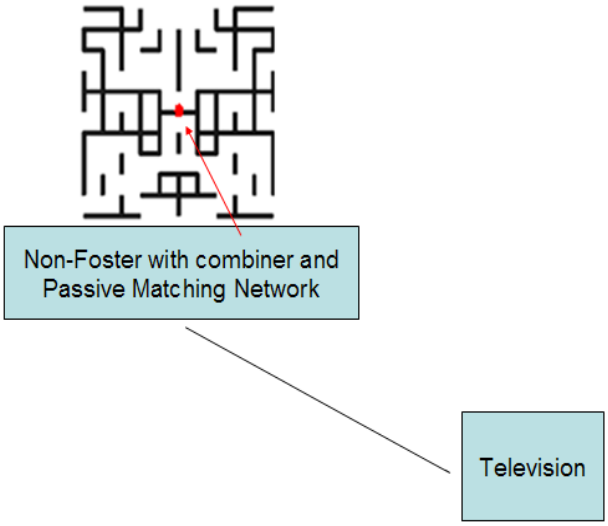

Figure 1. 13 x 13 Inch Planar Fragmented Non-Foster Matched VHF-UHF Antenna

An omni-directional version could also be designed. It should be stressed that the above is included here only to illustrate the notion of combining advanced computational broadband antenna element designs with emerging electronic antenna matching capabilities and that other antenna element geometries are also possible, depending on the starting conditions, trade space dimensions and performance goals provided to the optimizer.

The authors want to make clear that 90 percent of the techniques and ideas contained in this study are the work of others, as published in the open literature and referenced herein.

2.0 Specific Design Methods and Hardware Technologies Investigated

2.1 Advanced Computational Methods

2.1.1 Summary

Optimization methodologies abound, and they are extensively used in every aspect of engineering design, in particular antenna design. Optimization algorithms are useful in two ways. They can be used to optimize the design parameters for a user-specified antenna geometry (for example, element spacing, length and diameter in a Yagi-Uda array). They also can *generate designs* that are impossible to achieve otherwise. In both cases, optimization involves meeting specific performance objectives (typically, VSWR, gain, bandwidth, and so on).

Optimization algorithms have become progressively more important as the limitations of classic analytical techniques have become progressively more apparent. While the equations underlying electromagnetic theory are well understood and accurately describe all electromagnetic phenomena, in most practical cases they cannot be solved analytically or, oftentimes, even numerically. Designing better antennas requires improved methodologies, and state-of-the-art optimization algorithms have proven very effective. There is no question that these techniques are applicable to the set-top antenna design problem, and that they should receive considerable attention in future design activities.

There are many different optimization methodologies that fall into two broad categories: analytical methods and heuristic methods. Analytical methods are based on precise mathematical formulations of the optimization problem. Even though they may be fundamentally numerical in nature, they involve standard mathematical operations such as computing derivatives or evaluating integrals. Heuristic methods may involve equations, but the equations are not the result of an analysis. Instead, they are offered without "proof" based on the fact that they "work."

Many optimization heuristics are Nature inspired. The steps an algorithm performs to optimize an *antenna* are based, for example, on how *bacteria* forage for food. As disparate as these entities may seem, there is a connection, at least in the sense that bacteria finding a good food source is similar to finding an antenna with a good gain-bandwidth product. Optimization algorithms of this type are usually referred to as "metaheuristics," a term intended to emphasize that the method is both *empirical* and *conceptual* in nature. Thus, an effective bacteria foraging algorithm can be implemented in many different ways because the bacteria foraging metaheuristic simply suggests an analogy to Nature that is implemented in a computer algorithm working on

an antenna problem. The metaheuristic thus is an *algorithmic framework* instead of a list of steps or instructions.

Several Nature inspired metaheuristics are described. A brief summary of each algorithm is provided, and several example antenna problems solved by a variety of algorithms are discussed. The algorithms include Ant Colony Optimization (ACO), Particle Swarm Optimization (PSO), Genetic Algorithm (GA), Simulated Annealing (SA), Central Force Optimization (CFO), Invasive Weed Optimization (IWO), Intelligent Water Drop (IWD) algorithm, and Bacteria Foraging Optimization (BFO). There are many other optimization algorithms [for example, Space Gravitation Optimization (SGO), Integrated Radiation Optimization (IRO)], but they have not been applied to antennas or antenna related problems.

Each of these algorithms, except one, is inherently *stochastic* because its Nature inspired algorithmic model relies on randomness in its functioning. The underlying equations contain true *random variables* whose values are computed from a probability distribution and consequently cannot be known in advance. As a result, every time a stochastic optimizer run is made, its results are different than the previous run even when exactly the same run setup parameters are used. The performance of stochastic optimizers is necessarily characterized statistically (for example, average values, standard deviations). This may be a limitation in the utility of optimization algorithms if they are used in a set-top antenna on a real time basis. For example, a self-structuring antenna (SSA) must reconfigure itself in real time in response, for example, to a changing environment.

The one algorithm that is not inherently stochastic is Central Force Optimization (CFO) whose Nature inspiring metaphor is gravitational kinematics, the branch of physics that deals with the motion of masses moving under the influence of gravity. The underlying equations are Newton's equations of motion, which are completely *deterministic*. CFO analogizes these equations in "CFO space" by flying "probes" that are similar to small satellites to search a decision space "landscape" for the maximum (optimal) values of a function (for example, antenna gain as a function of element length and polar angle). CFO has been applied to antenna design and network synthesis, and tested against many recognized benchmark functions used to evaluate optimization algorithms. It therefore may be especially useful for the set-top antenna problem.

2.1.2 Introduction

This section describes developments in antenna design optimization over the past fifteen years or so that have been driven largely by the availability of progressively more powerful computers. A plethora of new optimization algorithms have been

introduced and tested and are now in widespread use. The new antenna designs often are non-intuitive, occasionally even counter-intuitive, but all share the common feature of not being accessible in any other way. State-of-the-art optimization algorithms can effectively solve intractable problems that have no analytical solutions or are too complex to apply traditional analytical techniques. These approaches are useful right now in designing set-top television antennas, and they will continue to be useful whatever form future set-stop systems take. Some of the more important and interesting optimization algorithms are described here.

Optimization Methodologies. The problem of locating the maximum values of a function is generally referred to as "multidimensional search and optimization." As pointed out above, any problem involving three or more design parameters ("decision variables") is a multidimensional problem, and simple methods such as plotting the function to be maximized cannot be used. Methods for solving these problems fall into two broad categories: analytical methods and heuristic methods. Analytical methods, which involve computing derivatives and gradients, are of limited use, especially in the complex landscapes associated with antenna design. Stringent performance requirements in terms of bandwidth, radiation pattern, and standing wave ratio (SWR) make antenna optimization problems particularly difficult because the landscape is usually extremely multimodal with narrow resonances and often high sensitivity to slight parameter variations. Heuristic optimization methodologies, which are inherently numerical in nature, are effective in dealing with these issues, and consequently they are considered here while analytical approaches are not.

An entire class of heuristic optimization algorithms are "Nature inspired", and these appear to be the most effective. A Nature inspired algorithm is a computer search and optimization program whose function mimics some natural process. These programs are described as being "metaphorical" because they analogize some natural process without precisely modeling it. For example, "Ant Colony Optimization" (ACO) is an algorithm that simulates (to some degree) the behavior of ants seeking food. Thus, ACO is *inspired* by the *metaphor* of ant foraging. All such algorithms *evolve* a solution to the optimization problem over a series of steps or iterations, and almost all such algorithms are *stochastic population*-based methodologies. An initial population (of ants, for example) randomly (stochastically) moves through the decision space (landscape) step-by-step (iterating) in such a way that it converges on the largest food supply (maximum function value). The ants' progress is controlled by a set of equations that mimic real ant behavior in Nature. There are many Nature inspired algorithms, ACO being one of the earliest ones. The more important algorithms are discussed below with examples of their application to antenna optimization.

2.1.3 Ant Colony Optimization

Figure 1 illustrates the basic idea behind Ant Colony Optimization (ACO) [1]. The irregular objects represent the ants' nest (bottom) and a desirable source of food (top). It has been observed that ants seeking food eventually traverse the shortest path between the nest and food by marking that trail with a chemical pheromone that each ant can sense (probably by smell). If the path is unobstructed [(a) in the figure], then the ants simply walk a more-or-less straight line between home and the food supply. But, if an obstruction is imposed [(b) and (c) in the figure], then more ants eventually end up on the shorter trail between the food and the nest, which in turn results in a greater pheromone concentration along that "optimal" trail. By depositing progressively more pheromone on the shortest path, almost all of the ants eventually end up on that path, and the "best" solution has been found. The red lines in the bottom part of the diagram illustrate the path evolution with the eventual result that the shortest path is identified.

The ACO algorithm mimics the ants' behavior using equations that represent the *random* motion of individual ants subject to their pheromone environment. Instead of searching for food, the metaphorical ACO ants search the landscape of a decision space for the maximum value of the function to be maximized. But the process they follow is a simplified model of ant behavior as observed in Nature. And, just as real ants eventually discover the best food source, ACO's "ants" eventually converge on the function's global maximum value.

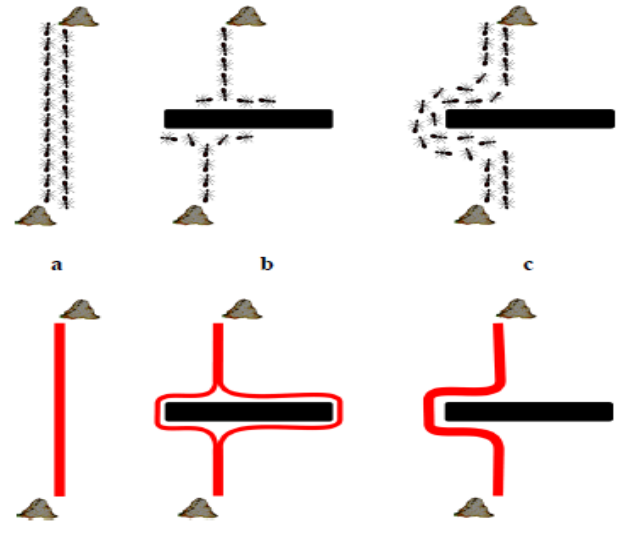

Fig. 1 Ant Colony Optimization: ants searching the shortest route using a pheromone trail.

Figure 1. Ant Colony Optimization Metaheuristic (reproduced from [1]).

2.1.4 Particle Swarm Optimization

Particle Swarm Optimization (PSO) [2] is another stochastic population-based Nature inspired evolutionary algorithm. PSO analogies the swarming behavior of fish or bees seeking food. Unlike ACO in which each "ant" creates a pheromone trail for other ants to follow, PSO's population of "agents" collectively communicate two pieces of information: each individual agent's "best" solution (greatest food concentration) and the population's overall (global) best solution. Equations that mimic bee and fish swarming then control each agent's subsequent motion in the decision space based on the competing tendencies of moving toward the global best and randomly exploring the vicinity of its best solution. As shown in Figure 2 for bees swarming around a flower concentration, after many steps PSO agents converge on the global best solution (highest flower concentration) because the local search fails to reveal any better solutions.

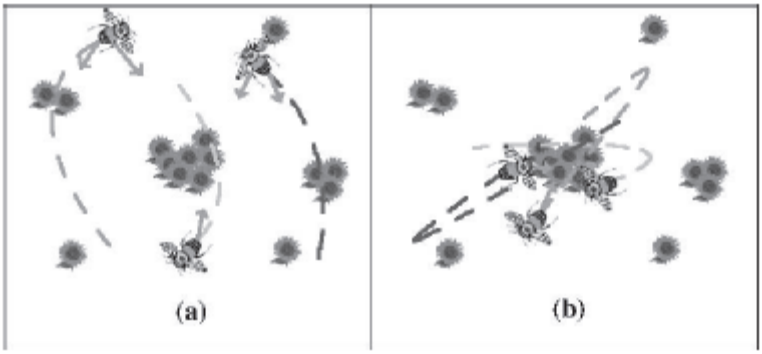

Figure 2. Particle Swarm Optimization metaheuristic (reproduced from [2]).

2.1.5 Genetic Algorithms

A Genetic Algorithm (GA) [3] analogizes the process of natural evolution or "survival of the fittest." When biological parents "mate," they exchange DNA to create a new individual ("child") whose characteristics are drawn from both parents by combining the parents' DNA. A GA creates successive generations of children who then serve as parents for the next generation whose children, in turn, will exhibit better "fitness" than the previous generation. In the context of search and optimization, the fitness is the value of the function to be maximized, so that the "best" fitness corresponds to the function's global maximum. As the GA progresses generation after generation, the best discovered fitness improves and eventually converges on the function's global maximum.

Figure 3 shows a typical GSA flowchart for an antenna optimization algorithm. It starts with a definition of the decision space (parameters to be optimized) and the "fitness function" to be maximized (for example, antenna directivity, or some specified combination of performance parameters such as gain, bandwidth, and so on). An initial population of "individuals" is randomly created, and each individual is defined by a *chromosome* that may be a binary sequence or a real number. Each chromosome comprises a set of *genes*, and each gene is one of the design parameters. For example, if the three design parameters were element length, inter-element spacing, and element diameter in a four element Yagi-Uda array, then there is a total of eleven design parameters, and each one is a gene. Thus, the optimization problem is defined on an 11-dimensional decision space, and the objective is to determine each of the eleven parameters so as to maximize some specific *fitness* function, say, the array's gain-bandwidth product. A separate computer program is used compute the fitness at each step for each chromosome (the "evaluate fitness" box in Figure 3).

After the initial population's fitnesses are evaluated, the "selection" process chooses two parent chromosomes that will mate ("crossover") to produce two children chromosomes in the next generation. The selection and crossover processes take many varied forms. For example, the selection of parents may be random, or "best mates worst," or best pairs pair wise through the population, and so on. The crossover operation likewise can take many forms. For example, the parents' chromosomes may be split at the midpoint with first and second parts being swapped, or a random break point might be used, or some other combinatorial approach taken. Finally, the children thus created are subject to some level of *mutation*, a random perturbation of the chromosome structure just as real chromosomes are mutated in Nature. The steps described thus far are essentially common to all Gas, but the next step in the flowchart ("elitist model") is not. In this GA, the worst individual in the new generation is replaced by the best individual from the previous generation, thus preserving the best solution from generation to generation as the algorithm progresses. As a final step, the best fitness is tested for convergence, and the process repeated until convergence is achieved.

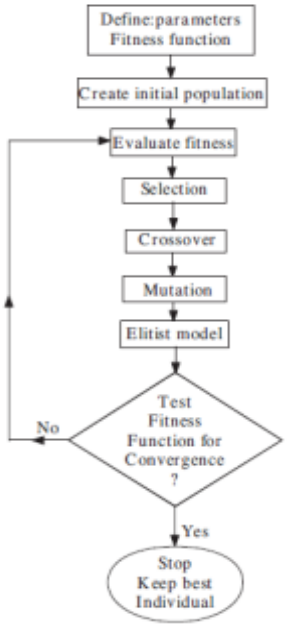

Figure 2. Flow chart diagram of real-coded GA.

Figure 3. GA flow chart (reproduced from [3]).

2.1.6 Simulated Annealing

Simulated Annealing (SA) [4] is a stochastic algorithm based on a metaphor drawn from physics instead of biology, as ACO, PSO, and GA are. SA analogizes the statistical mechanics of physical systems in thermal equilibrium with many degrees of freedom. In particular, the physical processes involved in annealing a solid as it cools forms the basis of the SA optimization algorithm, which has proven effective in optimizing problems with large numbers of decision variables. Because of SA's complexity, the algorithm is not described in detail. Instead its performance against a classic test problem is discussed.

The Traveling Salesman Problem (TSP) is a recognized example of combinatorial optimization that SA was used to solve because it constitutes a good test of an algorithm's effectiveness. The salesman must visit *N* different cities once each and return to his starting point. The problem is to determine the least costly route using a "cost" or "objective" function that is specified beforehand. Minimizing the cost is the same as maximizing its negative (note that minimization and maximization problems are exactly the same except for multiplying the objective function by -1). The TSP is a multidimensional search and optimization problem in the same vein as an antenna optimization problem, so that an algorithm suitable for one very likely is applicable to the other.

For the SA test, the TSP cost function is simply the total distance travelled by the salesman (to be minimized). Two different distance metric can be used, the standard Euclidean distance ("square root of the sum of the squares"), or the "Manhattan" metric (sum of the separations along the two coordinate axes), the latter being used in this case because it is simpler (less computationally intensive). Evolved solutions for TSP appear in Figure 6 and show a clear tendency towards removing redundancy in the travelled route, with the final solution (d) being close to optimal as discussed in [4].

Figure 4. Evolution of SA solutions to TSP (reproduced from [4]).

2.1.7 Central Force Optimization

Central Force Optimization (CFO) [5] is a new algorithm that departs significantly from all other Nature inspired metaheuristics. ACO, PSO, SA, and the other algorithms described below are all inherently *stochastic*. Every run with the same setup parameters in general produces a different set of solutions. No two runs yield the same results because these algorithms rely on true randomness in their functioning. The values of certain key variables in the algorithm are, by definition, random variables that are computed from a probability distribution. The values of these variables must vary from one calculation to the next, and their values are completely unknown and unknowable until the probabilistic calculation is performed.

CFO is quite different. It is based on an analogy drawn from gravitational kinematics, which in turn is based on Newton's laws of gravity and motion. Newton's laws are mathematically precise (completely *deterministic*) and, as a result, so too is CFO. CFO searches the decision space by "flying" probes through it whose trajectories are computed by deterministic equations that analogize Newton's laws of motion.

Figure 5 shows how CFO's probes move through a 3D decision space at each time step sampling the decision space by computing the fitness of the function to be maximized (shown by the darkened circles). CFO thus provides some major advantages over stochastic algorithms, *viz*, every run with the same setup returns exactly the same answers, and because of that characteristic only one run is necessary (stochastic algorithms usually are run many times and the results averaged). CFO has been effectively used for antenna optimization, and it holds considerable promise for use in set-top antenna design.

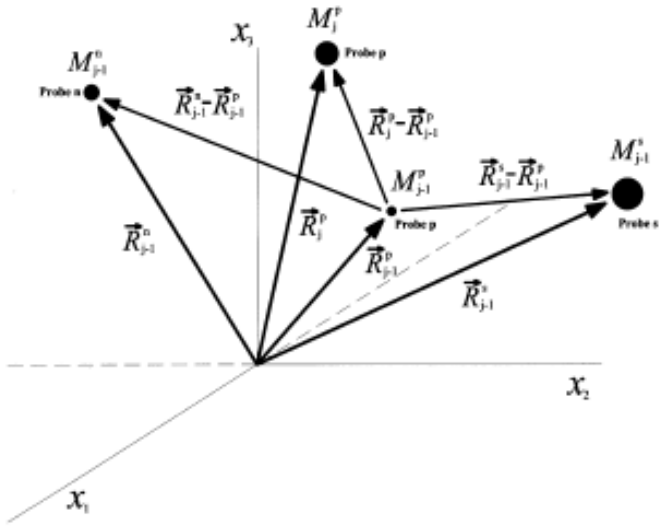

Figure 5. Central Force Optimization metaheuristic (reproduced from [5]).

2.1.8 Invasive Weed Optimization

Invasive Weed Optimization (IWO) [6] draws its inspiration from the colonization characteristics of invasive flora as understood from weed biology and ecology. Like ACO, PSO, GA, and SA, IWO is a population-based stochastic algorithm. Weeds exhibit a very strong tendency to opportunistically occupy (colonize) the interstitial spaces is a cropping field. Spaces not occupied by crops, which usually do not spread, become weed-filled, and the weed then grows and propagates by consuming unutilized resources in the field. The weed that uses these resources most effectively becomes the dominant (fittest) weed. When a weed flowers, it produces seeds that are randomly dispersed throughout the field until all interstitial space is occupied and all resources utilized.

Figure 6 shows a flow chart the IWO implementation used to solve electromagnetic problems in [6]. This flowchart starts out much the same as the GA flowchart with a randomly generated population whose fitness is evaluated in the initial step. Each weed then produces a number of seeds (reproduction) based on its fitness, with weeds having better fitnesses being allowed to produce more seeds. The seeds are

then randomly dispersed through the decision space using a normal (Gaussian) distribution of random numbers with mean value equal to the weed's location. After the new seeds have been dispersed, they are allowed to grow into new flowering weeds, and the process is repeated until a convergent solution is generated. Because the number of weeds grows constantly, a maximum weed population serves as a ceiling on weed count. Whenever it is exceeded, the bottom worst plants are "weeded out" by being discarded.

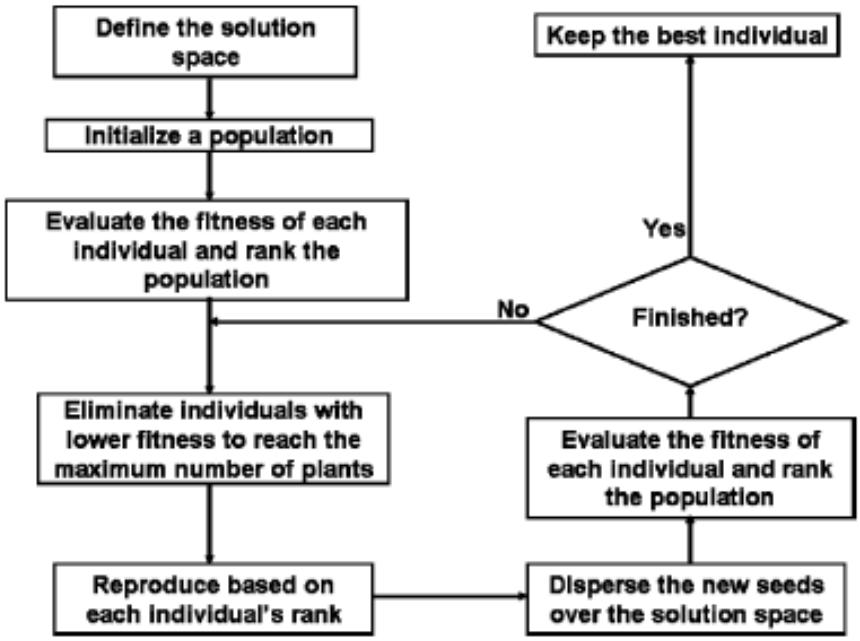

Figure 6. Invasive Weed Optimization flow chart (reproduced from [6]).

2.1.9 Intelligent Water Drop Algorithm

The Intelligent Water Drop algorithm (IWD) [7], like SA and CFO, analogizes a physical process. But, like SA and unlike CFO, it is stochastic in nature instead of deterministic. IWD is inspired by the notion that the seemingly random meanders in a river or stream bed are, in fact, based on mechanisms that can be applied to effectively solve optimization problems. Two principal factors are considered in IWD: water velocity and soil characteristics. Each IWD flows from a source to a destination, initially with non-zero velocity and zero soil. Along its route, velocity and soil both may be gained and lost. Soil inhibits drop velocity, so that between points the IWD's velocity increases inversely with soil (in a non-linear manner). Figure 7 shows typical IWD results for the Travelling Salesman Problem (see also discussion above on SA and TSP).

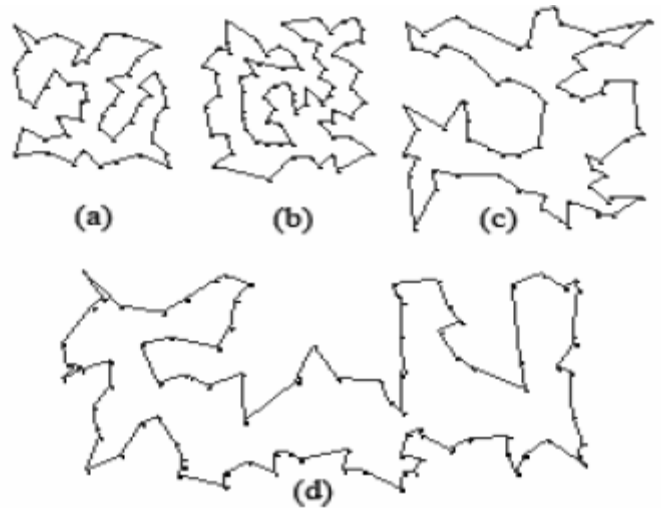

Figure 7. IWD results for the Traveling Salesman Problem (reproduced from [7]).

2.1.10 Bacteria Foraging Optimization

Bacteria Foraging Optimization (BFO) [8] mimics the natural behavior of bacterial seeking food. The motion of individual bacteria is driven by avoiding noxious elements in the environment while "swimming" upward along the food concentration gradient hopefully locating a denser source of food. *Chemotaxis* is the process by which a bacterium tumbles to orient itself, swims a fixed distance, and samples the food concentration at its new location. If the concentration is greater than at the previous location, then the bacterium continues in the same direction for another step. But if the concentration is lower, then the bacterium tumbles into a new direction and explores it instead. Each bacterium has a finite lifetime that limits the number of steps it can take. At the end their lifetime bacteria that are in the highest food concentration regions are allowed to "reproduce" by splitting into two new bacteria, while those in other regions die. Because the bacteria are dispersed, after the reproduction step, only the best half are retained, while the others die, thus preserving the total number of bacteria. The user specifies the maximum number of chemotactic and reproductive steps, maximum swim length, and maximum swims in a given direction.

2.1.11 An Antenna Optimization Example

This section presents a specific example of an optimized antenna design, a Self-structuring antenna (SSA) that can alter its electrical shape in near-real time in response to factors such as a changing environment or a change in mission. Typically these structures comprise wire segments that can be interconnected using control signals from a micro-controller device. An example of a SSA that was optimized using three different optimization algorithms appears in Figure 8 [9]. The antenna in this case is an asymmetric wire array containing 39 switches resulting in 549 *billion* possible antenna configurations.

The specific problem addressed in [9] was whether or not the optimization algorithms would provide better performance than a simple random search for a configuration that met specific performance criteria.

The wire structure was modeled with the Numerical Electromagnetics Code (NEC) following all modeling guidelines with respect to wire segmentation and segment length to diameter and wavelength ratios. The objective was to obtain low VSWR (< 2) values at frequencies of 40, 100 and 400 MHz. The antenna grid measured 0.6 meter square (0.08λ on a side at 40 MHz), which electrically is quite small. Figures 8, 9 and 10 compare the results of a random search to those produced by the three optimization algorithms. Random search performed very poorly at the lowest frequency, while each of the optimization algorithms performed relatively well. The GA produced the "tightest" results at 40 MHz (minimum standard deviation), and achieved the design objective in 60% of the trials. This example shows that real-time-optimized SSAs are within reach for the set-top antenna application at this time, and that fairly economical designs may be possible.

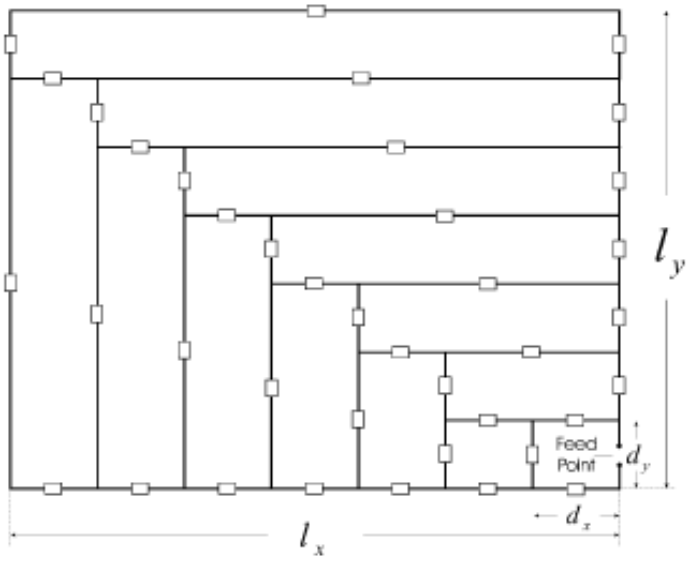

Figure 8. SSA geometry (reproduced from [9]).

2.2 Fragmented Antennas

As an additional illustration of the power of an electro-magnetic (EM) optimization algorithm, this section describes the computer program ***FAopt*** that begins with a grid of wires as shown in Figures 1 and 2 and optimizes the placement of these wires using a Binary Genetic Algorithm (BGA) and the NEC-4 [1] Method of Moments (MoM) FORTRAN code. Each bit in the BGA chromosome is either a 1 or a 0, representing the presence or absence of a wire, respectively. Quadrant 1 and 3 are a mirror image of each other as well as quadrant 2 and 4, so that the antenna is symmetrical about its diagonal. The resulting antenna is comprised of a series of plated conductors, some of which are connected to one another. Some are capacitively/inductively coupled and act as parasitic elements to increase the element impedance and radiation pattern bandwidth. These types of radiating elements, when implemented as pixels rather than wires, (see Maloney et al of GTRI [2]) are generally called "fragmented" antennas [3]. ***FAopt*** allows the user to choose the polarization as either vertical or horizontal, and the antenna can be either directional or omni-directional. The user also can choose the dimensions for the desired antenna, as well as the frequency range. This program was used to design a set-top antenna to operate in the VHF and UHF bands. (See Section 3.0). During optimization a window is shown that updates the progress of the optimizer with the best "figure of merit" (FoM) displayed along with the standing wave ratio.

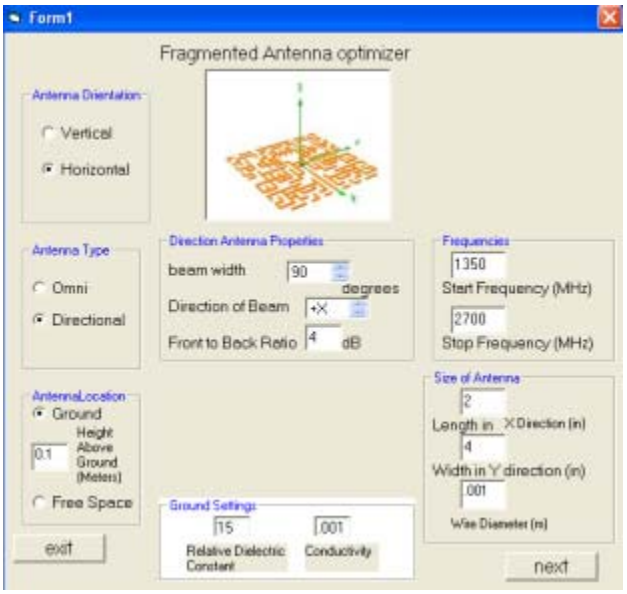

Figure 1: FAopt Code's GUI

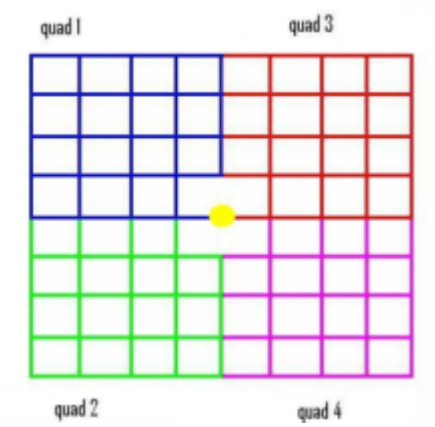

Figure 2: Wire Grid

As an example, a thin planar directional antenna was optimized using ***FAopt*** as a horizontally polarized antenna from 2400-2480MHz with 8 blocks per row/column per quadrant. The orientation appears in Figure 1, and the antenna model is shown in Figure 3. The dimensions for this antenna are 2" by 2". A prototype was built as shown in Figure 4.

Figure 3. Fragmented Directional WiFi Antenna

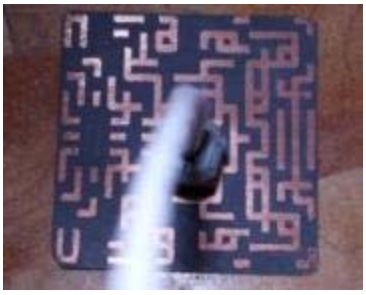

Figure 4. Fragmented Directional WiFi Antenna

The simulation results, which were confirmed by measurements, shows the average gain of this antenna to be better than 1.9 dBi. This antenna is a directional WiFi antenna optimized to have a F/B ratio of about 6 dBi. Its radiation pattern is very consistent

across the band as shown in Figure 6, and its measured VSWR is better than 2:1 across the band. Further work, such as changing the grid template or the optimization routine, could be undertaken to make this approach more efficient for designing set-top VHF/UHF antennas.

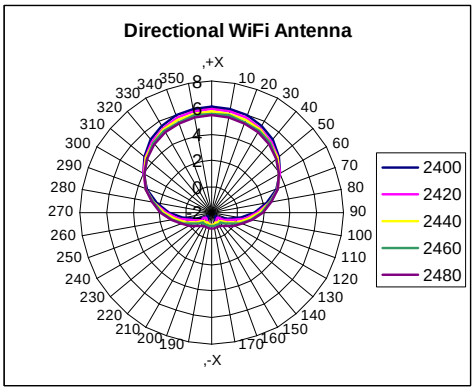

Figure 5. Pattern of Directional WiFi Antenna

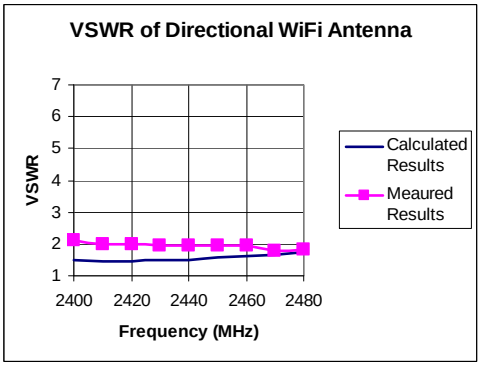

Figure 6. VSWR of Directional WiFi Antenna

The F/B ratio of simulated and measured are in fair agreement as shown in Figure 7.

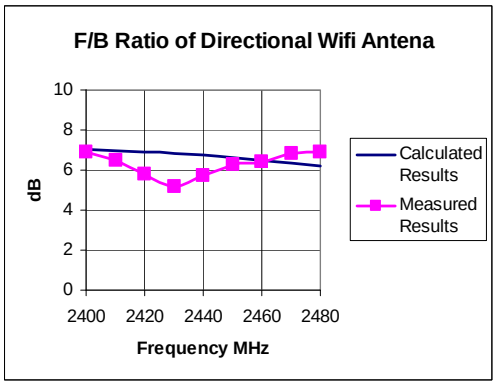

Figure 7. F/B Ratio of Directional WiFi Antenna

2.3 Non-Foster Impedance Matching

Foster's reactance theorem, which dates to 1924, states that a lossless reactance must have a positive slope with frequency. Any lossless matching network presumably satisfies the theorem, but a great deal of research that has been done on "non-Foster matching" in the past 15 years suggests otherwise. This section examines how non-Foster networks may be useful in set-top antennas to match an electrically small element (characterized by a low real and high negative imaginary complex impedance) within, for example, the low-VHF band.

Until recently no one has created a practical antenna system using this method that showed much of an improvement in performance. This was due to limitations in the semiconductor technology at the time that permitted only narrow band solutions. Semiconductor technology has improved considerably in recent years resulting in increased bandwidth, lowered noise, and decreased losses in the devices. Electrically small antennas present high Q impedances characterized by large reactances and small radiation resistances. For such antennas, the effectiveness of passive matching circuits is severely limited by gain bandwidth theory, which predicts narrow bandwidths and/or poor gain. The result inevitably is a poor signal to noise ratio compared with a larger antenna.

Non-Foster matching uses negative impedance converters (NIC) to create "negative" capacitors and "negative" inductors [1-2]. It is possible, for example, to use negative capacitance to cancel out the reactance in a short dipole or monopole. This leaves only a small real impedance which could then be matched to, say, 75 Ω using a transformer. One disadvantage of this approach is that transformers add to the antenna size which could be undesirable. An alternative to matching could be achieved by placing the non-Foster matching circuit away from the feed to control both the real impedance as well as the reactance of the antenna [3]. The potential improvement in antenna performance is very significant. Theoretical bandwidth improvements have been shown for a small loop (increasing bandwidth from 50 MHz to 300MHz at a center frequency of 700MHz), as well as a small broadband dipole (increasing bandwidth from 250MHz to 1000MHz, lowering the lower operating frequency from 250 MHz to 190 MHz).

It should be noted that the Figures and Tables in this section were taken from references 2 through 5, listed at the end of this section.

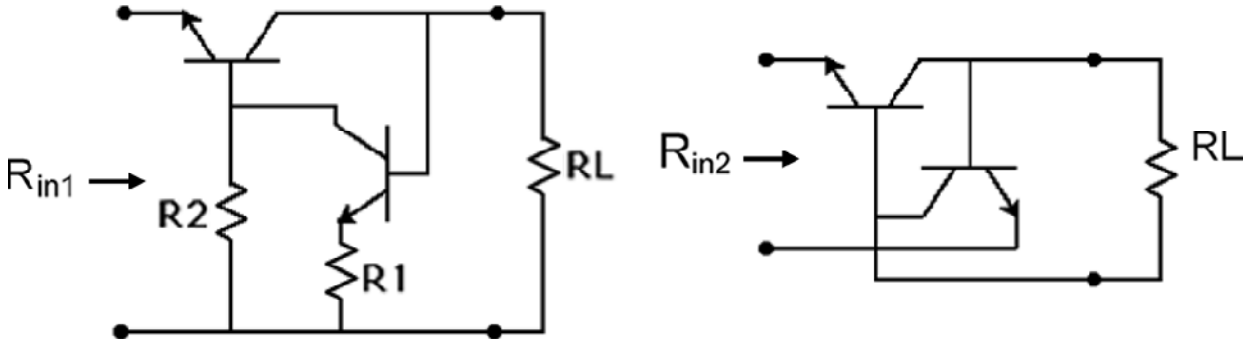

Figure 1. Linvill's ideal OCS NICs terminated in a resistance.

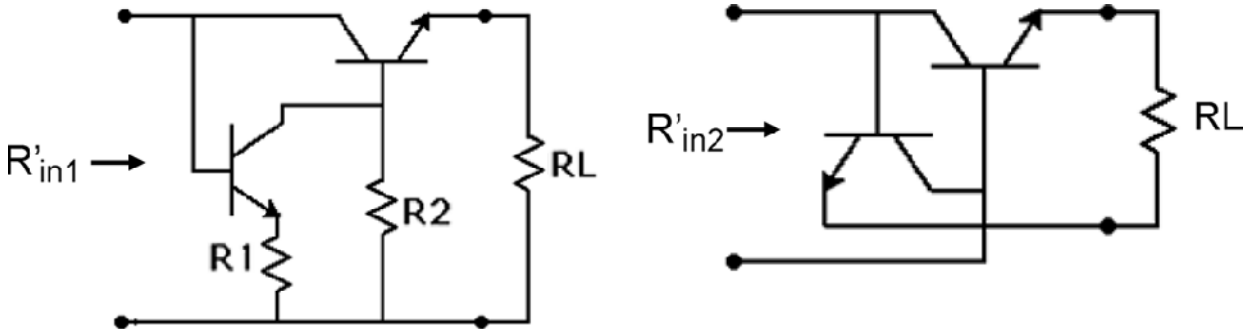

Fiugre 2. Linvill's ideal SCS NICs terminated in a resistance.

With an ideal transistor, a pure negative resistance is achievable. In Linvill's actual realizations (Figures 1 and 2), a substantial reactive component of the input impedance Z accompanies the negative resistance, resulting in a low Q, where the "resistive" Q is defined as: Q=Re(Z)/Im(Z). The circuits shown are "open-circuit stable" (OCS), meaning, practically, that if a very large resistance terminates the negative-resistance one-ports on the left, then the overall network will be stable. The networks of Figure 1 can be turned around as shown in Figure 2, where negative resistances of the "short-circuit stable" (SCS) variety are obtained. Again, practically speaking, this means these networks will be stable if a very large conductance is placed across the input. An initial step in improving the power efficiency of non-Foster matching is simply to use a single-transistor version of the NIC [4].

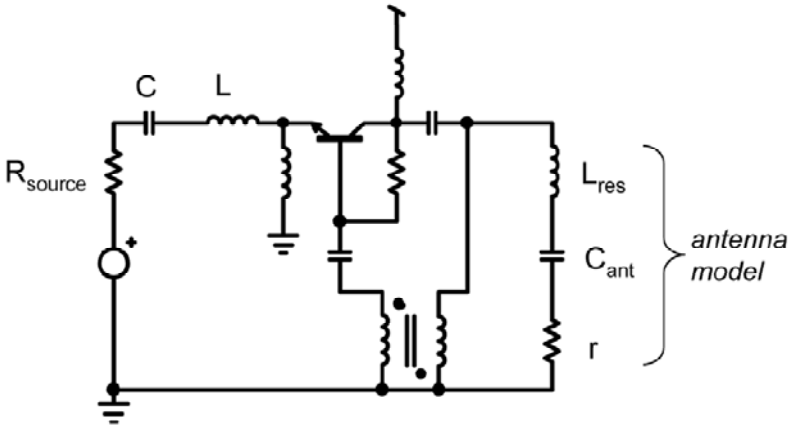

Figure 3. Non Foster Matching

An example of a non-Foster matching circuit is shown in Figure 3. Although not shown in the schematic, a transformer would be used at the input to make the effective value of R_{source}, as seen by the matching circuit, to be 18.75Ω (4:1 impedance ratio).The circuit negates antenna's Capacitance C_{ant} and the voltage-managing resonating inductor L_{res}, as well as the radiation resistance r. The idea is to cancel the negated L_{res} and C_{ant} with C and L on the left, respectively. The negated r is absorbed by the much larger source resistance and does not affect operation of the circuit. The source resistance would be 75 ohms in this case.

An example of non-Foster matching for a 12 inch dipole is shown in Figure 4. It is shown in Figure 5 that this non-Foster matching network creates a negative capacitance that is used to cancel out the reactance of the 12" dipole. This is used along with a transformer to help match the radiation resistance of the antenna to the source impedance of 50 Ω. The non-Foster matching network is compared to a similar dipole with a lossy passive network for improvements in signal to noise as shown in Figures 6 and 7. The improvement in SNR is quite remarkable, as much as 25 dB around 44 MHz.

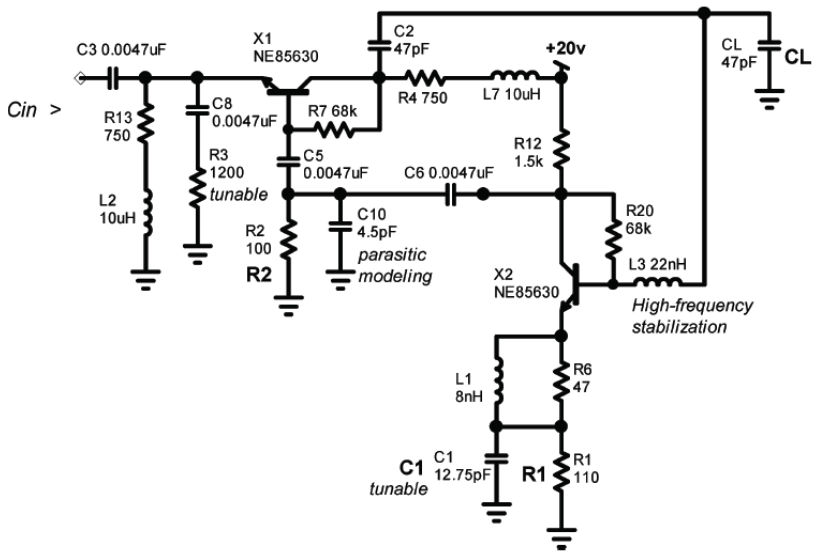

Figure 4. Non-Foster Matching Network for a 12" Dipole.

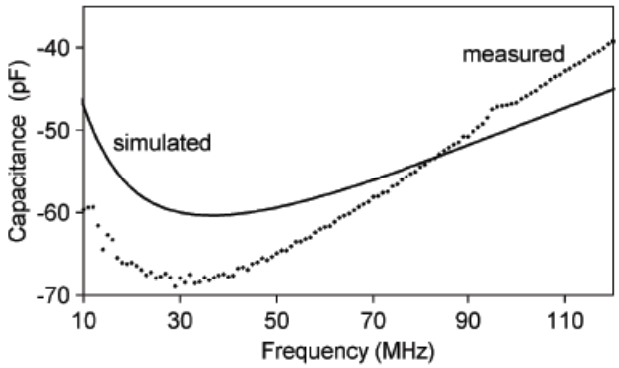

Figure 5. Measured and simulated results for capacitance of non-Foster matching network.

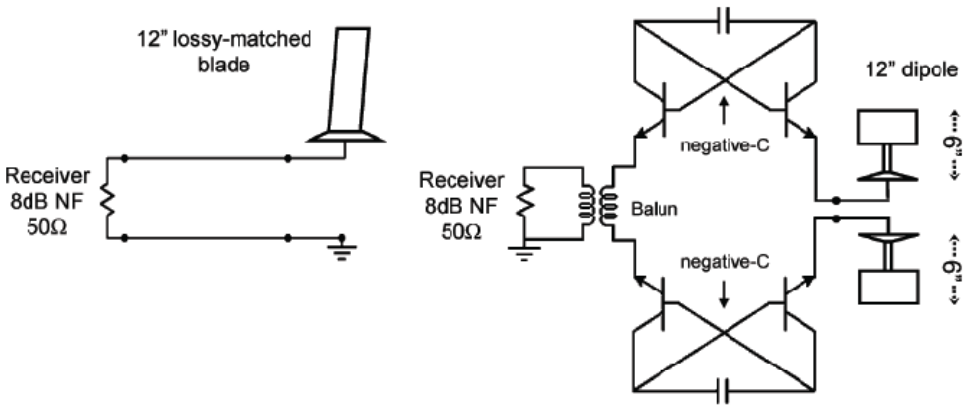

Figure 6. Setup for Signal to Noise improvement measurement.

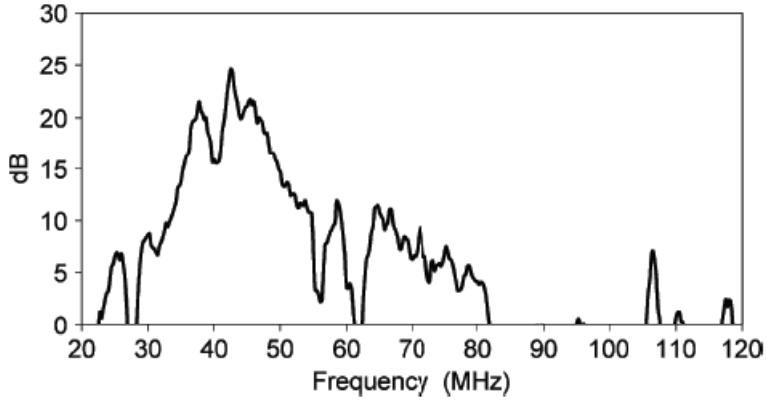

Figure 7. Measured Improvement of Signal to Noise

Non-Foster matching may be particularly useful for the set-top application because it works best with electrically small antennas. Therefore, this type of match could be useful when designing a small VHF/UHF DTV set-top antenna. Improvements in signal to noise measurements have been shown from 20MHz to 400 MHz [5]. In particular, the use of non-Foster techniques to impedance match a lossy electrically-small dipole antenna has been quite effective. On an antenna range, there was a measured 30 dB gain improvement over 60 – 200 MHz, with several dB of improvement as high as 400 MHz. Again, the comparison was to the same antenna with no matching at all. Although no S/N measurements were made, the circuits used were based upon the same low-noise designs developed earlier for lower-frequency circuits. Because of the lossiness of the antenna, passive matching can do a little better than no matching at all, and these results are illustrated in simulation. This computer simulation designed a number of "best-effort" passive matching networks and calculated the transducer gain (S21) between a 50 ohm source and the complex impedance of a 6-inch monopole. S21 for no matching and S21 for a single, ideal negative capacitance whose value (-5.54pF) exactly cancels the antenna reactance at 30 MHz, were calculated. Plots of the real and imaginary parts of the antenna impedance are shown in Figure 8. The various matching networks are illustrated in Figure 9; each of these would appear in place of the NIC in Figure 10b.

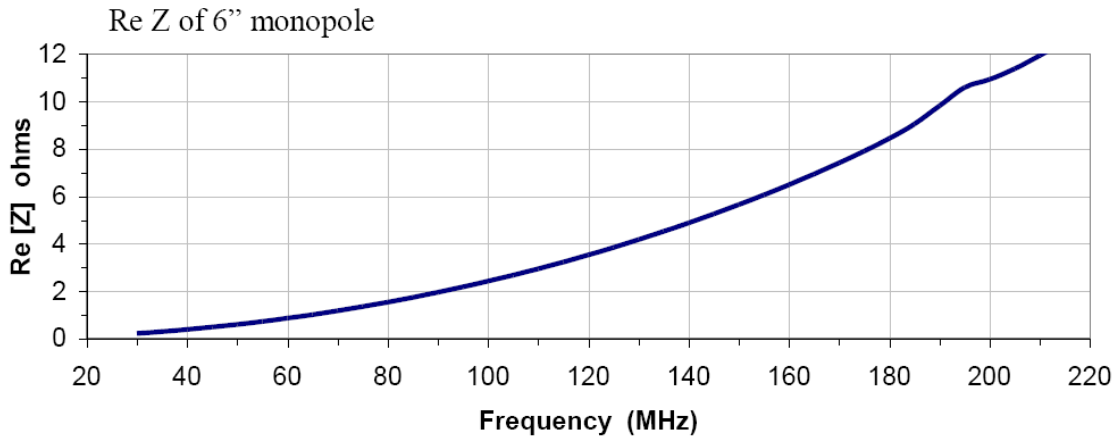

Figure 9-A. Real Part of Antenna Impedance for a six inch monopole

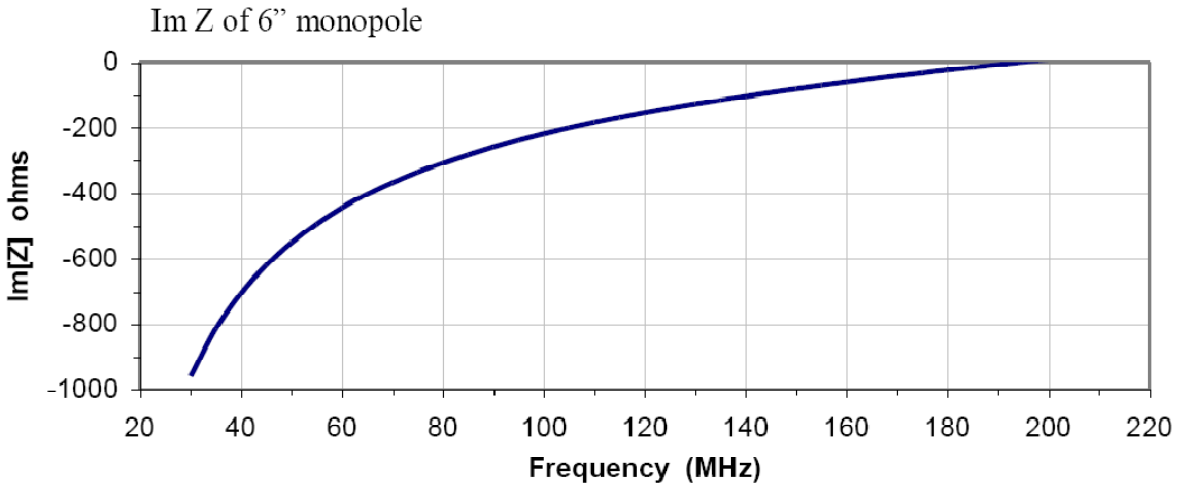

Figure 9-B. Imaginary Part of Antenna Impedance for a six inch monopole

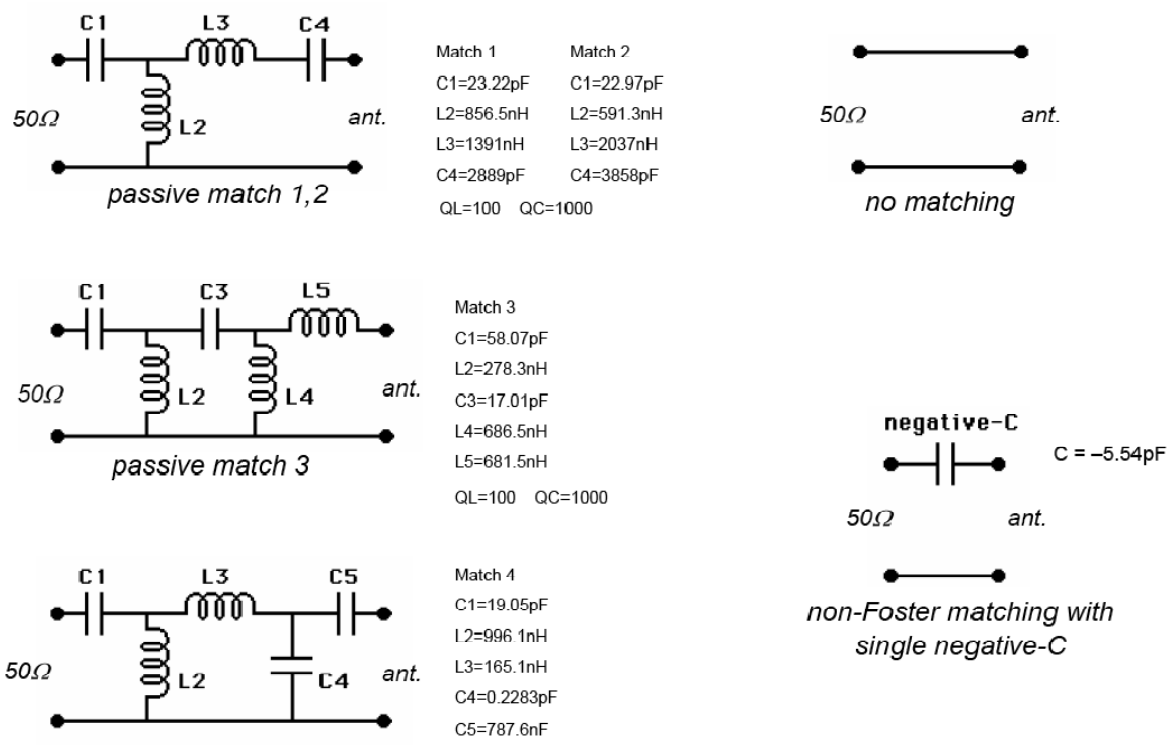

Figure 10. Various Matching Techniques for six inch monopole

Average gain 30-220 MHz	
Non-Foster neg-C:	**-13.2 dB**
Passive match 4:	-21.9 dB
Passive match 3:	-23.1 dB
No matching:	-23.9 dB
Passive match 1:	-26.7 dB
Passive match 2:	-28.4 dB

Table 1. Computed Average Gain of all matching techniques.

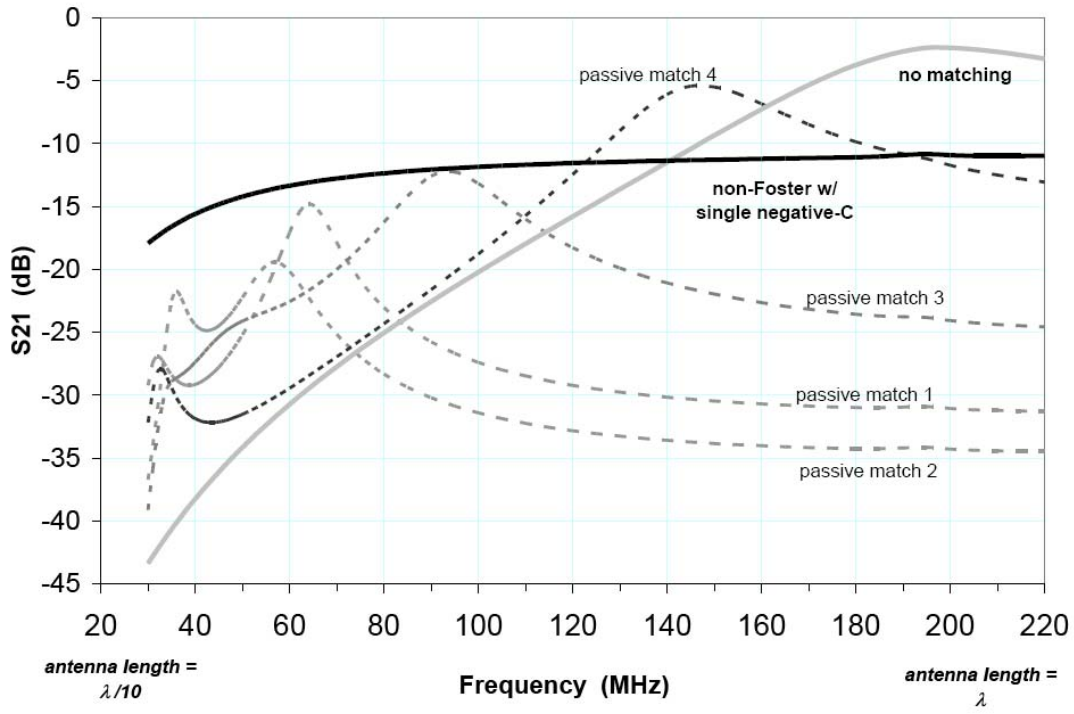

Figure 11. Plots of Computed Gains of all matching techniques for a six inch monopole

The six inch monopole was then built using both the non-Foster matching network and an unmatched antenna. They were both measured with the results shown in Figure 12. In the design, NE68019 BJTs were used in the NICs because these devices provided good overall performance over the entire frequency band. Again, the results are quite remarkable, with the non-Foster antenna showing average gain improvements between about 2 and 28 dB. It is noteworthy that the greatest improvements are at lower frequencies, between about 60 and 210 MHz, approximately the low and high VHF bands.

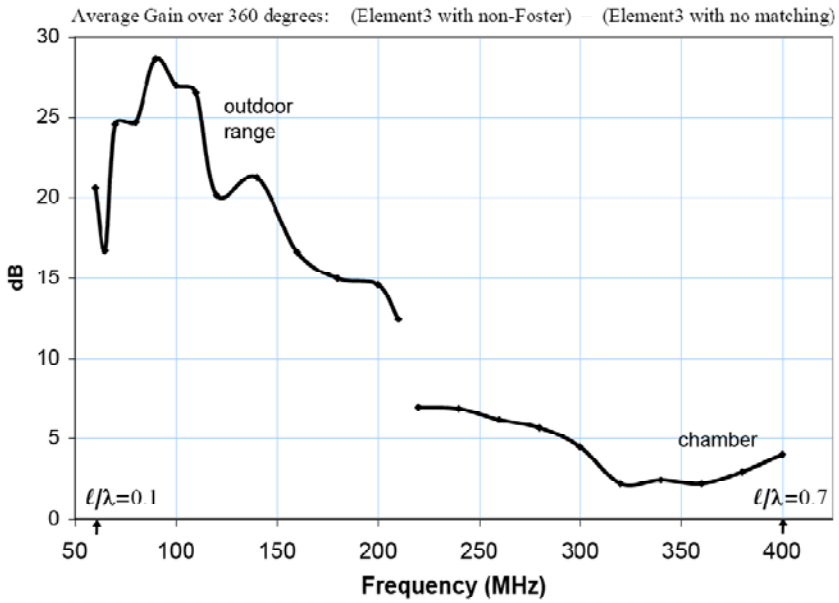

Figure 12. Gain of a non-Foster matching network over the same antenna with no matching.

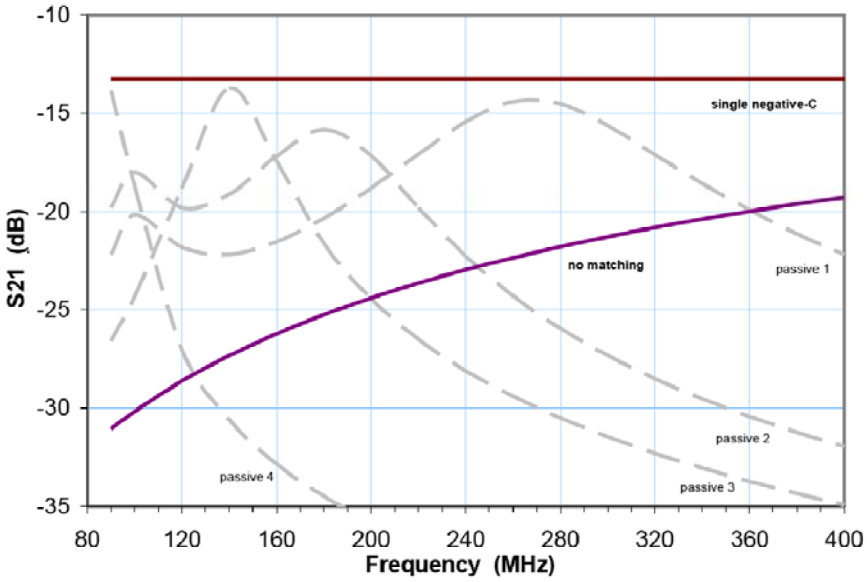

Figure 13. Plots of Computed Gains of all matching techniques for a six inch dipole

Results for an electrically small lossy dipole are shown in Figure 13 (this antenna was simulated, not measured). The actual gain may be less due to noise of the device if this were to be built and tested. Thus, realization of non-Foster technology is still limited by the analog circuitry performance. With respect to the set-top application, it is very reasonable to expect that as better silicon devices are developed covering the entire television frequency range will be possible with substantially better antenna performance in terms of gain and signal-to-noise ratio.

2.4 Active RF Noise Cancelling

Considerable work has been done to mitigate noise from devices near receiving antennas, as is particularly useful in set-top antennas. An antenna placed on top of a television is especially vulnerable because it may pick up noise from internal circuitry. But this noise can be reduced, which in turn reduces the noise floor, or, equivalently, increases the signal-to-noise ratio (SNR). Intersil [1] has created the QHx220 chip that accomplishes this e.g. at UHF frequencies, or more precisely from 300 MHz up to >3GHz. MegaWave has evaluated the Intersil noise cancelation chip QHx220 shown in Figure 1. The chip was tested for signal to noise improvements at 535MHz as shown in Figure 2. Measured results showed an improvement of about 12dB in SNR as shown in Figures 3 and 4. This technology has been extended down to FM covering the VHF III band [2], which is necessary for this approach to be viable in the set-top environment.

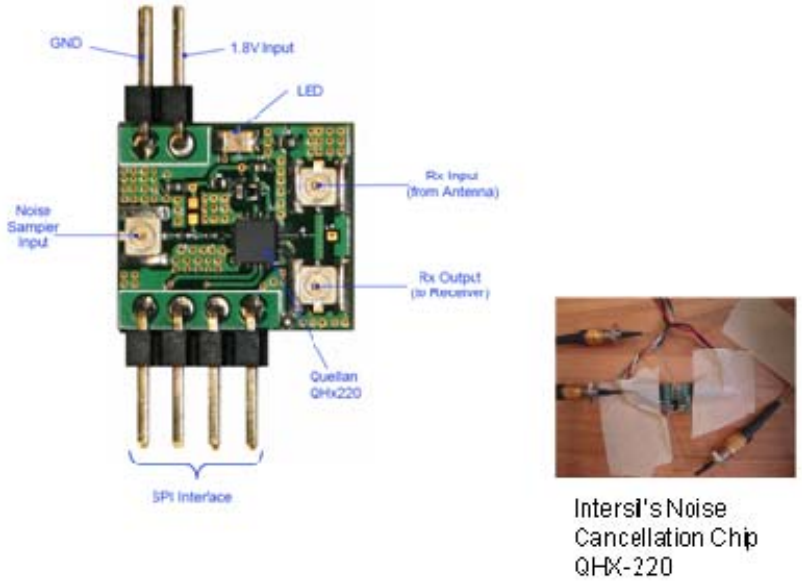

Figure 1: Intersil's Noise Cancellation Chip QHx220

This system works on a principle similar to Bose and Sony noise cancelling headsets, but at a ~1,000,000 times higher frequency. It requires an I and Q setting obtained from the DTV receiver's channel setting and the system's link quality parameter (BER, SNR, RSSI, etc.). This is done on either a micro-processor or in the baseband processor, which run a set of small algorithms. As a result the noise minimum is centered in the desired TV channel and signals - formerly buried in the noise floor - are being restored (Figure 4, e.g. at 549MHz).

2.5 Automatic Antenna Matching Systems

2.5.1 Summary

From an impedance matching point of view, the ideal antenna has a perfectly flat, purely resistive input impedance across its entire operating frequency range. The value of that impedance should be 70 Ω because this is the nominal industry standard characteristic impedances of the coaxial cable used in television receivers. Of course, no antenna is perfect. Quite to the contrary, most antennas' impedance variations with frequency are usually quite dramatic. This is particularly true for electrically small antennas, which tend to exhibit low radiation resistances and very high reactances in a narrow frequency range. Set-top DTV television antennas are not necessarily electrically small in the high VHF and UHF bands, but are at low VHF. Due to their required bandwidth (54-698 MHz) they invariably exhibit wide impedance fluctuations.

An impedance mismatch leads to losses and reflected energy that is not transferred to the receiver. These inefficiencies can be mitigated to a great degree by precise impedance matching that is provided by an "antenna tuner" (AT) connected between the antenna output terminals and the receiver input port. The AT may comprise a network of discrete components, or it may be a distributed, continuously varying structure (a tapered transmission line, for example), or some combination of both.

Lumped element matching networks go back to the earliest days of radio, and they often require manual adjustment of the matching elements (usually variable capacitors or roller inductors). In the early 1960s the military developed "ALE" (automatic link establishment) systems that employed remotely controlled automatic antenna tuners. These networks are usually located at the antenna feed and remotely tuned automatically based on VSWR (voltage standing wave ratio) measurements made at the transmitter. Essentially the same approach is taken with the built-in automatic ATs that are common in modern transmitters (most amateur radios contain built-in auto ATs, for example).

Modern low-power ATs use relays to switch lumped elements (inductors, capacitors) in and out of the matching network until the desired match is achieved. This technology is highly developed and readily available for use in set-top TV receive antennas. It therefore is not reviewed in this report. Instead, the emphasis here is on new, developing technologies that may be useful for antenna impedance matching. Four broad categories have been identified.

(a) *Voltage controlled reactive elements* are capacitors and inductors whose values are controlled by an applied voltage. Instead of switching discrete components

in and out of a matching network using relays, the same operation is accomplished by varying the voltage applied to the reactive element. This type of non-mechanical system provides faster response time and more continuous control in a less noisy and probably smaller space than a relay-based AT.

(b) *Integrated ATs* are "antenna tuners on a chip," a complete device that is fabricated on a single chip or in a very small module with only a few external components. Integrated ATs have received considerable attention for cellular applications, and they work quite well. Chip-level devices successfully match up to 10:1 VSWRs in the highly fluctuating cellular antenna environment with rapid response times and high efficiency. These devices are constantly improving, and it is likely that existing technology can meet set-top AT requirements.

(c) *Tunable tracking filters* are already used across the VHF/UHF TV bands for wideband DTV (digital television) tuners, and they work quite well, providing very flat passbands, steep skirts, and harmonic suppression from the tuner's local oscillator. Extremely small devices have been designed and computer-simulated, and some measured data are available confirming achievement of design objectives. This is an evolving technology that may be transferrable to set-top AT requirements.

(d) *Software defined radio (SDR)* is a new concept in wireless communications that seeks to move system properties from the hardware layer to a high-level software layer by developing hardware modules that are fully software-controllable and configurable. SDR radios are gaining wide acceptance in many applications, and it is a developing technology. SDR "smart antenna" technology, which may be applicable to the set-top environment, consequently is a candidate technology for a television AT.

2.5.1.1 **Voltage Controlled Reactive Elements**

(a) *BZN (pyrochlore bismuth zinc niobate)* is a non-ferroelectric dielectric material that shows great promise for a new class of voltage tunable thin film capacitors [1]. When it was introduced in 2006, BZN exhibited the lowest loss of any room temperature complex oxide film with a very high dielectric constant and high tunability of (loss tangent ~0.0005, dielectric constant ~180, ~55% tuning range @ 1 MHz). Losses increase in the microwave range, but are controllable by modifying the electrode structure.

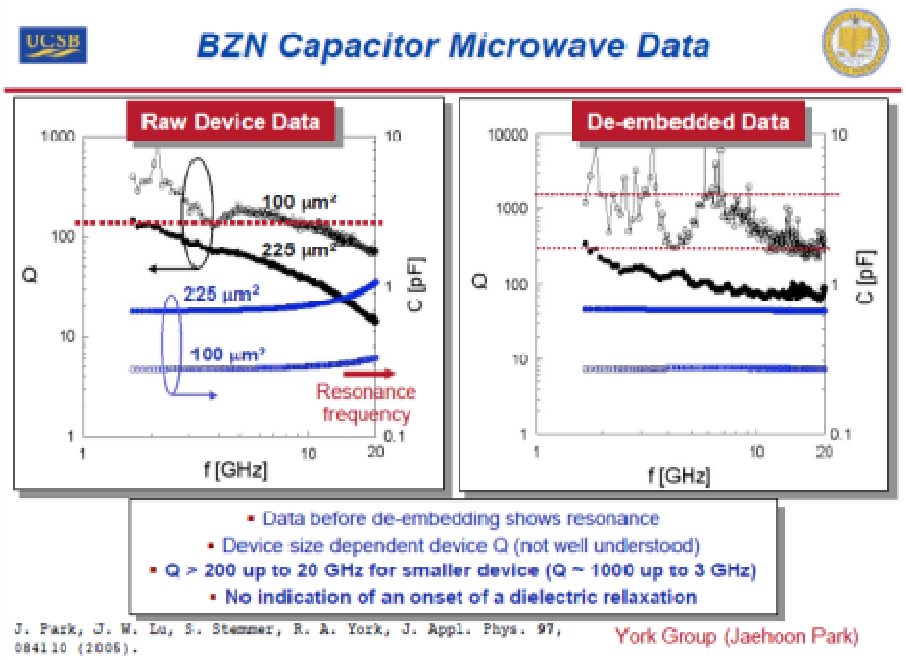

Figure 1. BZN capacitor high-frequency measurements (reproduced from [1])

Measured data for different size BZN thin film capacitors at higher frequencies appear in Figure 1. For small devices (100 μm^2) the *Q*-factor exceeds 200 up to 20 GHz (de-embedded data, right plot). Through about 3 GHz *Q* ~ 1000. In addition, self-resonance in the BZN thin film structure is well above 20 GHz. By comparison, the best state-of-the-art thin-film BST (barium strontium titanate) devices in 2006 exhibited *Q*s that decreased monotonically from about 100 at 1 GHz to around 20 at 20 GHz. BZN is a far superior tunable dielectric. BZN and similar materials (see below) hold considerable promise for the development of completely solid-state ATs that can be used to tune set-top TV broadcast band antennas.

(b) *PZN (lead zinc niobate)* thin film interdigital capacitors (IDC) have been fabricated to increase tunability and reduce bias voltage compared to BZN IDC implementations. Cubic pyrochlore PZN thin film dielectrics provide superior performance through the microwave range. Figure 2 shows a typical configuration. The IDC is fabricated on a silicon substrate in the usual coplanar waveguide (CPW) configuration. Figure 3 plots the measured low-frequency dielectric constant (blue) which increases from just over 200 to about 230 at 10 MHz. The tenability as a function of applied bias voltage decreases from unity to about 0.75 with an applied electric field of 2 mV/cm (bias voltage of 5.5 volts). At 1 GHz the device *Q* falls to about 10 at all bias voltages, but the tunability remains at 26% (compared to 25% at 1 MHz) for 5.5 volts applied bias. The PZN tunable capacitor thus is a strong candidate for voltage-tunable

set-top television antenna ATs, and its performance is comparable or better than that of BZN devices.

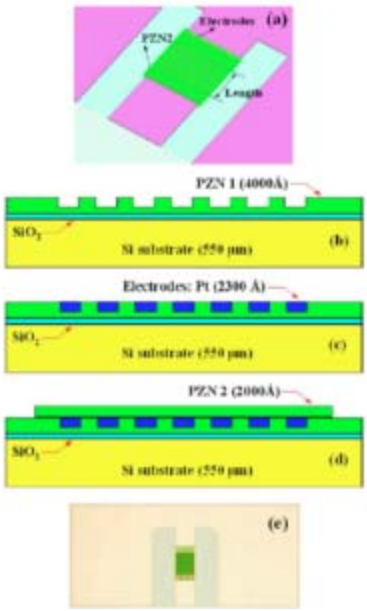

Figure 2. PZN IDC structure (reproduced from [2]).

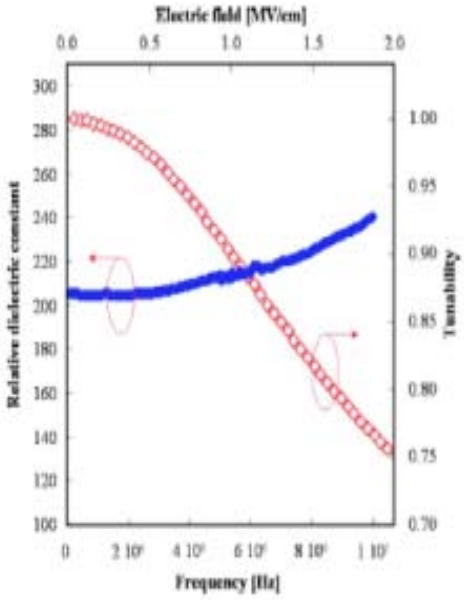

Figure 3. PZN IDC performance (reproduced from [2]).

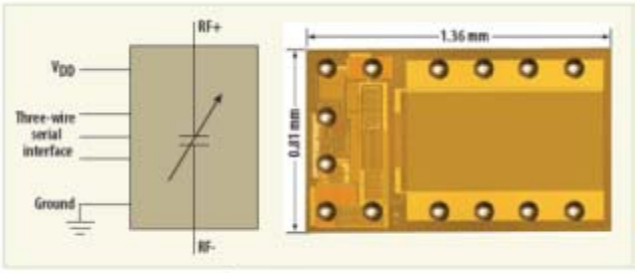
(c) *DuNE™ capacitors* are a new patent-pending technology developed by Peregrine Semiconductor [3] for DTCs (Digitally Tunable Capacitors). The manufacturing process is based on Peregrine's proprietary UltraCMOS™ technology supplemented by its HaRP™ design methodology. UltraCMOS™ is a patented low-power SOI (silicon on insulator) variant chip architecture that reduces transistor capacitance resulting in increased switching speed. HaRP™ is a design technology that produces significant improvements in harmonic results, linearity and overall RF performance.

The company claims that its DTCs provide digitally controllable capacitances in the range 0.5 to 10 pF with either 3:1 or 6:1 tuning ratios and 32 addressable states (5 bits). *Q*s range from 40 to 80 between 1 and 2 GHz with device switching times below 5 µsec. Power handling capability is quite good (+38 dBm @ 50 Ω), while power consumption is low (100 µamps @ 2.4-3.5 volts DC). The manufacturer claims its DTCs provide better performance than currently available MEMS (*microelectromechanical system*) or BST devices, and they are readily available as off-the-shelf components.

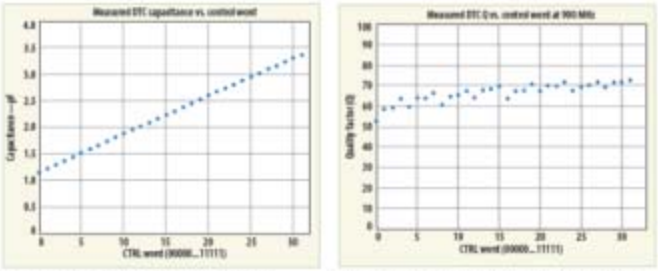
The digitally tuned capacitor schematic diagram and its "flip-chip" package appear in Figure 4. The DTC acts as a series capacitor with two RF terminals. It is powered by a single DC line, and controlled by a three-wire serial interface. The control word is five bits long. The device is extremely small (1.26 mm x 0.81 mm) and thus well-

suited for use in TV set-top antennas. Measured performance is shown in Figure 5. Capacitance variation is very linear with control state (32 increments), and the variation ratio is 3:1, from 1.15 pF to 3.4 pF. The DTC *Q*-factor at 900 MHz, a representative cellular frequency, varies from about 53 to about 72, which is quite good.



5. The schematic diagram shows the DuNE DTC (left) while the photograph (right) shows a flip-chip DuNE DTC prototype that measures just 1.36 x 0.81 mm.

Figure 4. Digitally Tuned Capacitor (reproduced from [4]).



6. The measured performance of a 5-b DuNE DTC prototype shows linear tuning characteristic and a 3:1 capacitance range from 1.15 to 3.4 pF.

7. These measurements show the DuNE DTC prototype with quality factor (Q) designed to be in the range of 60 to 70 at 900 MHz.

Figure 5. DTC measured performance (reproduced from [4]).

DTCs have been effectively applied in cellular phone ATs. A typical configuration is shown in Figure 6. The transceiver, in this case a cellular handset, is connect to its antenna through an AT comprising four main elements: (1) serial interface; (2) digital mismatch sensor; (3) tuning algorithm; and (4) DTC core. This structure is representative of ATs based on other tuning technologies besides DTCs. For example, this same architecture would be used with MEMS-based or tunable thin film capacitor ATs. Note that the diagram does not show the RF path between the antenna and transceiver, only the AT control data path. The serial interface exchanges digital data with the transceiver on the AT status. The mismatch sensor responds to reflected power resulting from any impedance mismatch between the antenna and the system's characteristic impedance. Digital mismatch level data are processed by the tuning algorithm that determines which DTCs should be activated and at what capacitance level. Control words are sent to the DTCs in the matching network (DTC core) to effect the impedance match between the antenna and transceiver.

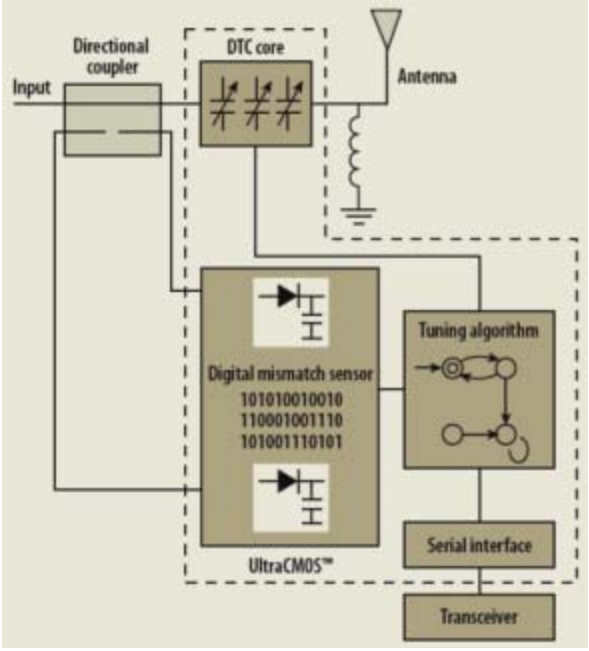


Figure 6. DTC-based AT (reproduced from [4]).

(d) *Dual-gap Tunable MEMS Capacitors* are made using a novel fabrication process that creates two gap device that has an extremely wide tuning range (as much as a factor of 15) with high *Q* [5]. Figure 1 shows the dual-gap structure schematically and as implemented using a "two hump" sacrificial layer which, when removed, creates two MEMS gaps instead of one. In the schematic, the two moveable electrodes are indicated by the double downward arrows. As these suspended elements move closer to the substrate electrodes the capacitance increases. The structure is a MEMS device designed for a linear capacitance variation with applied control voltage.

In the fabricated prototype, the central region (E_c) is 250µm x 80µm (LxW) with a 1.5µm fixed gap. The two "beams" are 800µm long by 80µm wide creating a variable gap because they are movable. The "actuation area" patches (E_a) are 200µm long and 80 um wide with a gap of 4.5µm with the beams not deflected. This structure produces a minimum capacitance of 0.12 pF that is voltage controllable to a maximum capacitance of 1.77 pF. The resulting tuning range is $\frac{C_{\max} - C_0}{C_0} = 1375\%$, which is quite remarkable. The required bias ("pull in") voltage is less than 12 volts. This device is not commercially available, but it represents a class of tunable devices that should be very useful in the set-top AT when (and if) they become COTS (commercial off-the-shelf) items.

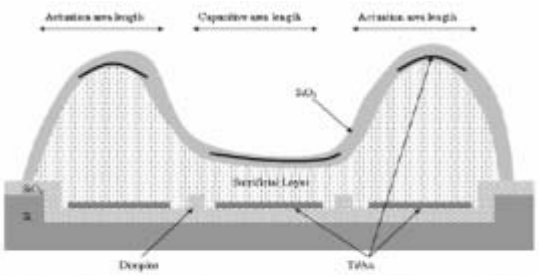

Figure 2 : Schematic representation of the tuneable capacitor based on dual pick profile of the sacrificial layer

Figure 7. Dual-gap tunable MEMS capacitor (reproduced from [5]).

(e) *MEMS floating dielectric capacitors* (MFDCs) are a recent promising development [6]. The movable dielectric is a new actuation principle in which a floating movable dielectric is electrostatically maneuvered to vary the capacitance. Figure 8 shows the new concept schematically. A mechanical spring returns the movable dielectric to its undisturbed position when no force is applied by the electrostatic comb drive. When the dive is activated, the dielectric moves closer to the top and bottom capacitor plates thereby increasing the capacitance. Preferentially the RF path is through the plates, not through the dielectric and spring, which increases losses.

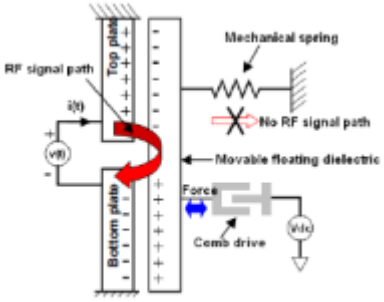

Fig. 1: Conceptual schematic view of the proposed tunable capacitor with an electrically floating dielectric.

Figure 8. MFDC concept (reproduced from [6]).

Figure 9 shows schematic RF signal path superimposed on the MFDC's actual structure as fabricated. In the left pane the signal flows through the spring, which increases the capacitance at the expense of increased losses. In the right pane the signal flows between the top and bottom plates through the movable dielectric. This configuration results in lower losses, but lower capacitance as well. Of course, either configuration can be used, depending upon the specific application.

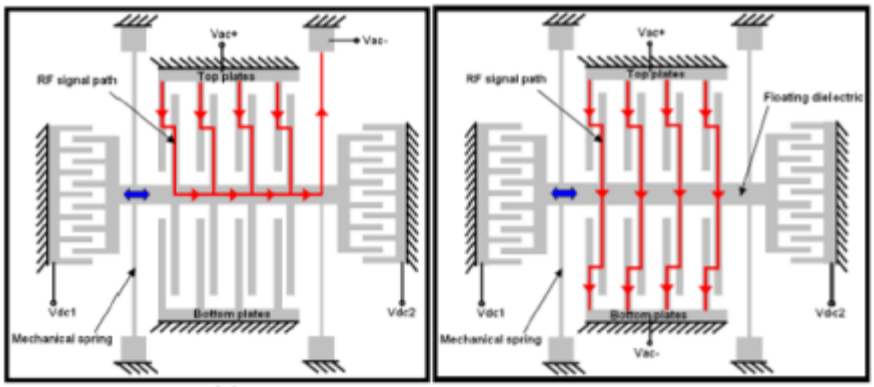

Fig. 2: Schematic views of tunable capacitor design with RF signal through spring (a) and dielectric (b).

Figure 9. MFDC as fabricated and measured data (reproduced from [6]).

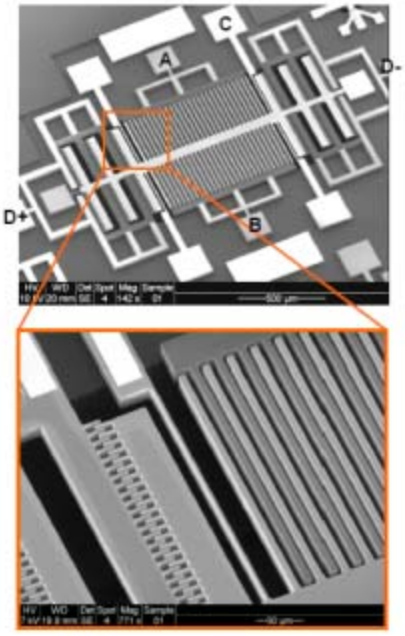

Fig. 4: SEM image of the micromachined tunable capacitor.

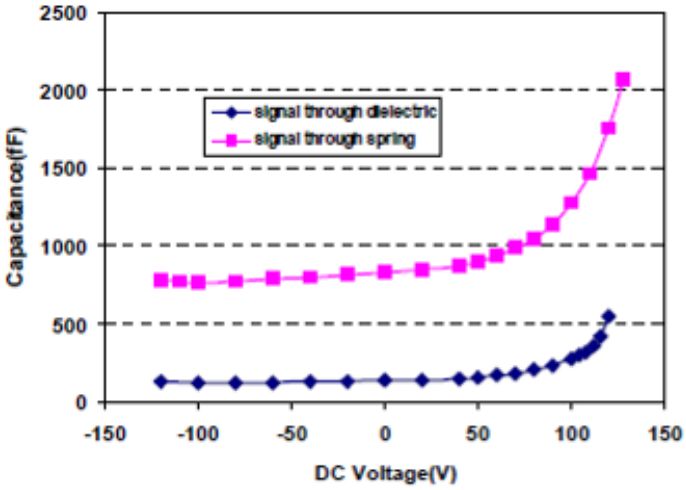

Fig. 5: Measured capacitor changes vs. applied dc bias

Figure 10. MFDC as fabricated and measured data (reproduced from [6]).

Figure 10 provides a scanning electron (SEM) microscope image of a fabricated MFDC (the area outlined in orange, lower pane) and measured performance data. Comparing Figs. 9 and 10, the features in the schematic are readily identifiable in the SEM photo. The actuator pads are labeled D+ and D- in the photo, while the spring is attached to pad C. Pads A and B are the connections for their associated comb plates.

The applied bias voltage ranged from -120 VDC to +120VDC, resulting in capacitance ranges of about 760 fF (femtoFarad) to 2100 fF for RF signals passing through the spring element (pink curve). The initial capacitance (no bias voltage) was 830 fF, leading to a tuning range of approximately 170%. The 1 GHz *Q*-factor was 0.35, which is low by comparison to other technologies. When the RF path is through the movable dielectric (blue curve), capacitance ranged from just over 100 fF to about 550 fF yielding a tuning range of approximately 370% with an initial capacitance of 135 fF. As expected, the reduced loss resulting from routing the signal away from the spring results is a much better *Q*-factor of 56 at 1 GHz. Overall, this performance is not as good as that provided by other technologies, but MFDCs are a new concept that requires further development. The MFDC approach certainly merits consideration as a potentially useful future technology for the set-top AT.

(f) The v*oltage controlled semiconductor inductor* (VCSI) is another reactive component that should be useful in set-top ATs. Inductor values are usually fixed, so that obtaining specific value of inductance in an AT is usually accomplished by mechanically switching small inductors in and out of the matching circuit using relays or MEMS RF switches. Recently disclosed VCSI devices [7] should be particularly useful at broadcast TV frequencies. The device addresses the problem of limited tuning range provided by voltage tunable capacitors by varying the inductance instead.

Generally is comprises regular coil turns of wire interconnected by semiconductor diodes that can connect individual turn to create a VCSI. Including a resistor and capacitor creates a complete tunable RLC circuit. Figure 11 illustrates this patented technology. The left pane shows a perspective view of the device, which includes conductive loops (205) connected to a semiconductor bar comprising P- and N-type regions at each end (208 and 210, respectively) connected by a depletion region (212). Applying a voltage across terminals L_A and L_B varies the length of the depletion region which acts as an insulator. Because its size is proportional to the applied bias voltage, individual coil turns are either connected or disconnected in proportion to the voltage, thereby creating a voltage-variable inductor.

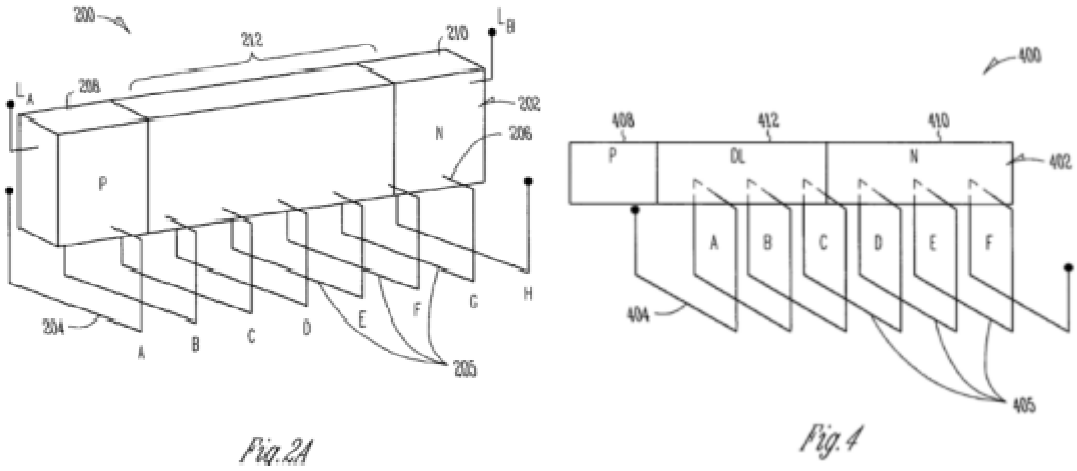

Figure 11. Voltage controlled semiconductor inductor (reproduced from [7]).

A helical-turn implementation of the VCSI is shown in the right pane of Figure 11. The same semiconductor diode structure comprising P- and N-type end regions connected to a central depletion layer (DL) whose length is voltage-variable. The figure provides a schematic representation of how the three regions' lengths vary with bias voltage compared to the "off" state shown in the left pane. In the diagram, coil turns C through F are electrically short-circuited because they are outside the insulating DL. In this case, only turns A and B are active elements in the inductor.

The VCSI may become an important element in set-top ATs because it provides a complete RLC tuning in a single chip-level device. A bank of VCSIs, for example, could comprise the switchable reactive elements in a set-top AT that are completely voltage-controllable, thereby eliminating the need for mechanical switching relays. VCSI therefore is an attractive emerging technology that merits watching.

2.5.1.2 Fully Integrated ATs

In addition to the emerging component-level technologies described in §1, fully integrated ATs have been developed that also merit consideration for set-top tuners. This section examines developments in that area.

(a) A *reconfigurable RF-MEMS-based matching network* is described in [8]. The chip-level device's circuit diagram is shown in Figure 12. It comprises two stages, the first of which is a Pi-match section with four shunt capacitor-series inductor (CL) sections. A total of eight RF-MEMS switches are employed yielding 2^8 impedances. The shunt capacitors are formed from bi-valued MEMS varactors. The variable capacitor in series with each fixed inductor, also a MEMS varactor, has the effect of adjusting the series inductance. The second section is a phase-shifter comprising a 3-dB 90-degree coupler connected to a reflective load. MEMS varactors adjust the load reflection

coefficient to control the overall phase shift. A total of 2^3 phase rotations are possible in the phase shifter, resulting in as much as 340 degrees of total phase shift that can be applied to the impedances at the output of the Pi-match. The network is designed to work at a 50 Ω impedance level.

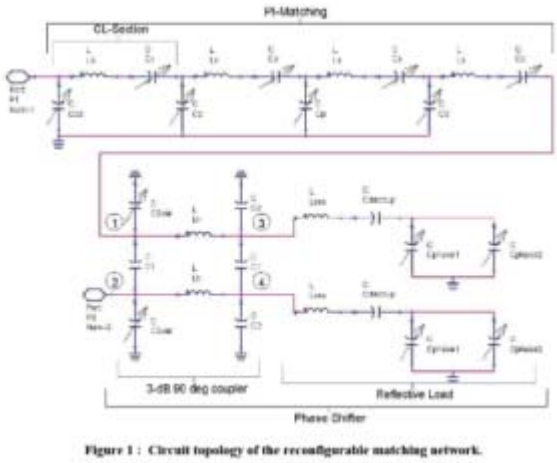

Figure 12. Reconfigurable RF-MEMS-based matching network circuit (reproduced from [8]).

The chip layout and fabricated device are shown in Figure 13 with the major sections being labeled on the layout diagram. The chip area is extremely small, only 40 mm^2 (slightly larger than 3x12 mm). The published report indicates that the chip has been fabricated and was undergoing testing, but no actual measured data were reported. Instead simulated performance at a single frequency (620 MHz) was calculated at each of the possible 2,048 impedance combinations and plotted on a Smith chart as shown in Figure 14. The circles are impedance values computed for the first stage alone, while the dots represent the show the performance of the complete reconfigurable matching circuit. The fairly uniform distribution of dots throughout the Smith chart suggest that the matching circuit will effectively match an extremely wide range of impedances to 50 Ω. This technology is directly applicable to the set-top AT and appears to be on the verge of realization. Future published results for reconfigurable RF-MEMS-based matching networks clearly bear watching.

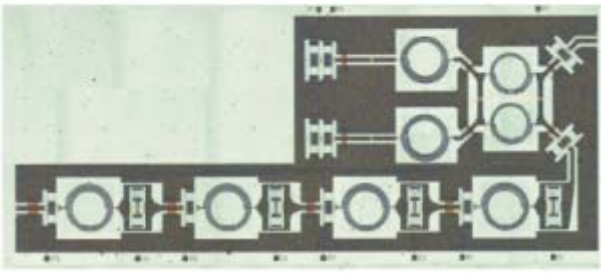

Figure 4 : Photograph of the fabricated circuit

Figure 13. Reconfigurable RF-MEMS-based matching network layout & fabrication (reproduced from [8]).

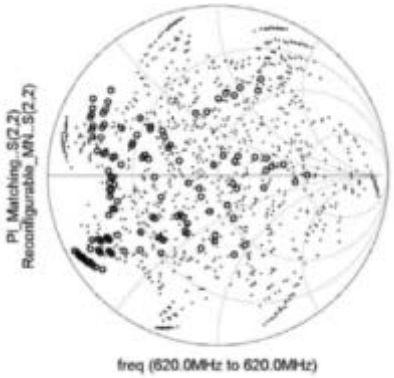

Figure 2 : Simulated impedance values (circles: first stage; dots: full reconfigurable matching network).

Figure 14. Reconfigurable RF-MEMS-based matching network performance (reproduced from [8]).

(b) The *AT using only RF signal amplitudes* described in [9] may be useful for the set-top application because it specifically addresses the issue of highly variable, unpredictable and uncontrollable environments. This new technology was developed for mobile applications such as cellular transceivers because their fluctuating environment often causes VSWR spikes approaching 10:1 in nominal 50 Ω systems. These fluctuations are frequently transient on time scales in the millisecond range. The new AT design accommodates this environment, and it may be useful in the highly variable TV set-top antenna environment as well.

The architecture appears in Figure 15, which includes schematic Smith chart representations of the impedance at various points. ATs generally comprise an impedance sensor, a tunable matching network, and control circuitry that changes the network parameters in order to achieve an acceptable VSWR (usually relative to 50 Ω with VSWR < 2-3:1). The general approach shown in Figure 15 therefore is applicable to any matching network. The new matching concept involves a two-step process: (1) the reactance is essentially tuned out using a series or shunt reactance; and (2) a tunable "transformer" changes the remaining resistive component to the desired value of impedance.

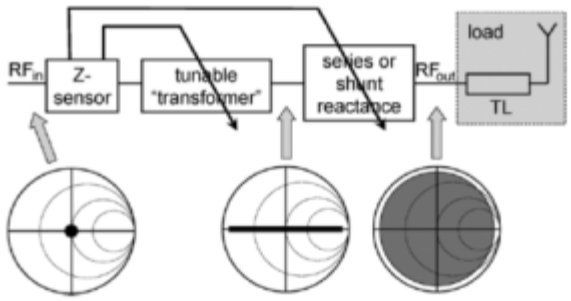

Fig. 2. Basic concept of the automatic antenna tuning system: tune out the imaginary part and tune the real part separately.

Figure 15. New AT architecture for fluctuating environment (reproduced from [9]).

In the new AT, the antenna impedance sensor makes a quasi-DC log-peak measurement of the RF signal amplitude at three points in the signal chain (V1, V2, V3 in Figure 16). Details of the log-peak detector circuit are shown in Figure 17. These data combined with the known transfer functions of the reactive elements (jX_{ext}) permit a calculation of the impedance's imaginary part. The real part of the impedance is determined from the signal level $V_{\Delta R}$ and an offset voltage that brings this level to a target value corresponding to 1:1 VSWR. The tunable transformer comprises a T-network lumped transmission line made of two adjustable inductors and an adjustable capacitor. Any appropriate device can be used to implement these elements.

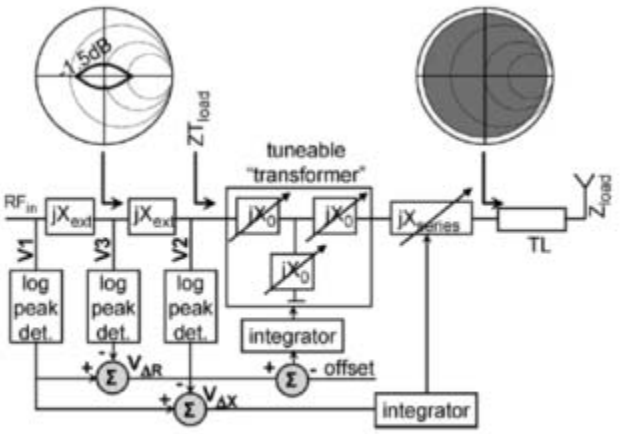

Fig. 3. Automatic antenna tuning system with low-frequency impedance detection; the target impedance (− 1.5-dB contour) is used in Section IV-A.

Figure 16. AT functional block diagram (reproduced from [9]).

Two demonstration versions of this new AT design was built and tested at 900 MHz. Measurements confirmed that they could reliably and quickly automatically tune antennas with $Z_{in} = [5-500] + j[15.8-158]\,\Omega$ (10:1 VSWR). Although the sizes were not reported, these demonstration units were intended for use in cellular handsets, so that the size is certainly consistent with use in a set-top television AT.

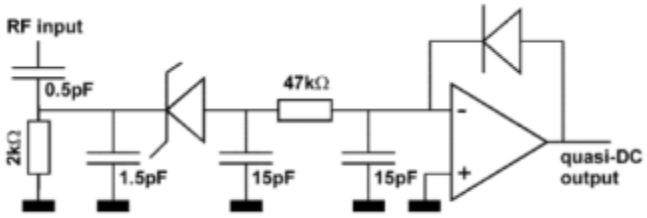

Fig. 4. Schematic diagram of the log-peak detector implementation.

Figure 17. Details of log-peak detector circuit in Figure 16 (reproduced from [9]).

2.5.1.3 On-Chip Tracking Filters

While tracking filters are not AT's, their technology likely is applicable to antenna tuners ATs, and consequently should be monitored for application in set-top devices. This section describes three different types of tracking filter.

A device developed specifically for DTV tuners is described in [10]. A new architecture is proposed that includes two separate filters, a harmonic rejection tracking filter (HRTF) and an RF tracking filter (RFTF) that are controlled by complementary digital switches. The new architecture is shown in Figure 18. The entire device is fabricated as a single integrated circuit (IC) chip. The filter stage is shown in blue located between the low noise amplifier (LNA) connected to the antenna and the DTV tuner.

Unlike narrowband RF receivers, wideband DTV tuners are prone to interference from local oscillator odd harmonics mixing with signals at the lower television channels (48-287 MHz). This problem is addressed by the HRTF that provides a high-order band-pass tracking filter with 3rd-order harmonic rejection greater than 60 dB. On the UHF television channels the RFTF tunes 287-860 MHz with narrow band response (20 MHz at -3 dB). This stage is implemented using a cascade of tunable 2nd-order bandpass tracking filters.

Computer simulation of the new architecture's performance predict 48-860 MHz operation with tunable adjustable bandwidth of 8-20 MHz, 5-15 dB N+2 channel rejection (16 MHz offset), and 3rd-order harmonic rejection of 60 dB from the HRTF. The RFTF stage provides 4.2 dB of N+2 channel rejection above 287 MHz. This device can be fabricated on-chip using 0.13 µm CMOS technology with 1.2 VDC supply voltage and 19.8 mA current draw (total of 24 mW power consumption).

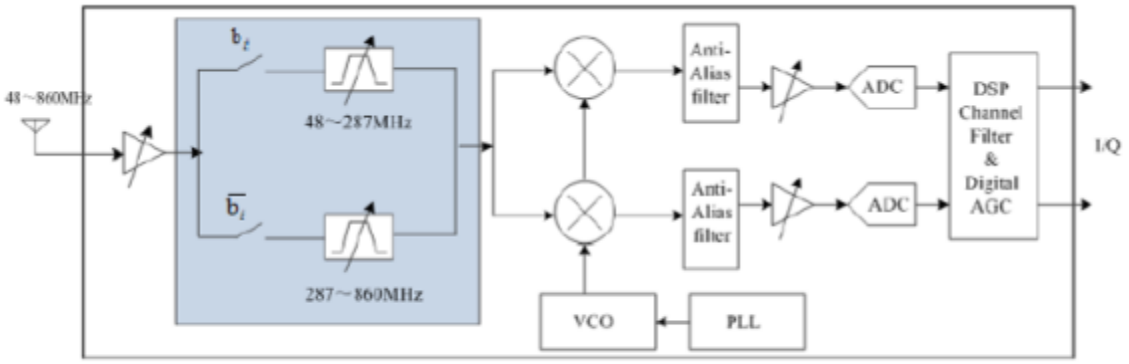

Figure 1. Direct Conversion TV tuner architecture

Figure 18. New DTV tracking filter architecture (reproduced from [10]).

Another potentially important emerging filter technology is the use of low-temperature co-fired ceramic (LTCC) technology to fabricate fully integrated multi-layer tunable filters for RF and microwave use. A typical device is shown in Figure 18. Passive

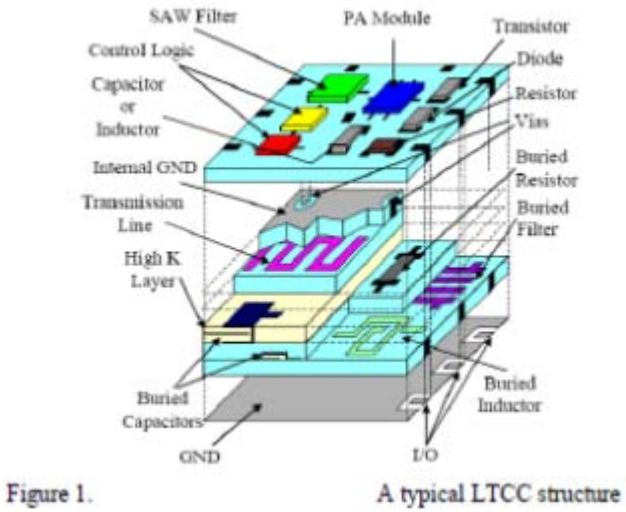

Figure 18. LTCC filter structure (reproduced from [11]).

Elements (resistors, inductors, capacitors) are integrated on the surface or embedded in a multilayer substrate. Various configurations have been demonstrated, including bandpass filters (380 MHz-2.4 GHz), 3-stage Butterworth bandpass filters (1.2 GHz), and an electronically tunable microstrip combline filter. These prototype devices point to LTCC technology's utility for RF and microwave applications. At this point the new multilayer architecture proposed in [11] that involves switching between layers for tuning is being computer-modeled, but working devices based on that approach have not been fabricated. LTCC technology may be very attractive in the television frequency range because of its potential for very high levels of integration resulting from the multilayer design.

A third example of an on-chip tracking filter is provided by [12]. A complete tunable structure was fabricated and tested. This chip occupied an area of only 2.8 mm^2 (fabricated with 0.18 µm CMOS) requiring 34-120 mA at 1.8 VDC. A photomicrograph of the chip appears in Figure 19, and its architecture in Figure 20. The device comprises cascaded RLC sections as shown in Figure 20, each containing a digitally programmable on-chip capacitor and resistor, and an off-chip fixed inductor. The resistor is adjusted with 8-bit resolution, while the capacitor uses a 10-bit control signal.

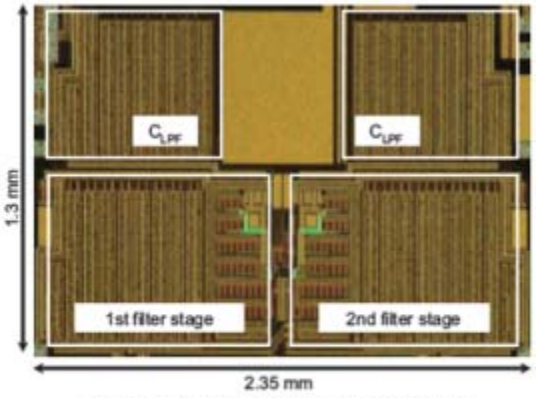

Fig. 7. Chip micrograph

Figure 19. Tunable LC-Tracking filter as fabricated (reproduced from [12]).

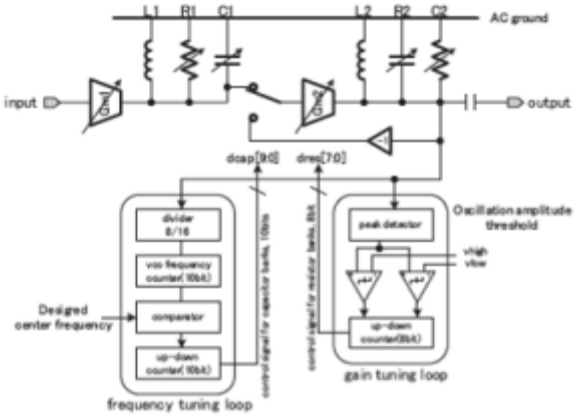

Fig. 1. RF tracking filter architecture

Figure 20. Tunable LC-Tracking filter architecture (reproduced from [12]).

Figure 21 shows the tracking filter's measured performance data from 125 MHz to 1.06 GHz. Its response in the 5.6 MHz passband is very flat with a ripple less than 0.2 dB. The noise figure in this device appears to be somewhat high (16.8-19.5 dB), but the third-order intercept points are good (~128/167 dBμV, in/out of band). Frequency selectivity is good at > 36 dB, and the power consumption quite low (<~0.2 W maximum). This example shows that very effective single-chip RF tracking filters with minimal off-chip components (in this case two inductors) can be designed and fabricated for set-top use using currently available technologies.

TABLE I
PERFORMANCE SUMMARY

Parameter		Measured value
Center frequency(f_C)		125 MHz – 1.06 GHz
Passband ripple	f_C =125MHz (BAND1)	< 0.2 dB
Signal bandwidth		5.6 MHz
Noise Figure (Input referred noise)	f_C =430MHz (BAND2)	16.8dB (17.4 dBuV)
	f_C =1.06GHz (BAND2)	19.5 dB (20.1 dBuV)
in-band IIP3		127.7 dBuV
out-of-band IIP2		167.0 dBuV
Frequency selectivity at 3rd LO freq.		> 36dB
Power consumption	f_C =380MHz (BAND2)	120mA @ 1.8V
	f_C =430MHz (BAND1)	34mA @ 1.8V
Si-area		2.8 mm2
Process		0.18um CMOS 1P6M with MIM cap

Figure 21. Measured performance of tunable LC-Tracking filter (reproduced from [12]).

2.5.1.4 Software Defined Radios

A software defined radio (SDR) is an element of a wireless communication network whose operational modes and parameters can be changed or augmented post-manufacture via software. The essential idea is that a flexible hardware layer exists whose function can be controlled and modified entirely by a computer program, as opposed to requiring hardware modifications of any kind. The SDR concept spans many radio network technologies including cellular systems, personal communications services (PCS), 3rd and 4th generation wireless (3G and 4G), mobile data, emergency services, paging, messaging, and military/government communications, and any future modifications to these existing services or entirely new ones. The FCC (Federal Communications Commission) definition is more restrictive in that it applies only to the transmitter side of an SDR. But, as a practical matter, the SDR concept applies to any wireless device whose characteristics are software-controllable, whether it be the transmitter, receiver, both, or some other element such as a modem.

SDR technology is relevant to the television set-top AT because there is a developing standard that specifically addresses the issue of “smart antennas” (SAs) in the context of SDR. This type of antenna and its associated AT may be useful for the set-top application and consequently should be monitored as an emerging technology. The high-level SDR smart antenna architecture appears in Figure 22. The hardware layer comprises M transmit antennas and N receive antennas because SDR in general supports two-way communication (in the step-top TV receive application, of course, there are no transmit antennas). Each antenna is has a separate RF/IF processing chain with the smart antenna signal processing (“waveform application”) being applied to the

baseband signal. Device drivers in the middleware layer control various programmable hardware devices, such as ASSPs (application-specific standard processors), FPGAs (field-programmable gate arrays), DSPs (digital signal processors), and GPPs (general purpose processors).

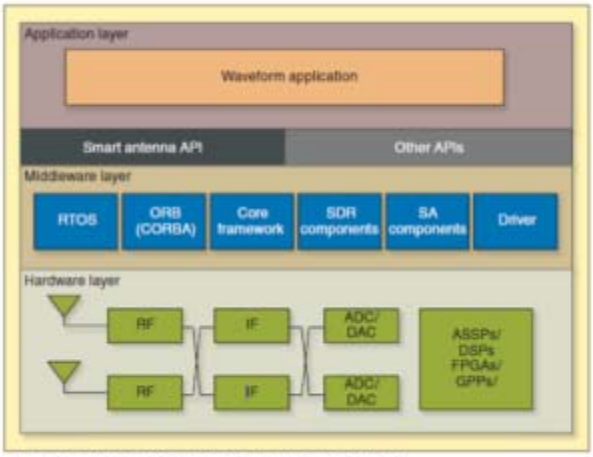

Figure 1. Example of an SDR-based smart antenna open architecture.

Figure 22. SDR smart antenna high-level architecture (reproduced from [13]).

Figure 23 illustrates a typical deployment of an SA API (application program interface). The SA control device (for example, an antenna tuner, tracking filter, MEMS-based controller, fluidic element controller, and so on) is operated by a GPP controlled by a CORBA interface (common object request broker architecture). The high-level SA algorithm controls appropriate CORBA-compatible drivers for DSP baseband processing, antenna control, and other functions such as synchronization and other SDR devices that may be controlled by the SA algorithm. The basic concept in this structure is that any hardware module involved in controlling the SA or processing its signal is controllable by the API with variable parameters.

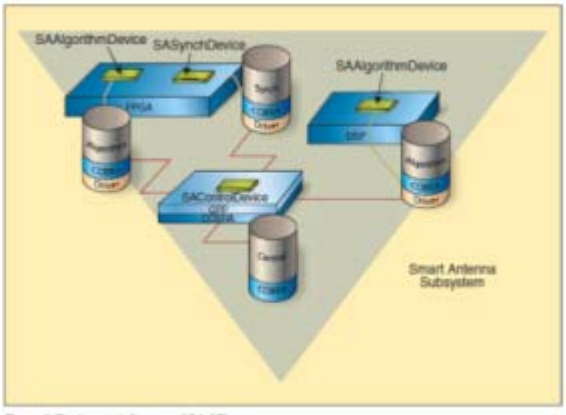

Figure 6. Deployment diagram of SA API.

Figure 23. SDR Smart Antenna API deployment (reproduced from [13]).

A typical SA hardware implementation for the SDR baseband signal processing module is shown in Figure 24. The two DSP integrated circuits (ICs), the GPP, and the FPGA ICs are labeled. This type of module is simply inserted into a backplane containing the other SDR modules to create a complete SDR. All chip-level functions are fully controllable by the SA API. As modifications are required, a simple download of the updated API is all that is necessary. No hardware modifications or swaps are necessary. The SDR approach thus provides exceptional flexibility in customizing radio performance and it well may be a very useful approach to developing effective set-top television ATs.

2.6 Physically Reconfigurable Antenna Elements

2.6.1 Summary

A *reconfigurable antenna* (RA) is an antenna whose physical and/or electrical properties can be changed in real time in order to achieve certain performance characteristics. The panoply of possible RA implementations makes RAs especially attractive for the television set-top antenna application. This section discusses some of the "typical" RA implementations, as well as some rather unusual technologies that may point the way to future developments that could be useful for set-top devices.

The essential concept underlying RAs is that some antenna property is changed "on the fly" to accomplish some objective, say tuning. An example is the tunable antenna in which the electrical length of a radiating element is changed by switching in and out reactive elements (capacitors/inductors) or remotely moving the tap on a roller-type tuning inductor. This type of reconfigurable antenna has been used for at least fifty years (see, for example, [1] p. 20.46 *et seq*.).

While an RA may be any electrical size, typically they are a substantial fraction of a wavelength, so that they are not (necessarily) electrically small antennas (ESAs). The problems associated with ESAs, narrow bandwidth, low radiation efficiency, highly reactive input impedance, are mitigated in RAs that are a substantial fraction of a wavelength in size. Nevertheless, the RA concept is applicable to ESAs as well, and it may be useful for ESA candidates for the set-top application. As a general proposition, RA technology is applicable across the entire range of antenna electrical sizes, which makes it particularly attractive for set-top devices.

Most recent examples of effective RAs are at frequencies well above the broadcast television channels, typically in the microwave region. However, because these RAs often are comparable to the operating wavelength in size, they may be readily used at lower frequencies, especially at UHF TV channel frequencies. On the lower VHF channels, RA approaches may be effective when applied to standard antennas such as bowties or spirals whose size is consistent wit set-top requirements.

Five candidate RA technologies hold promise for short or long term application to television set-top antennas:

(a) *Microelectromechanical System* (MEMS) RAs are antennas based on MEMS RF switches. These devices, which have been fabricated for well over a decade, have come to the foreground as the preferred approach for RAs. They can be used in all frequency ranges, and, in fact, perform better at lower frequencies, although current applications emphasize the high UHF and microwave ranges. Other similar switching

devices such as PIN diodes or GaAs (gallium arsenide) solid-state switches also are used to build RAs, but these technologies are older and perform less well. The latest developments in MEMS, nano-MEMS and the use of carbon nano-tubes (CNT), reduce sizes and improve performance to the point where there seems essentially no question that MEMS-based set-top RAs will be achievable in the near future.

(b) *Fluidic* RAs are a very recent development that promises simple, cost-effective, rugged reconfigurable wire antenna structures in almost any shape imaginable. Fluidic elements are fabricated from a flexible eslastomer enclosing human-hair-thin channels filled with eutectic gallium/indium (EGaln), a liquid metal. The resulting "wire" provides electrical performance similar to copper and can be stretched, bent, rolled, or twisted into almost any shape simply by applying mechanical stress. The wire returns to its original linear structure upon relieving the stress. These elements have been used to fabricate a simple center-fed dipole that is tuned by stretching. A similar approach using a multiplicity of wires or other geometries (for example, bow ties or spirals) may well be the basis of a simple, effective set-top antenna. This technology has only recently been reported, and it certainly bears watching as a candidate for set-top RAs.

(c) *Pixelated piston* RAs comprise small individually controllable and addressable "pistons" in a two-dimensional matrix. Each piston is controlled by an actuator which, in turn, is operated by an electronic controller. A conductive patch is mounted on the end of each piston, which in their quiescent position form a continuous, flat ground plane. Each piston moves back and forth above and below the ground plane to form reconfigurable antenna radiating elements or transmission lines. This technology, which is patented, has been demonstrated to provide high-gain, beam steerable, antennas operating from 500 MHz to 18 GHz with reconfiguration times less than one millisecond. Its utility for the set-top application is self-evident, but at this point in its development the cost likely is prohibitive.

(d) *Liquid crystal* (LC) RAs are fabricated using LC substrates sandwiched between two electrodes that apply a DC bias voltage to control the LC's dielectric constant by deforming its molecules. Very small unit cells are fabricated that can be formed or applied onto surfaces of various shapes. At this point in its development, LC RAs have been demonstrated only on planar surfaces, and only at extremely high frequencies (high microwave through millimeter wave ranges). An effective LC RA reflectarray antenna has been demonstrated at 77 GHz. It provided complete electronic beam steering over an angular range of 35 degrees with good gain and sidelobe performance. Whether or not this technology can be ported to low VHF television set-

top channels is not clear, but the technology bears watching because it is demonstrably effective for designing and building reconfigurable antennas.

(e) *Plasma* RAs are similar to the pixilated piston antennas, but instead of using conductive patches, they utilize ionized gas (plasma) as the conductive element. Each plasma element is turned "on" (ionized) or "off" (non-conducting) by a control voltage, so that the entire antenna aperture is electronically reconfigurable. Unlike pixilated piston RAs, the plasma elements lie in a single plane and cannot be positioned above or below the plane. This limitation, however, is minor in the context of set-top receive antennas because it is very likely that good receiving structures can be formed on a planar surface, which also simplifies the RA. The plasma RA has another potentially significant advantage over other candidate technologies. Existing plasma display technology, which is very highly developed and sophisticated, may be directly applicable to the design and manufacture of plasma RAs for the set-top application. Leveraging this existing technology may speed time to market and reduce costs substantially.

2.6.2 MEMS-based RAs

Microelectromechanical system (MEMS) radio-frequency switches have gained widespread acceptance as a standard element for implementing in RA structures. RF MEMS are routinely used to change both antenna feed networks to accomplish impedance matching and radiating element topology to control radiation pattern and efficiency. Most applications are in the microwave range, but MEMS use is not frequency-limited.

While there are other switching elements besides MEMS, notably sold-state PIN diodes and GaAs switches, MEMS offer several advantages. They are inexpensive, which is a major advantage for set-top applications, and they exhibit low insertion loss and low power consumption [2]. In recent years their availability as a commercial item has grown considerably, and they are now readily available as off-the-shelf components [3,4,5]. Demonstrated lifetimes exceed 100 billion cycles, which is consistent with consumer levels of usage over periods of several years.

Figure 1 shows a typical bi-layer curled MEMS structure. It is extremely small in size (300x1500µm). The two-layer switch element comprises materials with different thermal coefficients of expansion that pull it up away from the contact after annealing as shown in (a). The switch therefore is normally open (NO) when no control voltage is applied. Applying a DC voltage between the switch post and bottom electrode (1.5 µm thick polysilicon) creates an electrostatic field that pulls the switch element onto the contact as shown in (b). The microphotograph below the switch diagram shows its structure as actually fabricated.

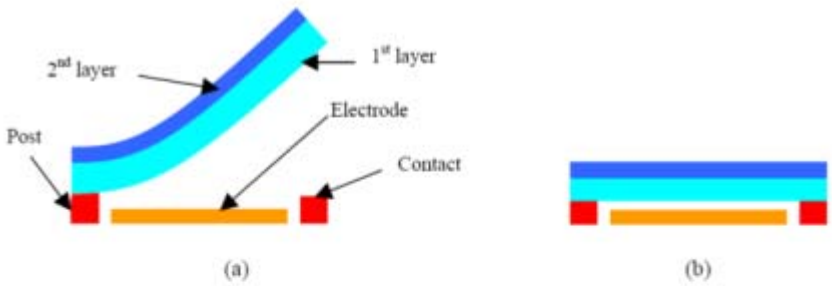

Figure 11. Operation of a bi-layer curled MEMS switch. (a) OFF state and (b) ON state.

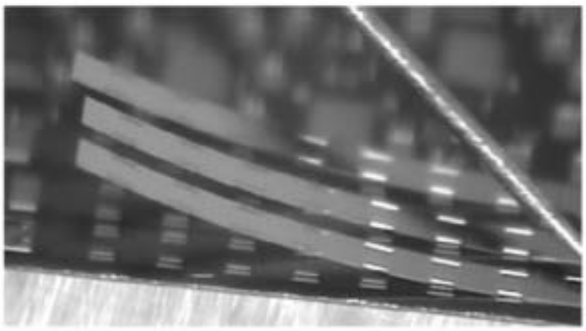

Figure 12. A photograph of the fabricated MEMS switches.

Figure 1. Typical RF MEMS switch (reproduced from [2]).

MEMS technology is improving at a rapid pace, and the latest generation of these switches are nano-scale [6]. *Nanoelectromechanical system* (NEMS) are laterally ~10-100 times smaller than a typical MEMS device, and they operate with actuation voltages below 10 volts, compared to 30-80 volts for MEMS switches. NEMS also provide faster switching times (<~1 μsec) compared to MEMS (~10-20 μsec). Figure 2 shows the new NEMS double-arm cantilevered switch schematically (a) and as fabricated (b) imaged by a scanning electron microscope.

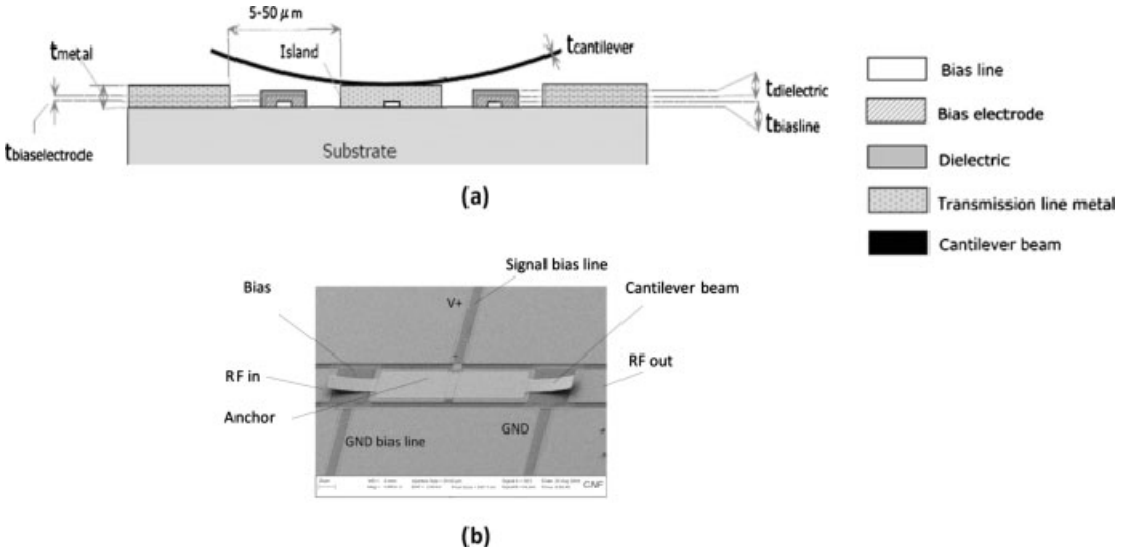

Figure 2. DC-contact NEMS switch (reproduced from [6]).

Another important recent development is the use of carbon nanotubes (CNT) to fabricate NEM switches [7]. These devices promise extreme longevity and reliability because of CNT's unusual physical and electrical properties. Carbon nanotubes are extremely strong with high electrical conductivity. In addition, their flexibility and extremely low mass suggest that switching speeds in the GHz range eventually may be attainable. Figure 3 shows two types of CNT-based NEM switches. Measured switching times were 26 ns for these devices, which while far short of the GHz range, are nonetheless faster than MEMS devices.

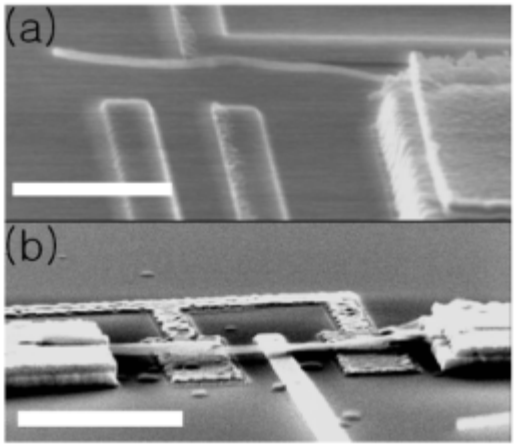

Figure 3. Two types of CNT-based NEMS switches (reproduced from [7]).

A typical MEMS-based reconfigurable array structure appears in Figure 4. This is an example of a complex RECAP (Reconfigurable Aperture) structure whose objective is wide bandwidth. Because a MEMS-based antenna can be reconfigured essentially in real-time, it can operate in multiple frequency bands. Aperture reconfiguration is achieved by switching in and out receiving and/or transmitting elements (radiating a signal, of course, is not an issue with set-top TV antennas). The structure shown in Figure 4 typically would be implemented using solid-state switches, but MEMS technology has leap-frogged that approach, so that MEMS provides better performance. In the array application, only the MEMS network departs from an otherwise standard design. The receiving/radiating element structure and its feed network are independent of the MEMS switch layer, as are the bias, FSS (frequency selective surface) and PBG (photonic band gap) layers. These last two elements may well not be required in an application like the set-top antenna because the operating frequencies are well below the microwave range where FSS and PBG structures are common.

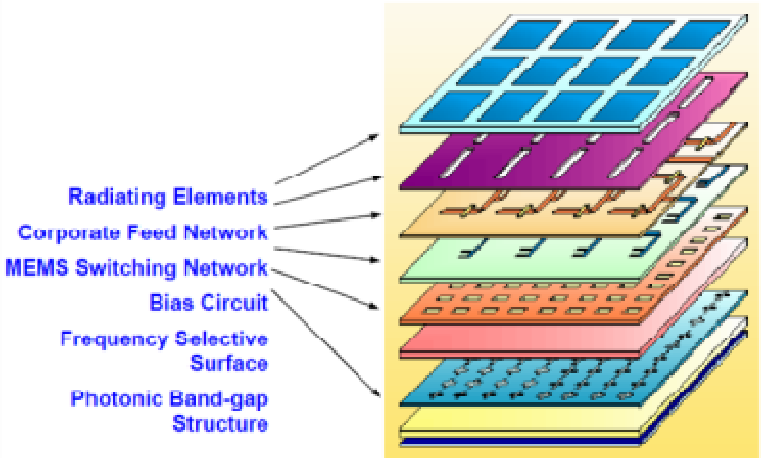

Figure 4. Reconfigurable MEMS-based antenna array (reproduced from [8]).

Another example of a state-of-the-art multiband MEMS-based antenna is reported in [9]. The design emphasizes a symmetric, repeatable topology which lends itself well to scalability, so that additional frequency bands are readily added. Scalability could be an important attribute in applying MEMS technology to the set-top environment, and this antenna demonstrates that scalability is achievable with MEMS. As configured the antenna covers four bands: 800-900 MHz; 1.7-2.5 GHz; 3.3-3.6 GHz; and 5.1-5.9 GHz. The lowest band lies just above the highest UHF television range, suggesting that this design likely could be easily modified to cover some portion of the upper TV channels. Table 2 reproduced below from [9] shows that this antenna indeed provides excellent performance in the four design bands. Its structure appears in Figure 5.

Table 2. Summary of Reconfigurable Antenna Performance

Band of interest	B1	B2	B3	B4
Frequencies covered (GHz)	0.8-0.9	1.7-2.5	3.3-3.6	5.1-5.9
Measured S11 (dB)	-13	-9	-7.7	-3.6
Measure Center Freq Gain	8.21 dB	7.96 dB	9.6 dB	8.4 dB

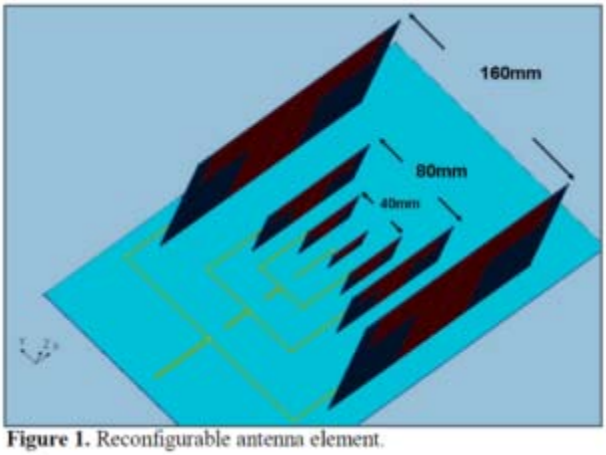

Figure 1. Reconfigurable antenna element.

Figure 5. Four band MEMS-based antenna (reproduced from [9]).

2.6.3 Fluidic RAs

An interesting new RA technology is the *fluidic* antenna. A fluid metallic alloy, eutectic gallium/indium (EGaln), comprising the metals gallium and indium, that remains liquid room temperature is injected into a microfluidic channel made from the silicone elastomer PDMS (polydimethylsiloxane). The channels are very small, about the width of a human hair, open at each end, and of any desired shape. After the channel is filled with EGaln, the alloy's surface oxidizes, creating a "skin" that holds the alloy in place while allowing it to retain its liquid properties. The alloy's mechanical properties are determined by the elastomer casing because it remains liquid.

The "wires" created by this process can be bent, stretched, rolled and twisted by applying a stress. Figure 6 shows a photograph of a twisted fluidic wire. Upon relieving the stress, the liquid conductor/elastomer reversibly returns to its original shape without hysteresis. An antenna fabricated of fluidic elements consequently is fully reconfigurable. The structure is self-healing to small cuts, and it is highly flexible and durable. Life expectancy therefore is very high, and fabrication costs reasonable because the elastomer's channels are formed using a technique known as "soft lithography" which avoids milling or etching in fabricating the fluidic antenna elements. However, the EGaln liquid metal is expensive, and at this time may be prohibitive for consumer applications.

A simple center-fed dipole was constructed from the fluidic element and tested. The antenna is shown in Figure 7. Its radiation efficiency was measured at approximately 90% over a frequency range of 1910-1990 MHz tuned by stretching the antenna. The efficiency is comparable to a copper element in this frequency range, so that the fluidic antenna is expected to perform as well as any metallic structure. In the television set-top application, this type of RA may be very attractive, especially if the price of EGaln alloy can be reduced because of volume. Of course, there are unanswered questions, for example, to what degree the elastomer casing can be stretched. The important conclusion that can be drawn from the reported research is that an entirely new fluidic technology may be close enough to maturity that it soon will be viable for reconfigurable set-top receive antennas.

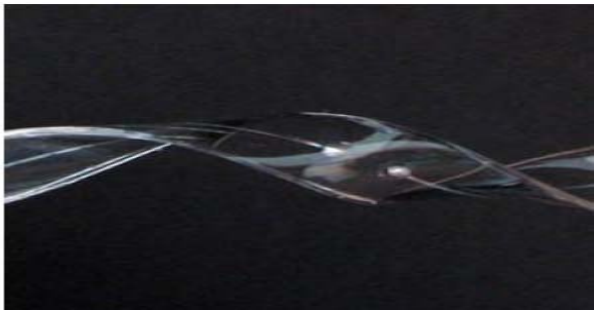

Figure 6. Twisted fluidic wire element.

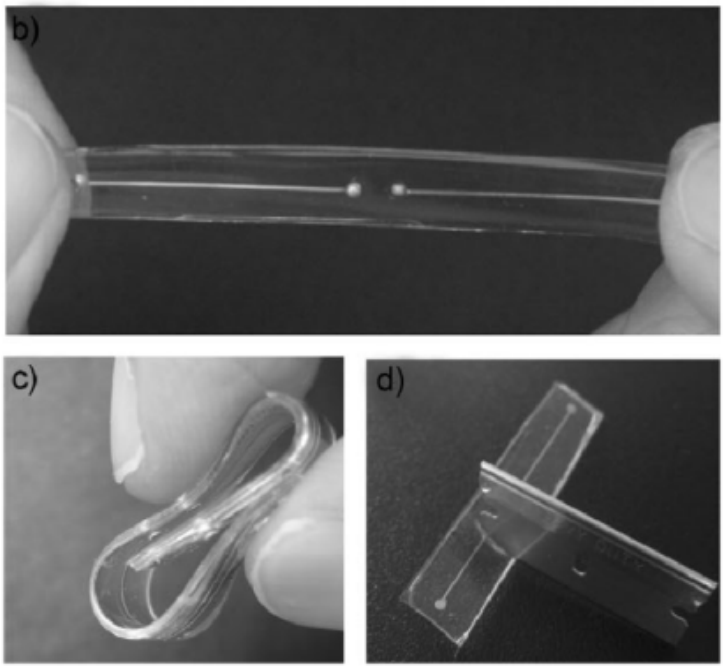

Figure 7 (a. b, c) Photographs of a prototype antenna being stretched and rolled. There is no hysteresis in the spectral properties of the antenna as it is returned to the ‘‘relaxed’’ state. d) The antenna self-heals in response to sharp cuts, such as those inflicted by a razor blade. Fluidic dipole antenna (reproduced from [10]).

2.6.4 Pixel Piston RAs

An interesting and potentially set-top feasible reconfigurable antenna comprises addressable conductive segments ("pixels") attached to the top of a movable piston in a two-dimensional array of pistons [11]. This RA appears in Figure 8. The piston includes a conductive patch (1010) sitting on top of a dielectric section (1020) that is attached to a conductive segment of the same triangular shape (1030), although other shapes are possible as well. The lower circular shaft (1040) is a dielectric material. This antenna is designed to operate at very high frequencies, 20 GHz being representative, and its dimensions are consequently commensurate. Typically the conductive pixel is about $\lambda/20$ across (0.7 mm at 221 GHz), while the height of the dielectric segment is $\lambda/10$ (1.4 mm at 21 GHz) with an overall height of about 11 mm.

The reconfigurable antenna is created by raising and lowering the pistons to form a transmission line and radiating elements in any desirable allowable pattern. If a pixel is in its lower position, it comprises an element in the array's ground plane. Otherwise, it is part of a transmission line or radiating element as shown in Figure 8 on the right. The entire structure is addressable on a pixel-by-pixel basis by a controller that operates a two-dimensional actuator for each pixel. Typical reconfiguration times are less than one millisecond, which is consistent with consumer requirements for the set-top application.

While the objective of this patented technology is electronically reconfigurable microwave patch antenna arrays, it may also be applicable to the set-top TV receive antenna if alternative element configurations are considered. For example, the pixel piston structure could be useful in creating folded element antennas, spirals, or bow-tie type elements. Each of these could be tuned to the required channel by sizing it appropriately.

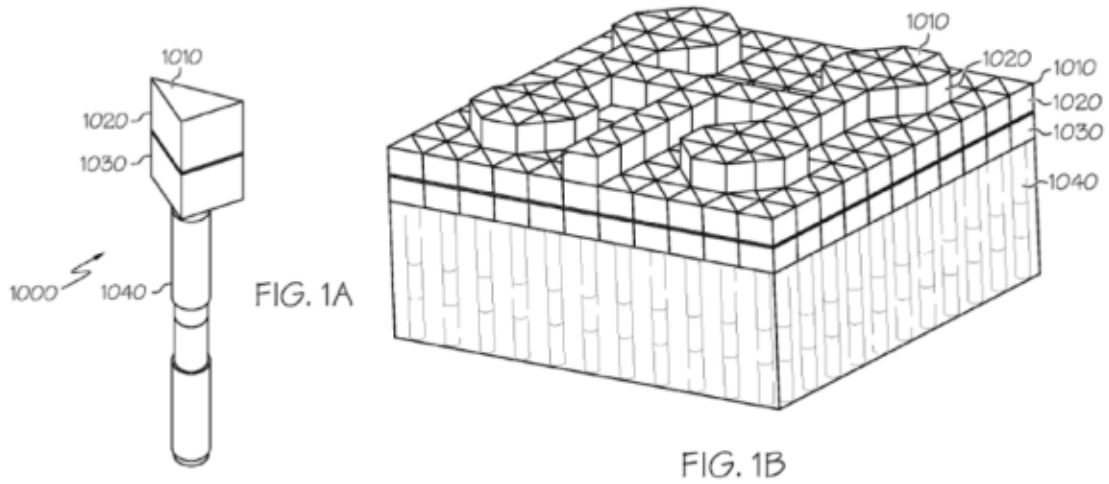

Figure 8. Pixel piston reconfigurable array (reproduced from [11]).

This technology has been implemented in commercially available antennas [12]. PARCA (Pixel-Addressable Reconfigurable Conformal Antenna) arrays are being developed for military applications requiring UWB (ultra wide-band) transmit antennas that adaptively reconfigure operating frequency, gain (beam width), and polarization while handling high power (~2 KW). A typical implementation operating from 1 to 18 GHz using approximately 100,000 ~1.65 mm diameter pixels would be 0.5 meter (20.5 in) square in size with a thickness of about 20 mm (0.8 in). Approximate weight is 12 lbs. This PARCA array would provide gain of 15 dBi and 40 dBi at 1 GHz and 18 GHz, respectively. The antenna is shown schematically in Figure 9.

Testing of microstrip transmission line and patch pixelated antennas has been done with good performance being demonstrated from 500 MHz to 18 GHz [13]. Whether or not this technology can be extended an order or magnitude lower in frequency for the set-top application with reasonable overall size is an open question. But it is clear from the current state-of-the-art that pixilated RAs constitute a technology to watch for the set-top receive antenna.

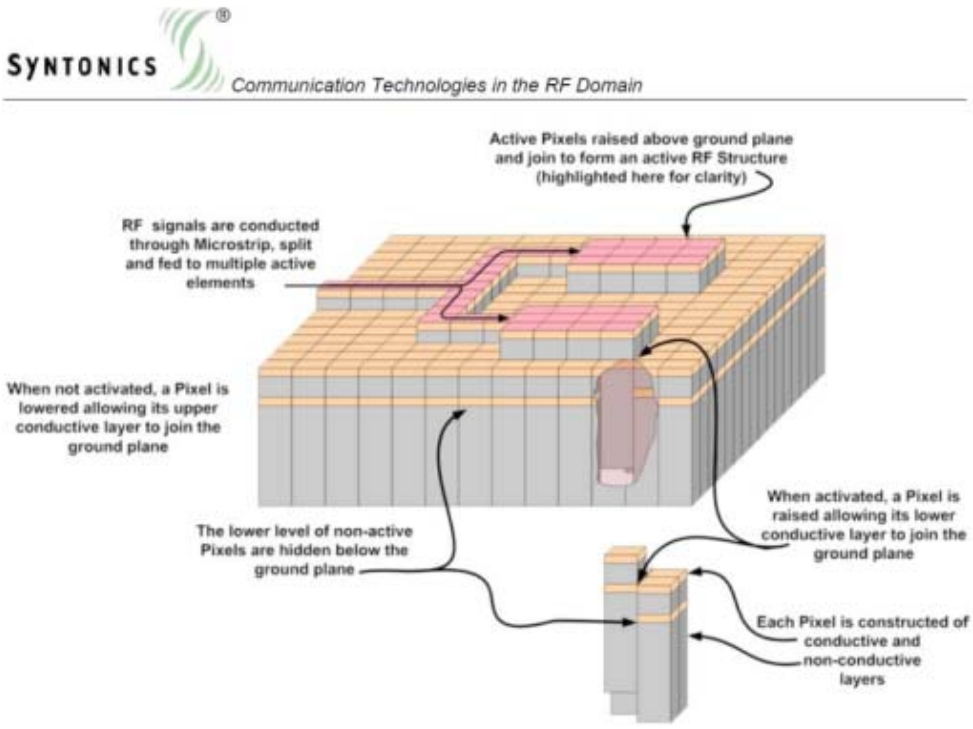

Figure 9. UWB PARCA array (reproduced from [13]).

2.6.5 Liquid Crystal Reconfigurable Antennas

Liquid crystal (LC) technology has recently been applied to RF front end components and array antennas for satellite applications, typically at quite high frequencies (> 20 GHz). Porting this technology to the low VHF range for a television set-top receive antenna simply may not be possible. Nevertheless, LC technology is worth monitoring because it may migrate to substantially lower frequencies, or it may inspire development of similar crystal-based technologies that are applicable in the VHF range.

Liquid crystals are inherently anisotropic and are so named because they simultaneously exhibit properties of liquid and crystalline materials. The class of *nematic* LCs provide the best dielectric characteristics from the microwave through millimeter wave bands, and therefore are the material of choice for very short wavelength RAs. A nematic LC molecule has a more or less rod-like shape a shown in Figure 10. Anisotropy is reflected in different perpendicular and parallel (relative to an incident electric field) dielectric constants, typical values being ~2.5 and ~2.8-3.5, respectively. Application of a bias voltage to an LC causes a deformation of the molecular alignment as shown schematically in Figure 10, the effect of which is to change the LC's dielectric properties. These changes, in turn, constitute the basis of a reconfigurable antenna element.

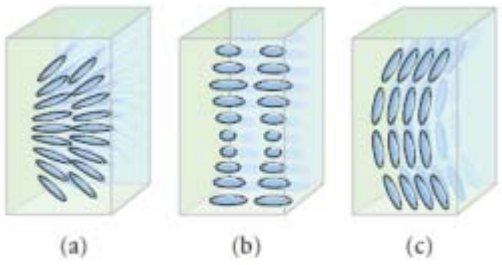

FIGURE 3: (a) The splay, (b) twist, and (c) bend deformation.

Figure 10. LC deformation modes (reproduced from [14]).

A reflectarray RA was fabricated using a dielectric substrate whose properties could be tuned using a bias voltage less than about 20 volts. The RA is a waveguide-fed planar reflecting surface capable of accurately steering the radiated beam into a wide range of directions. A unit cell comprising a single microstrip patch of dielectric sandwiched between two parallel plate electrodes is shown in cross-section in Figure 7 (left). The upper electrode patch is printed onto the dielectric substrate as is the lower electrode which acts as the antenna's ground plane. Initial LC molecule alignment is achieved using a thin (~300 nm) polyimide film on the electrode patch and ground plane. The applied external electric field created by the bias voltage reorients the LC molecules, thereby changing its dielectric properties. The figure shows the variation of dielectric constant as the bias voltage increases from zero to a value slightly exceeding the LC's threshold voltage, V_{th}, and then to a value that is much greater. As the effective dielectric constant changes, so does the capacitance per unit length of the microstrip patch, which allows the cell to be voltage-tunable as a reconfigurable antenna element.

The reflectarray antenna comprises 16x16 unit cells spaced 0.55λ. Each cell is 2.2 mm across with an LC cavity height of 50 μm. The complete antenna is shown in Figure 11, in which the individual cells are clearly visible, as are the control lines (bias lines). The antenna is fed using a right-angle bent WR-10 open-ended waveguide as shown in the figure. Figure 12 shows measured pattern data for different bias voltage levels. The main lobe is clearly steered into the desired directions of zero (blue), +25 (black), and -10 (red) degrees with good relative main lobe gain and sidelobe suppression.

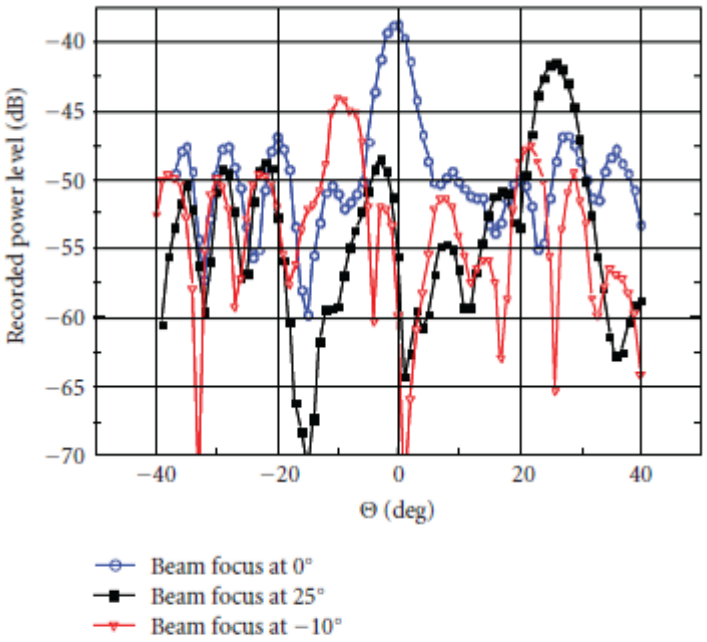

FIGURE 14: Three recorded E-plane patterns for three different voltage configurations, with the main beam pointing at different angles: −10°, 0°, and +25° (at 77.2 GHz).

Figure 12. LC reflectarray measured patterns (reproduced from [14]).

2.6.6 Plasma Reconfigurable Antennas

The plasma RA [15] is conceptually similar to the PARCA antenna in §4. It also uses electrically conductive/non-conductive surfaces to create radiating elements and associated components. But instead of conductive metallic patches, the plasma RA utilizes gas enclosures in which the gas can be made electrically conductive (plasma state) or non-conductive. The enclosures are interconnected and can be turned on (conducting) and off (non-conducting) by applying a control voltage. Figure 13 shows the basic plasma RA structure. It comprises square cells that contain four control electrodes, one on each edge. In the diagram, a cell that is turned on is shown by wavy lines between the electrodes. For example, cell 110 is "on" as shown by the wavy lines which indicate that the gas within the cell has been ionized into a plasma state. By contrast, cell 202 is "off" as indicated by the absence of wavy lines; its gaseous contents have not been ionized. Turning individual cells on and off in the manner forms the basis for a reconfigurable antenna system.

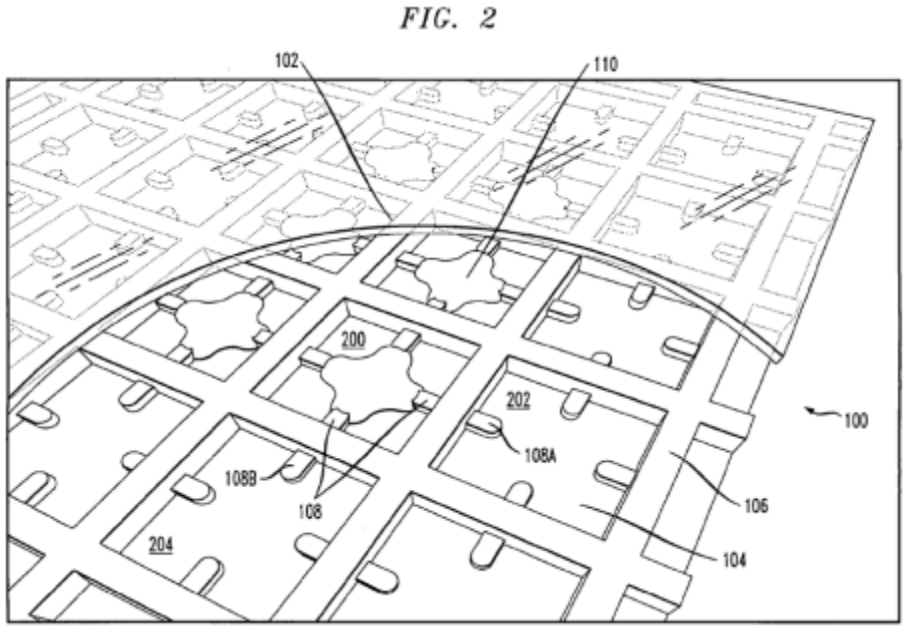

Figure 13. Plasma RA structure (reproduced from [15]).

While the reconfigurable aperture in Figure 13 can be used on a stand-alone basis, it frequently is coupled to backplane as shown in Figure 14. The backplane comprises control elements (304) that are arrayed on an insulating substrate (302) with conductive traces (312) that form the control lines. When mated with the plasma structure, the control elements turn individual gas enclosures on and off. A typical

complete plasma RA is shown in Figure 15, which adds a ground plane (404) printed on a dielectric substrate (402). The sandwich comprising the individually controllable plasma enclosures, the groundplane, and the backplane form an electronically reconfigurable antenna system.

The plasma RA may be particularly useful as a set-top antenna. One advantage is has over other approaches is that it almost certainly can benefit from the highly developed plasma screen technology used in consumer televisions. A plasma RA should be much simpler in structure and fabrication than a large plasma screen display. Applying existing display technology to manufacturing plasma RAs may be only an incremental step, thereby reducing time to market and costs.

2.7 Use of Metamaterials in Antenna Systems

2.7.1 Summary

Traditional antennas are fabricated from electrical conductors such as copper or aluminum and insulators such as plastic or rubber. Their performance is limited by their electrical size, that is, the largest dimension measured in wavelengths. Electrically small antennas are narrow-band, inefficient, and difficult to impedance-match. The demands on a television set-top antenna are for the most part antithetical. It must be small, but it requires a very wide bandwidth to cover all VHF/UHF broadcast channels with good gain and efficiency. Traditional antennas therefore have fallen short of providing good set-top performance.

A very promising emerging technology that may soon well address this limitation is the use of *metamaterials* (MTM) in the set-top antenna. This section examines whether or not MTM can sufficiently improve the performance of electrically small antennas to make MTM-based designs attractive for set-top use. While MTM have been available since the mid-1990s and the subject of much literature, they have not gained widespread commercial acceptance until recently. A recent survey paper examines this question and suggests some explanations for the MTM's slow acceptance, much of which is not based on the technology itself.

More recent developments show that well-designed MTM-based antennas indeed can provide significantly improved performance over traditional designs, but the reported designs are in frequency bands well above the TV VHF band. Wireless communication antennas have been designed, fabricated, and measured that improve on the "Chu limit" for small antenna performance by orders of magnitude using MTM. Substantially improved bandwidth, high efficiency, and good gain are available from antennas with maximum dimensions less than one-tenth wavelength. The question is whether or not this technology can be ported to the low end of the television broadcast band; and, while the answer is not guaranteed, it appears to be in the affirmative.

The MTM-based antenna is an attractive candidate for the set-top application, and it should be vigorously studied as a candidate architecture. Because MTM typically are formed from simple wire structures, they likely can be optimized for the set-top application, which may lead to designs that are different than those used at higher frequencies that still meet set-top performance objectives.

2.7.2 What is a *metamaterial*?

The term *metamaterial* (MTM) applied to antennas does not connote a material in its commonly used sense. The materials used to fabricate an antenna broadly fall into the categories of conductors (metallic elements), insulators (non-conductors), and, occasionally, semiconductors. Materials like copper, aluminum, silver, various plastics, rubber, paper, and so on, are what come to mind as typical antenna materials; and all of these share some common features. Whether naturally occurring or man-made, they are homogeneous with electrical properties determined by their chemical structure. Like all other naturally occurring substances (at least all that are known at this time), antenna materials exhibit positive relative permittivity (dielectric constant), $\varepsilon_r \geq 1$, and positive relative permeability, $\mu_r \geq 1$. Their electrical performance in the antenna is determined by these fundamental physical parameters.

In sharp contrast, a *metamaterial* is a "composite" whose electrical properties are not determined by chemical structure, but instead by the shapes and patterns of inclusions that often are imbedded in some other material or simply arrayed in a pattern on a substrate [1]. A common inclusion is the split-ring resonator (SRR), and often combinations of SRRs and small wires are arranged to create a "unit cell" from which the metamaterial is built. Arrays of cells on some surface or within some volume constitute the actual "metamaterial." As a concrete example, Figure 1 shows a unit cell comprising a double SRR on an insulating substrate and a parallel wire. The SRR and wire are normally conducting materials such as copper or aluminum. An array of unit cells deployed on or embedded in a surface of any shape or throughout some volume becomes the *metamaterial*, which evidently is quite different from a homogeneous piece of plastic, for example, whatever its shape.

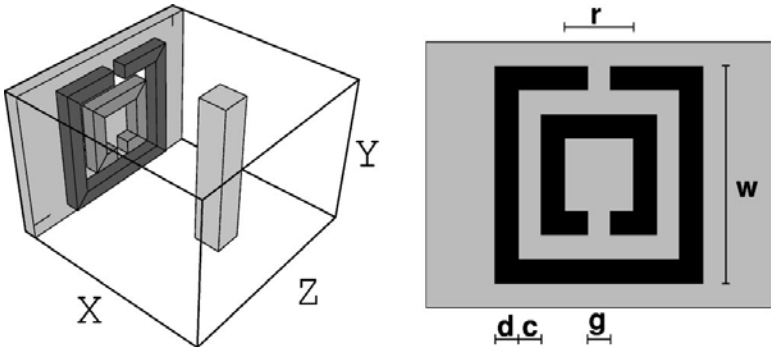

Figure 1. SRR/wire unit cell (reproduced from [1]).

What makes metamaterials attractive as antenna components is that they are *left-handed*, in distinction from all naturally occurring materials, which are *right-handed*. In right-handed materials (RHM), the electric field, $\vec{E}$, the magnetic intensity, $\vec{H}$, and

propagation (wave) vector, $\vec{k}$, are related by the "right-hand rule," *viz*, $\vec{E}$ x $\vec{H} \approx \vec{k}$. The phase and group velocities in RHM are in the same direction, parallel to the wave vector. A *left-handed material* (LHM) obeys a "left-handed rule" in which the phase and group velocities propagate in *opposite* directions. Physically this results in energy flow (Poynting vector) antiparallel to the direction of wave propagation. For LHM, both the effective permittivity and permeability are negative, $\varepsilon_r \leq 0$ and $\mu_r \leq 0$, which gives rise to LHM's unusual electromagnetic (EM) properties.

While the notion that this type of behavior can arise from as simple a unit cell as an SRR close to a wire perhaps seems counter-intuitive, it is not. There are examples of very simple wire structures exhibiting similar behavior. For example, the three-dimensional mesh of orthogonal crossed wires in Figure 2 exhibits a negative dielectric constant for frequencies $\omega < \omega_p$ where $\omega = 2\pi f$, $\omega_p = (c/\mathrm{d})[2\pi/\ln(\mathrm{d}/\mathrm{w})]^{1/2}$, and c is the velocity of light [2]. Thus, properly arrayed unit cell structures comprising conducting and insulating elements simply exhibit a similar behavior that is determined by the specific details of how the unit cell is structured.

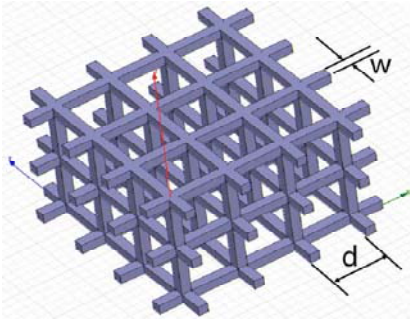

Figure 2. Crossed-wires metamaterial (reproduced from [2]).

Without doubt, the most important consequence of having $\varepsilon_r \leq 0$ and $\mu_r \leq 0$ is that the metamaterial's refractive index is negative, $n < 0$, which leads to some very non-intuitive EM effects. Besides energy flow opposite to the propagation direction, $n < 0$ results in *negative refraction* as shown in Figure 3. In the figure, air lies above the interface with either LHM or RHM. For both types of lower materials, a reflection takes place at the interface that follows the usual law of reflection (incidence and reflection angles being equal, rays 1 and 2). If the lower medium is RHM (normal material), the propagating ray (#4) is bent towards the normal. This is the usual refraction that takes place with all normal materials, and, for example, bends the image of a pencil in water towards the vertical. But, if the lower medium is LHM, just the opposite occurs. The propagating ray (#3) is bent *away* from the vertical, not towards it.

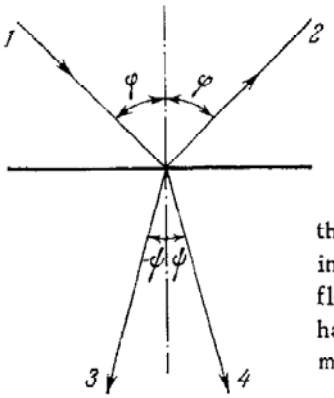

FIG. 3. Passage of a ray through the boundary between two media. 1 – incident ray; 2 – reflected ray; 3 – reflected ray if the second medium is left-handed; 4 – refracted ray if the second medium is right-handed.

Figure 3. LHM and RHM rays at air-metamaterial interface (reproduced from [3]).

2.7.3 Slow Acceptance of LHM Cellular Antennas

While there is no question that metamaterials offer intriguing possibilities for novel antennas, their use has not become widespread. Some possible explanations for this situation are offered in [4], which specifically addresses application to mobile-phone antennas. Because the cellular band (825-894 MHz, $\lambda = 0.36 - 0.335m$) lies just above the broadcast television band (54-806 MHz, $\lambda = 5.55 - 0.37m$), the issues raised in [4] are largely applicable to TV antennas.

An important consideration in whether or not LHM are useful is the antenna's *electrical size*, that is, its size measured in wavelength, λ. The wavelength at the highest TV channel 69 is the same order as the cell phone wavelengths, whereas TV channel 2 has a wavelength about 15 times larger than the longest cellular wavelength. This observation raises the question of whether or not general statements or conclusions made about antennas for cellular frequencies hold up for low-band TV antennas. The answer is a clear "maybe."

A typical cell phone antenna with a largest dimension of 0.1m has an electrical size of 0.28λ at 825 MHz. A channel 2 TV antenna has the same electrical size if its largest dimension is 1.55m, which is too large for a set-top antenna. A more reasonable set-top dimension might be 0.5m, which is 0.09λ at 54 MHz. So the question is whether or not observations about a 0.28λ antenna can be applied to one that is about three times smaller. There is no definitive answer, but the electrical sizes are close enough that some attributes of metamaterials applied to cellular antennas can be ascribed to TV antennas as well. Thus, some of the reasons in [4] why LHM are not widely used in cellular antennas may apply to TV antennas as well. Among those limitations are:

1. *Bandwidth.* Metamaterials tend to exhibit strong resonances accompanied by substantial dispersion and losses. The result is a high-*Q*, narrow-band structure that makes it very difficult to cover the entire range of VHF and UHF television frequencies. An antenna covering all cellular frequencies has a fractional bandwidth (BW) of 8% (relative to band center). If a set-top TV antenna contains two antennas, one low-band (channels 2-13, 54-216 MHz) and the other high-band (channels 14-69, 470-806 MHz), they must have fractional bandwidths of 120% and 53%, respectively, to cover all channels. If achieving 8% BW in a LHM cellular antenna is difficult, then meeting the requirements of a set-top antenna is even more difficult.

2. *Other Factors.* Whether or not an antenna is "good" for a specific application depends on many factors, many of which are not electrical in nature. Antennas that perform well electrically (gain, bandwidth, efficiency) may be too costly, too large, too heavy, too difficult to manufacture, and so on. Reports of successful LHM-based antennas usually do not address these factors, and as a result it may be difficult to analyze the benefits and risks associated with that type of antenna. This consideration has slowed the adoption of LHM antennas for mobile phones and likely applies to TV set-top antennas as well.

3. *Marketing*. Like any consumer product or component thereof, LHM antennas must be properly marketed to be effectively used. Many types of man-made materials are used in antennas, especially in the microwave range, and the resulting designs are considered "traditional." LHM-based designs often resemble traditional ones, so that they share many common features. Yet LHM antennas are frequently described as being fundamentally "different," which leads to some measure of reluctance in adopting them. A better approach would be to characterize LHM antennas as *alternatives* to traditional designs rather than a fundamental departure.

2.7.4 Examples of LHM Antennas

Even though the speculation in [4] provides possible reasons why MTM-based antennas are not more widely used, recent developments show rather convincingly that technical objections are not valid reasons. Quite to the contrary, state-of-the-art MTM antenna designs support the view that they well may be able to meet set-top TV performance requirements. This section consequently examines some typical designs in the context of porting them to the low VHF television channels.

(a) *Compact Broadband Monopole.* An example of the state-of-the-art in small broadband LHM antennas is shown in Figure 4(a), which is reproduced from [5]. The antenna comprises a PCB (printed circuit board) monopole loaded with a left-handed

negative-refractive-index transmission-line (NRI-TL) metamaterial. The loading reduces the electrical size of the antenna while providing large bandwidth.

This particular antenna was designed for dual-band use in the WiMax and WiFi bands [3.3-3.8 GHz, ($\lambda = 0.09\text{m} - 0.08\text{m}$) and 5.15-5.85 GHz ($\lambda = 0.06\text{m} - 0.05\text{m}$), respectively]. Its physical size of 0.03m [W_g in Figure 4(a)] corresponds to 0.3λ at the lowest frequency, which is comparable to the electrical size of a cellular antenna and about three times larger than a typical 0.5m set-top antenna at channel 2. Adding NRI-TL loading increased BW over the unloaded structure by approximately 1.5 GHz without increasing its size. The LHM monopole's BW (return loss below -10 dB) is 3.84 GHz from 3.15-6.99 GHz (fractional BW of 76%). The computed radiation efficiency is close to 90% across both the WiMax and WiFi bands. Input impedance is plotted in Figure 4(b), and it shows moderate values across a very wide frequency range, from about 5GHz to 10 GHz, so that good impedance matching should be readily achievable without requiring a balun.

The compact LHM monopole provides a good example of enhancements directly attributable to NRI-TL loading of a simple structure: excellent impedance bandwidth and high efficiency in an electrically small structure. Although this particular antenna would not meet a set-top TV antenna's requirement of 120% BW (see §3), it certainly suggests that with further improvements that objective might be reached.

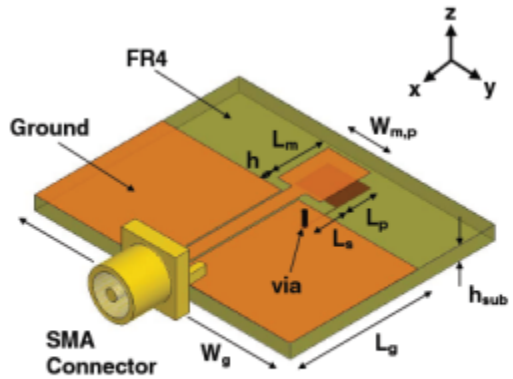

Fig. 1. NRI-TL metamaterial monopole antenna. All dimensions are in mm: $L_m = 6$, $W_m = 5$, $L_g = 15$, $W_g = 30$, h = 1, $L_p = 4$, $W_p = 5$, $L_s = 3.45$, $W_s = 0.1$, $h_{sub} = 1.59$, $S_{cpw} = 0.2$, $W_{cpw} = 1.55$, via diam. = 0.5.

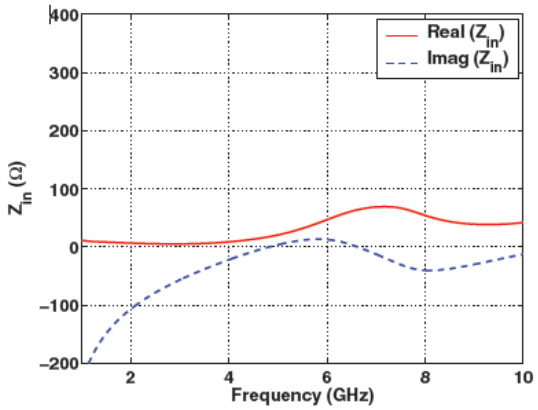

Fig. 4. Simulated input impedance characteristics of the unloaded monopole antenna from Ansoft HFSS.

(a) (b)

Figure 4. Broadband LHM monopole: Structure (a); Input impedance (b) (reproduced from [5]).

(b) *Efficient Electrically Small Antenna (EESA).* An MTM-based Efficient Electrical Small Antenna (ESSA) [6] is shown in Figure 5. It provides another example of how LHM antennas can achieve performance that is not possible with traditional designs, and suggests that porting MTM designs to TV set-top antennas is a viable approach to achieving improved performance.

The ESSA comprises a monopole surrounded by an SNG (single negative) MTM structure mounted on a plane substrate. It achieves a voltage standing wave (VSWR) bandwidth ≤ 2 of 470 MHz (1.75-2.22 GHz) [fractional VSWR bandwidth of 24%] in a package with an electrical size of only 0.07λ. The addition of LHM in this case resulted in a much broader bandwidth than could achieved otherwise because the effect MTM's effect is to lower the system *Q*-factor from the theoretical "Chu limit" of 16.72 for traditional materials to 2.23. Significantly, the increased bandwidth is not accomplished at the expense of radiation efficiency or gain, which often must be sacrificed in traditional designs. The ESSA's measured maximum gain and efficiency were 2.44 dBi and 83.61%, respectively.

The radiation patterns generally exhibited broad lobes with fairly shallow nulls ($<\approx -25\text{dB}$, Figure 6), which lend themselves well to omnidirectional reception as required in a set-top antenna. Because the ESSA's electrical size is comparable to that required for a set-top antenna (see §3), it may be possible to "stack" several ESSA's covering different band segments in a fairly small set-top package. This particular ESSA design suggests that MTM-based antennas may well meet TV set-top reception requirements.

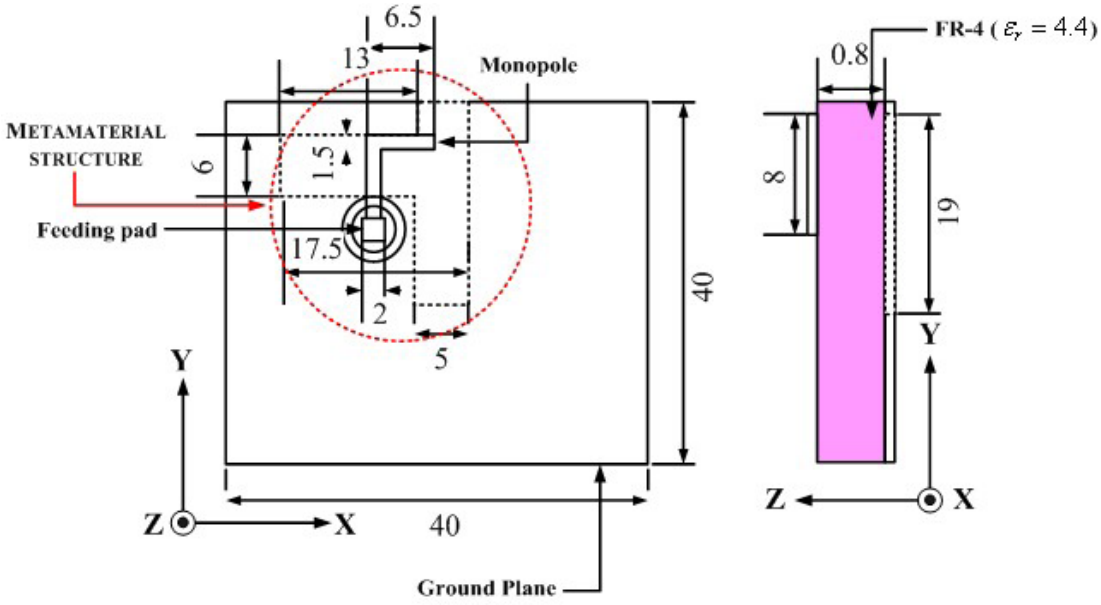

Figure 5. MTM ESSA geometry (reproduced from [6])

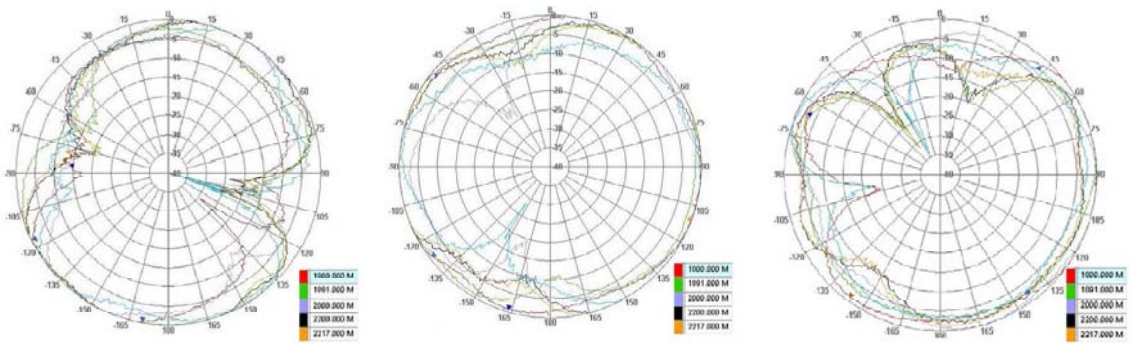

Figure 6. ESSA measured radiation patterns (reproduced from [6]).

(c) *LHM Topologies.* There are some general approaches to MTM-based antennas that appear to be useful regardless of the specific type of radiating element [7], and these likely should be the focus of future efforts to apply LHM to television set-top antennas. Various types of materials are available as shown in Figure 7. "Normal" materials have positive permittivity and permeability, and are referred to as Double Positive (DPS). "Epsilon negative" (ENG) materials can occur naturally in unusual states of matter (for example, plasmas), while *homogeneous* "mu negative" (MNG) materials can be man-made (for example, ferrite). LHM materials, on the other hand, do not occur in Nature and are "Double Negative" (DNG) because both permittivity and permeability are negative. While composite MTMs usually are DNG, ENG and MNG types also can be made and sometimes are desirable in antenna applications.

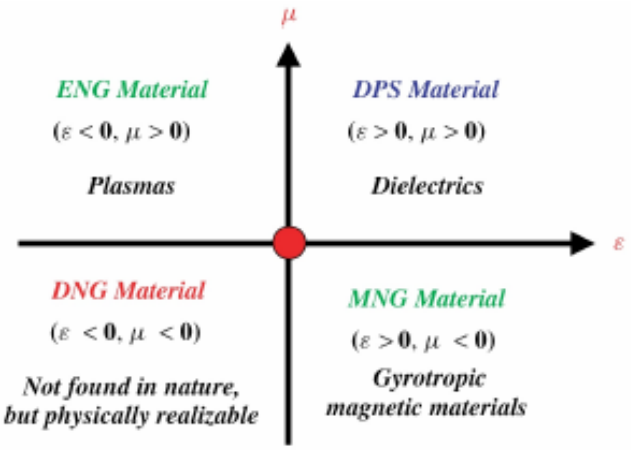

Figure 7. Material classification (reproduced from [7]).

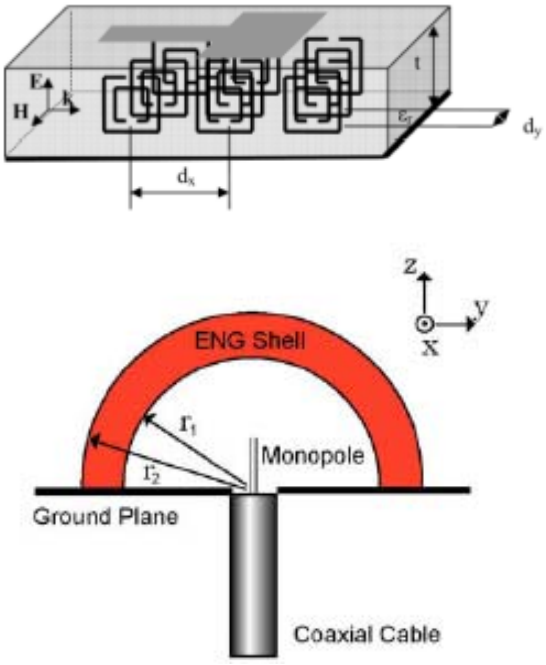
Figure 8 shows two LHM configurations that should be useful in a wide range of applications and, in particular, TV set-top antennas. In Figure 8(a) a PCB antenna is placed on an MTM substrate in order to decrease radiating element size while in creasing radiation efficiency and bandwidth. In this example, the substrate is an MNG

array of square SRRs imbedded in a homogeneous dielectric medium. Figure 8(b) shows an ENG shell surrounding a radiator fed against a PEC (perfectly electrically conducting) ground plane. The shell can be very thin ($<\approx 0.01\lambda$) so that it has little effect on attenuating signal level, yet it substantially reduces antenna input reactance over a fairly wide range of frequencies. While the "Chu *Q*-factor" is the recognized theoretical limit for antennas made from normal materials, the ENG shell can lower *Q* by a factor of 1,583 while providing a good match to 50 Ω and efficiencies approaching 98%, at least over some range of frequencies. These examples illustrate LHM's potential benefits for TV set-top antennas, and they should be vigorously pursued for the next generation of set-top antennas.



(a) (b)

Figure 8. Generally useful LHM configurations (reproduced from [7]).

2.7.5 LHM Antenna Patents

An online search at Patent Storm (http://www.patentstorm.us/) using the keyword 'metamaterial' returns 521 U.S. issued patents and applications, many of which are related to antennas or optics. The application of MTM to antennas is a very active technology area, both in the scientific and engineering literature and in the realm of patented proprietary technology. While a thorough review of the patent literature is beyond the scope of this report, it is instructive to examine a specific development as representative of the state-of-the-art.

Figure 9 shows a typical implementation disclosed in U.S. patent #7,592,957 B2, which issued recently (Sept. 22, 2009) and consequently representative of the state-of-the-art. The figure illustrates one implementation of many described in the patent (forty-nine drawing sheets, many with multiple figures). This patent discloses composite right- and left-handed (CRLH) MTM structures as the basis of electrically small antennas and antenna arrays for use in wideband multi-band communications. One design, for example, provides 5.6 dBi gain with a 2.35-4.42 GHz BW (S_{11}<-10 dB). This level of performance is representative of what can be achieved today for wireless communication applications, and it is quite good compared to the performance of traditional antennas. It bodes well that LHM-based antenna designs likely can be useful for the TV set-top application.

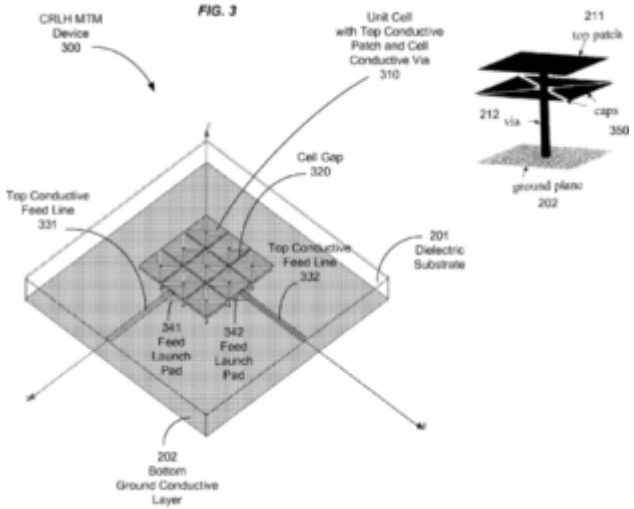


Figure 9. Typical CRLH MTM 2-D array (reproduced from U.S. patent #7592957)

2.7.6 Theory of LHM

A *metamaterial* (MTM) or *left-handed material* (LHM) has simultaneously negative values of relative permittivity (ε_r) and permeability (μ_r). There are no known naturally occurring substances with this attribute, but there are artificial media exhibiting left-handedness. MTM are useful antenna components because unusual electromagnetic effects occur when ε_r and μ_r are both negative. For example, the direction of power flow, wave refraction, Doppler shift, and the direction of Cherenkov radiation are all dramatically different than they are in "normal" media. These and perhaps other unusual electromagnetic properties of MTM may be useful in antenna system design, particularly in the microwave region.

Artificial MTM can be manufactured from arrays of conducting elements, such as small wire segments, split ring resonators, or other similar structures. These discrete elements may mimic continuous media, because, surprisingly, their left-handedness can extend to frequencies where the wavelength is much larger than either the element size or spacing. MTM slabs may be useful as coatings on metallic antenna parts. If the metamaterial can be "worked" appropriately, then major antenna components might be fabricated from it directly. The utility of these materials is an open question, because they are not well understood either theoretically or experimentally. In fact, serious investigation of these materials has occurred only in about the past decade. What follows is a discussion of how metamaterials behave and some of the issues in using them as antenna components.

Maxwell's Equations

All electromagnetic (EM) phenomena, including the EM behavior of metamaterials, are described by Maxwell's equations. Maxwell's equations are completely general, and apply to EM phenomena in all media at all frequencies, including electrostatics ("zero" frequency). MTM behavior must be consistent with Maxwell's equations in every limiting case for which theoretical results are available, whether electrostatic or time-varying. Limiting cases may be useful in understanding the counter-intuitive behavior of metamaterials.

Maxwell's equations are:

$$\nabla \cdot \mathbf{E} = \frac{\rho_t}{\varepsilon_r \varepsilon_0} \tag{1}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{2}$$

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0 \tag{3}$$

$$\nabla \times \mathbf{B} - \varepsilon_r \varepsilon_0 \mu_r \mu_0 \frac{\partial \mathbf{E}}{\partial t} = \mu_r \mu_0 \mathbf{J}_m \tag{4}$$

in which: $\mathbf{E}$ is the electric field (volts/meter).

$\rho_t = \rho_f + \rho_b$ is the total charge density (coulombs/cubic meter).

ρ_f is the free charge density, and ρ_b is the bound charge density.

$\vec{B}$ is the magnetic induction (teslas or webers/square meter).

$\mathbf{J}_m = \mathbf{J}_f + \partial\mathbf{P}/\partial t + \nabla \times \mathbf{M}$ is the total current density (amperes/square

meter), consisting of $\mathbf{J}_f$, the current density of free charges; $\partial\mathbf{P}/\partial t$, the polarization current density; and $\nabla\times\mathbf{M}$, the magnetization current density.

$\mathbf{M}$ is the magnetization (amperes/meter).

ε_0 is the permittivity of free space (farads/meter).

ε_r is the relative permittivity, or dielectric constant.

μ_0 is the permeability of free space, which is arbitrarily set equal to $4\pi\times10^{-7}$ teslas meter/ampere (henrys/meter).

μ_r is the relative permeability.

In materials where Ohm's law applies, the free current density is related to the electric field by $\mathbf{J}_f=\sigma\mathbf{E}$, where σ is the conductivity (Siemens/meter).

Physically, the two fundamental vector fields are $\mathbf{E}$ and $\mathbf{B}$, because it is these fields that produce forces on electric charge according to the Lorentz force law $\mathbf{F}=q(\mathbf{E}+\mathbf{v}\times\mathbf{B})$. It is customary, however, to write Maxwell's equations in terms of the fields $\mathbf{E}$ and $\mathbf{H}$, where $\mathbf{H}$, the "magnetic field" or "magnetic intensity" (amperes/meter), is proportional to $\mathbf{B}$. The primary reason for doing this is that the quantity $\mathbf{E}\times\mathbf{H}$ is the energy flux density, which is of paramount importance is determining a system's electromagnetic behavior.

Media Parameters

It is necessary to specify the electrical and magnetic properties of the medium supporting the electromagnetic field in order to solve the field equations, subject to appropriate boundary conditions. Without this information, Maxwell's equations do not form a determinate system.

The EM behavior of any medium is determined by its material properties, the electric permittivity and magnetic permeability. There are other material parameters, but they are secondary in nature. For example, in linear media the electric susceptibility is the proportionality factor between the applied electric field and induced polarization. Similarly, the magnetic susceptibility relates magnetization to the applied magnetic

field. Each of these parameters is included indirectly in the relative permittivity and permeability, respectively, and therefore they have no independent significance.

Various classes of media exit. The simplest is *free space*, in which the relative permittivity and permeability are both unity. The EM properties of *isotropic* media are independent of the direction of the EM fields. Media in which the electrical properties are the same everywhere are *spatially homogeneous*. In some media, the EM properties vary in time, and such media are described as *temporally inhomogeneous*. The most complex media are *anisotropic*. The EM properties are direction-dependent, and may also vary spatially or temporally. The permittivity and permeability of anisotropic media are described by tensors instead of real or, in the case of lossy media, complex scalars.

Wave Velocity and Refractive Index

Time-varying fields in the form of propagating electromagnetic waves follow directly from Maxwell's equations. The equations are combined to obtain a "wave equation" whose solutions are coupled electric and magnetic field that move through the medium carrying energy as they do.

In a lossless medium, ε_r and μ_r are real numbers. A monochromatic EM wave's phase velocity, the velocity at which the wavefront (surface of constant phase) propagates, is completely determined by these two material parameters. The propagation velocity is

$$v = \frac{1}{\sqrt{\varepsilon_r \varepsilon_0 \mu_r \mu_0}} = \frac{c}{\sqrt{\varepsilon_r \mu_r}}, \tag{5}$$

where c is the velocity of light in free space, or simply "speed of light" (very nearly 3×10^8 meters/second).

In lossless "normal" media, ε_r and μ_r are positive real numbers greater than 1 (this is not true in a metamaterial). Waves in normal media always propagate slower than the speed of light. The velocity ratio is the medium's *refractive index*, given by

$$n = \frac{c}{v} = \sqrt{\varepsilon_r \mu_r}\ . \tag{6}$$

When n is real, EM waves can propagate in the medium. If n is purely imaginary at some frequency, then no wave mode (field configuration) can propagate at that frequency.

In lossless anisotropic or inhomogeneous media, ε_r and μ_r vary with propagation direction or position, and are represented mathematically as matrices of positive real numbers. In lossy materials ε_r and μ_r are complex numbers with non-zero imaginary parts that result in energy dissipation as the wave propagates through the medium. In such media the refractive index varies with direction or position or both.

n^2 may be negative (n is imaginary) in some naturally occurring media. At frequencies below its plasma frequency, for example, a gaseous plasma has a negative dielectric constant but positive permeability, resulting in $n^2 < 0$. This situation occurs in the earth's ionosphere, and provides an example of unusual wave propagation resulting from the negative permittivity. Instead of being refracted, as it would be if n^2 were positive, below the plasma frequency an incident radio wave is instead reflected. This is the mechanism that supports long distance high-frequency (HF) radio communication.

In normal media, both ε_r and μ_r are frequency-dependent, often strongly so. For example, the dielectric constant of water decreases from 81 at DC and very low frequencies, to 78 at 1 Mhz, 34 at 10 Ghz, and about 2 at optical frequencies. The refractive index varies correspondingly from 9 at DC to 1.4 in the optical region. In magnetic materials (water is not one), the frequency variation of relative permeability can be several orders of magnitude.

The effective ε_r and μ_r of metamaterials are also are frequency-dependent (in fact they must be), and they change sign just as the dielectric constant does in a plasma. As a result, in certain frequency ranges the metamaterial's novel EM properties disappear, and there is a strong analogy between the behavior of a metamaterial and naturally occurring plasma. The variation of permittivity and permeability with frequency may be very important in practical antenna applications, particularly in view of the wide spectrum used by modern communication systems. Metamaterials may be quite useful in the microwave range, but less so at lower frequencies.

Right and Left Handed Media and Power Flow

Another important parameter describing the propagation of an EM wave is its *wave vector,* $\mathbf{k}$, whose magnitude is the *wavenumber*. $\mathbf{k}$ is in the direction of propagation and perpendicular to the wavefront. In normal media, not in a metamaterial, it also coincides with the direction of energy flow.

The wavefront consists of electric and magnetic fields which are orthogonal to each other, and to the direction of propagation. The triad of vectors $\mathbf{E}$, $\mathbf{H}$, and $\mathbf{k}$ constitute a mutually orthogonal set related by the "right hand rule". When the vector

$\mathbf{E}$ is rotated into the direction of $\mathbf{H}$ through the included angle ϕ in the plane containing $\mathbf{E}$ and $\mathbf{H}$, curling one's fingers in the direction of rotation with the thumb extended perpendicular to the fingers determines the direction of the wave vector $\mathbf{k}$ (hence, right "hand" rule). The *handedness* of a medium is determined by the vector triplet $\mathbf{E}$, $\mathbf{H}$, and $\mathbf{k}$. The right hand rule relationship holds in normal media, which are consequently described as *right handed*. A metamaterial, by contrast, is *left handed* as discussed below.

The direction of energy flow in the wavefront is $\mathbf{E}\times\mathbf{H}$, which for a plane wave in normal media corresponds to the direction of the wave vector $\mathbf{k}$. The vector $\mathbf{S}=\mathbf{E}\times\mathbf{H}$ is known as the *Poynting vector*, in units of watts/square meter. Integrating $\mathbf{S}$ over a closed surface gives the amount of energy per unit time (joules/second) flowing out of that surface.

Theoretical Basis of Metamaterials

Veselago's Model: In a seminal paper published in the late 1960s, the Russian physicist V. G. Veselago theoretically investigated the effects on EM fields of negative values of relative permittivity and permeability [3]. Because the refractive index is equal to the square root of their product, changing the signs of *both* ε_r and μ_r produces no change in the refractive index. Veselago suggested three possible interpretations of what simultaneously negative values of ε_r and μ_r might mean:

(1) The electromagnetic properties of any material are independent of whether or not ε_r and μ_r are both positive or both negative.

(2) Having simultaneously negative values for ε_r and μ_r is inconsistent with the laws of physics, and no such material can ever exist.

(3) Materials with negative permittivity and permeability may exist and possess unusual electromagnetic properties.

Veselago acknowledged that, at the time of his paper, there were no materials, naturally occurring or artificially made, with $\varepsilon_r<0$ and $\mu_r<0$. He nevertheless proceeded to analyze the properties of such media in the event that they might be discovered or man-made.

In the case of a monochromatic plane wave described by the propagation factor $e^{-i(kz-\omega t)}$, Maxwell's equations lead to the following relationships:

$$\mathbf{k}\times\mathbf{E}=\frac{\omega}{c}\mu_r\mu_o\mathbf{H} \tag{7}$$

$$\mathbf{k}\times\mathbf{H}=-\frac{\omega}{c}\varepsilon_r\varepsilon_o\mathbf{E} \tag{8}$$

If $\varepsilon_r > 0$ and $\mu_r > 0$, then the triad $\mathbf{E}$, $\mathbf{H}$, and $\mathbf{k}$ are related by the right hand rule. The medium is therefore *normal* or *right-handed* (RH). If, instead, $\varepsilon_r < 0$ and $\mu_r < 0$, the sign of the right hand side of equations (7) and (8) changes. As a result, the vector triplet is now left-handed (curling the fingers of the *left* hand). The direction of the wave vector $\mathbf{k}$ therefore is reversed when the material parameters are both negative. A metamaterial with negative permittivity and permeability is consequently called a *left- handed* (LH) material (LHM).

Power Flow in LHM: Compared to its orientation in RHM, the wave vector $\mathbf{k}$ in LHM points in the opposite direction relative to $\mathbf{E}$ and $\mathbf{H}$. An immediate consequence is that the Poynting vector and wave vector are in opposite directions. Because the Poynting vector $\mathbf{S}=\mathbf{E}\times\mathbf{H}$ always forms a right-handed triad with $\mathbf{E}$ and $\mathbf{H}$, regardless of the sign of the permittivity and permeability, allowing $\varepsilon_r < 0$ and $\mu_r < 0$ changes the direction of $\mathbf{k}$ but not of $\mathbf{S}$.

The wave propagates in one direction, but the power flow is in the opposite direction. Veselago points out that this situation corresponds to a negative group velocity ($V_{group}=\frac{\partial\omega}{\partial k}$, computed at the average value of the wavenumber). While perhaps somewhat surprising, there are examples of just this effect. Some naturally occurring anisotropic media and certain media in which spatial dispersion exists exhibit negative group velocity.

Doppler Effect and Cherenkov Radiation in LHM: Other unusual effects occur in LHM. The Doppler effect is reversed. The measured frequency of an approaching emitter will be lower than the stationary frequency, not higher as in RHM. Cherenkov radiation, electromagnetic radiation emitted by a charged particle moving at high speed in a LHM, will be directed backward relative to the direction of motion, which is the opposite of what happens in RHM.

Reflection and Refraction at a Plane Interface: EM plane waves incident upon a plane material surface are *refracted* as they enter the medium. For waves propagating between normal media, the wave bends towards the normal upon entering a denser medium (higher refractive index), and away upon entering a less dense medium. Figure 10 shows this effect in which the upper medium is less dense than the lower one. Φ is

the incidence angle, and Ψ the refraction angle. If the wave propagates from a RHM into a denser LHM, the refracted wave is bent towards the normal, but on the opposite side of the normal as shown in Figure 2. Interestingly, the direction of the reflected wave is the same (reflection angle equals the incidence angle) regardless of the nature of the lower medium.

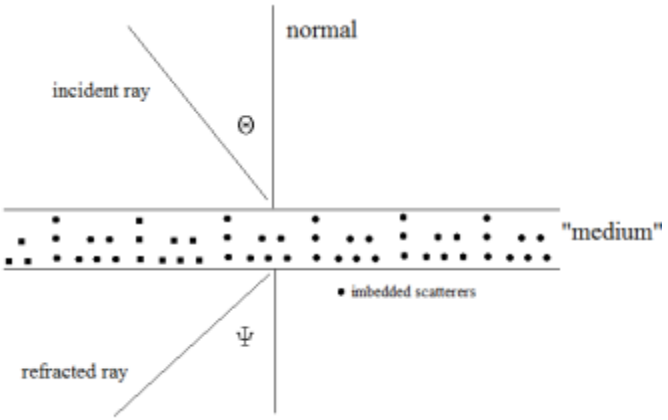

Figure 10. Refraction at MTM interface

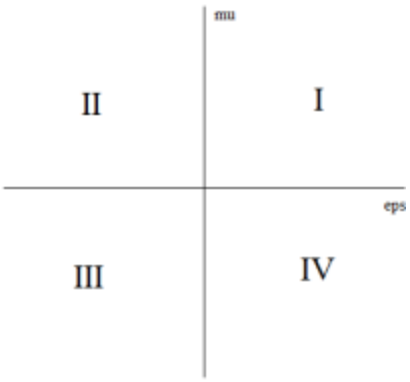

Figure 11. Media classification

Media Classification: In order to classify media based on permittivity and permeability, Veselago introduced the $\varepsilon - \mu$ diagram shown in Figure 11. The plane is divided into the four standard quadrants, labeled I through IV proceeding counter-clockwise from the upper right-most quadrant. Considering only isotropic materials, normal dielectrics with $\varepsilon_r > 0$ and $\mu_r > 0$ are contained in quadrant I. Quadrant II contains media with $\varepsilon_r < 0$ and $\mu_r > 0$, which is characteristic of gaseous and solid-state plasmas. The dielectric constant of a gaseous plasma is given by $\varepsilon = 1 - \sum \frac{\omega_o^2}{\omega^2}$, where ω_0 is the plasma frequency, and the summation is over all species in the plasma. At sufficiently low frequencies, the second term in this expression becomes greater than 1, which leads to a negative permittivity. Quadrants II and IV, however, are unoccupied, at least by isotropic materials, because there is no known naturally occurring material with negative permeability.

The $\varepsilon - \mu$ diagram can be used only for scalar values of permittivity and permeability. Certain anisotropic materials with tensor permittivity and permeability fall into quadrants III and IV for propagation in specific directions within the medium, because in those directions ε_r and μ_r are scalars. An example is propagation along the magnetic field direction in a gyrotropic medium, such as a plasma in a magnetic field. In

the propagation direction ε_r and μ_r are scalars, while generally in the medium they are second-rank tensors (3x3 matrices).

Requirement of Dispersion: A non-dispersive LHM cannot exist. This result follows from the fact that the energy density of an electromagnetic field is given by $W = \varepsilon_r \varepsilon_o \mathbf{E} \cdot \mathbf{E} + \mu_r \mu_o \mathbf{H} \cdot \mathbf{H}$. If both ε_r and μ_r are negative, then the total energy is negative, which is not possible.

In order to assure positive total energy, the medium must be *dispersive*. In a dispersive material, the expression for energy density is different, and includes the variation of permittivity and permeability with frequency:

$$W = \varepsilon_o \frac{\partial(\varepsilon_r \omega)}{\partial \omega} E^2 + \mu_o \frac{\partial(\mu_r \omega)}{\partial \omega} H^2 . \qquad (9)$$

W is always positive if $\frac{\partial(\varepsilon_r \omega)}{\partial \omega} > 0$ and $\frac{\partial(\mu_r \omega)}{\partial \omega} > 0$. In general, therefore, the permittivity and permeability must be frequency-dependent in LHM. Media in which both ε_r and μ_r are negative and constant with respect to frequency cannot exist. It does appear possible to have only one parameter depend on frequency, as long as its derivative is large enough to avoid a negative total energy; but Veselago did not consider this possibility.

The same conclusion about the necessity of dispersion can also be reached by considering the limiting case of a parallel plate capacitor at DC. Neglecting fringing, the capacitance is $C = \frac{\varepsilon_r \varepsilon_o A}{d}$, where A is the plate area, and d is the plate separation in consistent units. Physically, capacitance is the ratio of free charge on the plates, Q, to the potential difference (voltage) between them, V, taken as positive quantities. Thus, $C = \frac{Q}{V}$, must be positive at DC. If a metamaterial were used as a dielectric between the capacitor plates, its permittivity therefore must be positive in the limit of zero frequency (DC). This is necessary to avoid the physically impossible case of a negative capacitance. But, by definition, ε_r in a metamaterial must be negative at some frequency in order for the medium to be a metamaterial. Consequently, the metamaterial's relative permittivity must change sign with frequency, from a positive value at DC to a negative value at some non-zero frequency. This is dispersion. Note that this brief discussion does not address how the capacitor behaves as a circuit element at frequencies where $\varepsilon_r < 0$. Doing so should be quite interesting.

Realization of Metamaterials

Because metamaterials do not occur naturally, the only way to obtain a metamaterial is to manufacture it. The very nomenclature, *metamaterial*, conjures up the image of a "substance", generally a solid material with some specific chemical composition. Existing metamaterials, however, could not be further from that image.

Smith [8] recently described a LHM that was modeled theoretically and measured experimentally. Building upon the split ring resonator (SRR) medium created by Pendry [9], short, small-diameter wires were added to a an array of SRRs to create the left-handed metamaterial. The medium is actually an array of discrete electromagnetic scatterers arranged so that the *effective* ε_r and μ_r are negative at some frequencies. It is not at all a "substance" in the usual sense.

Figure 10 represents this concept schematically. Imagine two parallel planes in space, between which an array of scattering elements is deployed. The scatterers, represented by dots in the figure, might be short wire segments, other geometrical shapes, SRRs, other resonant structures, or any number of EM elements fabricated from conductors and/or dielectrics.

In the realm of every possible configuration, it seems intuitively plausible that some arrangements will result in anomalous propagation such as seen in metamaterials. In Figure 10, for example, it is not difficult to imagine that there is some scatterer arrangement that will "refract" a wavefront incident at the angle Φ in the direction opposite to "normal" refraction as shown. This type of propagation is a characteristic of a left-handed material. If the volume between the planes is thought of as a "medium", it would be properly described as one with negative effective permittivity and permeability, that is, a metamaterial.

Metamaterials that are "substances" may eventually be developed or discovered. But current research focuses on creating LHMs using imbedded scatterers. This is not a limitation, however, and indeed may actually provide more flexibility than attempting to create purely chemical substances. Designing the scattering matrix may permit engineering metamaterials whose properties could not exist in chemical substances. Creating solid materials consisting of a matrix containing small conductive scatterers, possibly even carbon nanotube scatterers, might permit the designer to actually tailor the LHM properties to the EM application.

The idea of using a matrix of scatterers to create a "medium" with a negative effective permittivity is not new. In the 1950s, Bracewell [10] and Rotman [11] experimentally investigated ionospheric propagation using a three-dimensional array of

intersecting thin, straight wires. Dispersion in this "medium" is similar to that in a neutral plasma, such as the ionosphere.

Just as the real ionosphere does, the artificial one has $\varepsilon_r < 0$ for frequencies below the "plasma frequency". However, unlike the ionosphere's plasma frequency, which depends on the charged particle density, and particle charge and mass, the artificial medium's "plasma frequency" depends on the arrangement and dimensions of the wires. Because LHM must exhibit $\varepsilon_r < 0$ at some frequencies, and because the dispersion relation has the same form as a gaseous plasma's, metamaterials made from scatterers are often described in terms of a *plasma frequency*. It is important to remember that the term used in the manner is a purely formal construct, not to be confused with the parameter of the same name describing a gaseous plasma.

The effective permittivity of Smith's wire medium is given by

$$\varepsilon_{eff}(\omega) = 1 - \frac{\omega_p^2}{\omega^2} \qquad (10)$$

where ω_p is that medium's plasma frequency. ω_p depends in a complicated way on the wire scatterers' electrical properties and geometrical arrangement. At frequencies below ω_p, ε_{eff} is negative, which is one of the requirements for LHM. The other requirement is that μ_r simultaneously be negative. The SRR medium has an effective permeability given by

$$\mu_{eff}(\omega) = 1 - \frac{F\omega_o^2}{\omega^2 - \omega_o^2 - i\omega\Gamma} \qquad (11)$$

where F is the fractional area of the unit cell occupied by the SRR's interior, and Γ is the SRR dissipation factor. ω_o is the SRR medium's plasma frequency. Equations (10) and (11) assume that the array of wires and the array of SRRs do not interact appreciably, which was true in Smith's medium.

When the scatterer arrays are uncoupled, the wire array produces the medium's ε_{eff}, and the SRR array produces its μ_{eff}. Under these conditions, the effective refractive index of the composite medium is $n_{eff}(\omega) = \sqrt{\varepsilon_{eff}(\omega)\mu_{eff}(\omega)}$. If there is an overlapping band of frequencies in which the effective permittivity and permeability are both negative, then the effective index of refraction is real, and propagating modes exist. The medium is LH, however, because of the negative material parameters, so that the unusual propagation effects associated with LHM occur.

The SRR, wire segment, wire-SRR media were modeled using a commercial EM software package to generate dispersion curves (the problem is far too complex for an analytical solution). The SRR array alone showed a pronounced band gap from 4.2-4.6 Ghz. No modes would propagate in this band. The wire array alone exhibited an even wider band gap, from just above DC to 13 GHz, the array's plasma frequency. No modes would propagate in this range. The reason propagation cannot occur is that μ_{eff} and ε_{eff}, respectively, are separately negative in these bands, which results in a purely imaginary refractive index.

A metamaterial is created by combining the wire and SRR arrays. The wire-SRR array has overlapping bands from 4.2-4.6 GHz where the simultaneously negative material parameters combine to create a metamaterial. Computer modeling of the dispersion characteristics of the combined arrays clearly showed propagation in the otherwise forbidden band. Experimental measurements further confirmed the LH nature of the medium by observing propagation between 4.2 and 4.6 GHz which was not possible in either array alone.

Analysis of Metamaterials

In calculating a metamaterial's performance, it is unlikely that analytical results are attainable for all but the simplest scatterer geometries. Analytically solving Maxwell's equations is almost certainly impractical. Computer modeling is likely to be the best approach, and possibly the only truly useful one. Metamaterials made of imbedded arrays of scattering elements can, in fact, be analyzed with existing modeling software, at least to some degree. Commercially available packages, and government-developed programs such as NEC-4, provide a starting point for modeling metamaterials. But many questions arise.

Most EM software approximates the modeled structure using some form of discretization. In NEC-4, for example, continuous wires are approximated by short segments. Continuous surfaces are approximated by patches of surface area. Other programs use the same or similar approaches.

One characteristic of the discretized models is that very substantial computer resources (memory and speed) are often required to obtain good results. In NEC-4, for example, the model size (a measure of required memory) is proportional to the square of the number of segments, and the computation time (a measure of required processor speed) scales similarly. Other types of models exhibit similar characteristics. Disproportionately greater resources are required with increasing complexity, modeling accuracy, and resolution in the frequency domain. It may be expected that these issues will be exacerbated for metamaterials, because LHMs fabricated from large numbers of

complex individual scatterers are indeed very complex structures. This level of complexity is likely to push existing modeling capabilities to the limit.

Metamaterials should be studied experimentally, not only to characterize available materials, but also to develop the experimental techniques and fixtures needed for such studies. Because of the anomalous propagation, it is likely that new measurement techniques will have to be developed to fully explore metamaterial properties. For example, direct measurement of the negative values of permittivity and permeability, key parameters in characterizing a metamaterial, is required. But it is not clear that suitable instrumentation or techniques for doing so exist.

Future of MTM

MTM hold great promise as components in antenna design, particularly at microwave frequencies. Whether or not they can be used effectively a low VHF frequencies is an open question because there simply is not enough data to reach a conclusion. At this time not enough is known about MTM's electromagnetic behavior. There are no "design handbooks" and essentially no low frequency data. Nevertheless, the performance of MTM-based antennas at microwave frequencies strongly suggests hat MTM antennas will be useful at VHF as well.

2.8 Electronic Band-Gap and High Impedance Surfaces

Introduction

Electromagnetic band-gap (EBG) structures recently have attracted a great deal of interest among researchers because EBG structures can significantly reduce surface waves, thereby improving patch antenna performance [1]. Reflection phase characteristics also can have a pronounced negative effect on antenna performance [2,3]. It is well known that when a dipole antenna is operated near a metallic ground plane as shown in Figure 1, the radiated waves are reflected from the ground plane, so that interference may occur. Antenna bandwidth and gain are degraded, which is readily demonstrated by applying image theory.

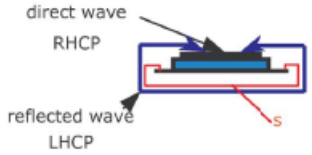

Figure 1. Antenna Near Ground Plane

To overcome these difficulties, dipoles are operated at a height of 0.2% or higher above the ground plane. In [1] the concept and feasibility of developing wideband, ultra-thin (substrate thickness < O.1) directional dipoles and dipole arrays using EBG structures are addressed. The reflection phase angle of an EBG surface varies from -180 to 180 degrees with frequency. The goal is to make the antenna operating frequency band coincide with the EBG stop band, and then to flatten the reflection phase curve within the stop-band region, which then will ensure wide-band operation of the antenna. This technology could be useful in an integral television antenna as well as set-top antennas that lay flat on the television.

The parameters generally adopted to characterize the performance of EBG structures include the surface wave attenuation and reflectivity. A double benefit can be derived from the use of artificial magnetic conductor type of EBGs because not only are surface waves suppressed, but also in-phase image currents are induced. The so-called reflection phase—frequency diagram gives information on how the structure reacts to a wave impinging on it. Normally, the configuration behaves similar to a metal plate (perfect electric conductor, “PEC”). However, another characteristic feature of EBGs is the existence of a certain frequency range over which an incident electromagnetic wave does not experience *any* phase reversal upon reflection (a rather remarkable phenomenon). In this range the structure behaves as a perfect magnetic conductor (“PMC”). The frequency range where the phase reversal is within from the PMC point (phase reversal) is conventionally used to define the bandwidth and is called the “bandgap.” The concept here is to introduce a ground plane for shielding purposes (reducing the contributions of LHCP signals), and cover this plate with EBG cells (cancelling out the surface currents)

Types of EGB-Cells

Various EBG structures from literature have been investigated. A small sample of different geometries is displayed in Figure 2. These EBG cells can be with or without vias to a ground plane on the opposite side of the substrate. A Mushroom EBG substrate is shown in figure 3. The EBG cells in this figure are shown with vias (each cell is shorted to the ground plane).

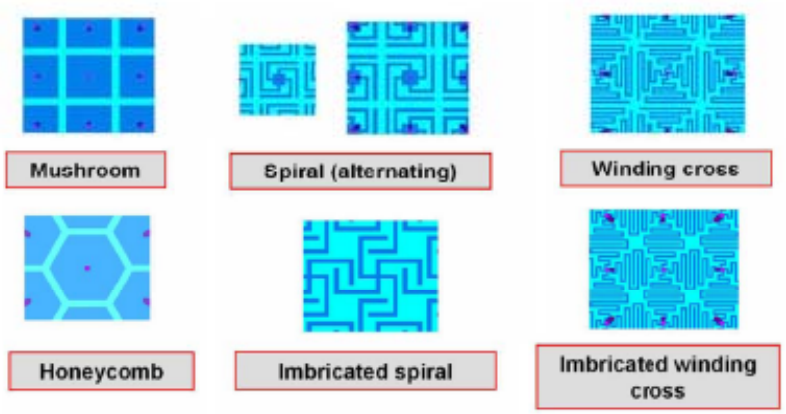

Figure 2. Different Types of EBG Structures.

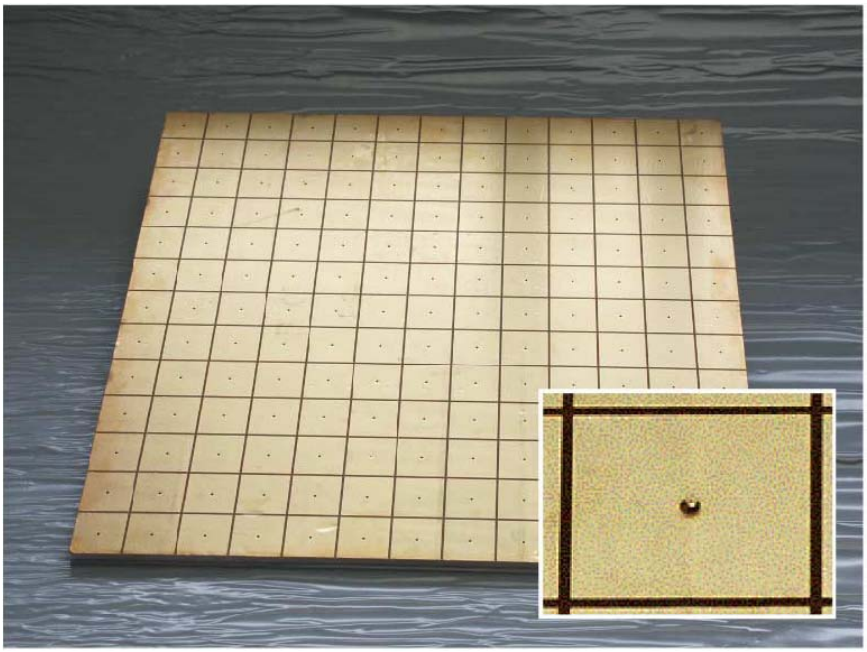

Figure 3 Mushroom EBG substrate (inset: Zoom on a single cell and a golden nail)

Performance of a Dipole Antenna on a Constant Reflection Phase EBG Surface

For a dipole antenna operating against a ground plane, the driving-point impedance is the algebraic sum of the self and mutual impedances when image theory is applied. For a PEC ground plane the driving point impedance is the self minus the mutual impedance since the reflection phase is 180 degrees. The driving point impedance of a dipole on an EBG structure with any other constant reflection phase characteristics can also be

calculated. For example, for a thin wire dipole the self and mutual impedances can be computed using the induced EMF theory. Of course, it may not be possible to achieve a constant reflection phase over a band of frequencies using an EBG structure, but that is the goal. As an example, the dipole under consideration is infinitely thin and resonant at 2.9 GHz in free-space with a 2:1 VSWR bandwidth of *5%.* The driving point resistance is negative (at low frequencies) for phase angles of -100 degrees to -160 degrees because the mutual resistance is larger than the self resistance and adds destructively with it. But for phase angles of 40 degrees to 110 degrees the mutual resistance adds constructively with the self-resistance. Thus, the driving point reactance for different phase angles is capacitive at low frequencies and inductive at high frequencies.

An EBG surface can be characterized by its reflection phase angle given by

$$\phi(f) = \mathrm{Im}\left[\ln\left(\frac{af^2 + bf - c}{af^2 + bf + c}\right)\right]$$

where a, b and c are the EBG design parameters with $a=4\pi^2\eta LC$, $b=2\pi L$ and $c=\eta$ [4]**.** Here ***L C*** and η represent the inductance, capacitance and intrinsic impedance of free-space, respectively. The slope of the reflection phase curve can be changed by varying the values of a and b*.* The bandwidth of this dipole antenna has been enhanced by flattening out the reflection phase curve at the useful phase angle regions, which corresponds to the EBG surface of having a stop band center frequency at 2.82 GHz.

EBG Dipole

Work on an EBG Dipole was completed in the past by MegaWave Corp. Figure 4 shows an EBG structure modeled in XFDTD. It consists of a double layer, mushroom-like structure embedded in FR-4 substrate with the bottom layer consisting of an array of 6 by 12 square patches and the top layer of an array of 5 by 10 square patches. The overall dimensions are 2”x4” with a thickness of 0.18”. The computed reflected phase of the EBG is plotted in Figure 5. The reflected phase was generated by comparing the phase of a plane wave scattered from the EBG surface with that from a PEC surface. The bandwidth of the EBG material was estimated to be from 1.66 to 2.35GHz as determined by the reflection phase being in the range of 90°±45°[2].

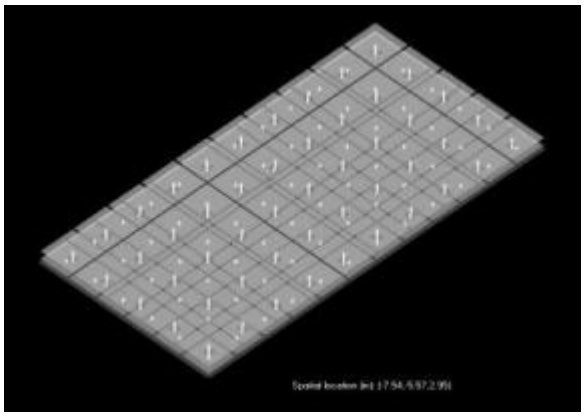

Figure 4: XFDTD Model of Dual Layer EBG Material

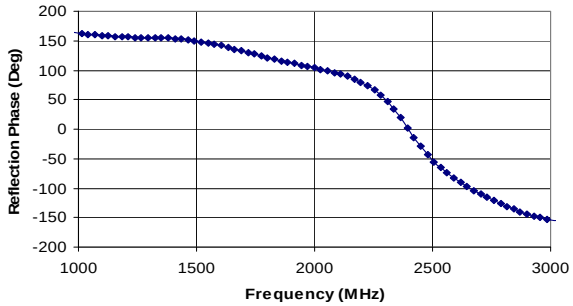

Figure 5: Computed Reflection Phase of EBG Material

A prototype of the MegaWave-designed EBG structure was fabricated as shown in Figure 6, and Figure 7 shows a wideband dipole placed 0.25" away from the EBG structure. The measured VSWR was less than 2.6:1 across a very wide operating frequency band from 1.35 to 2.7GHz as shown in Figure 8.

Figure 6: Lab Prototype of EBG Structure (Top and Bottom Layers Shown)

Figure 7: Lab Prototype of Wideband Dipole on EBG Material

The free space radiation patterns of both the wideband dipole on the EBG structure and the Phase I directional dipole antenna were measured and compared in MegaWave's laboratory. Figures 9 and 10 show the measured free-space patterns. This EBG technology could be implemented in the television UHF and VHF bands with an expectation of greatly improved set-top antenna performance.

2.9 Fractal and Self-Similar Antennas

There is no question that, among all the antennas existing today, one of the most interesting and visually appealing is the Fractal antenna. However it not clear exactly what benefits in bandwidth and gain they provide as compared to non-fractical elements of the same shape and area, but without the fine detailed geometries. The reader is directed to the section on pathological antennas (1.5) and its subsection 1.5.8 on fractals in Dr. R.C. Hansen's recent textbook, "Electrically Small, Superdirective, and Superconducting Antennas," Wiley Interscience, 2006.

First publications about electrodynamic characteristics of fractal structures were published in the 1980's, but first practical approach appeared 10 years later. Dr. Nathan Cohen, a professor at Boston University, designed, engineered and patented many fractal antenna designs, some of which are shown in Figure 1.

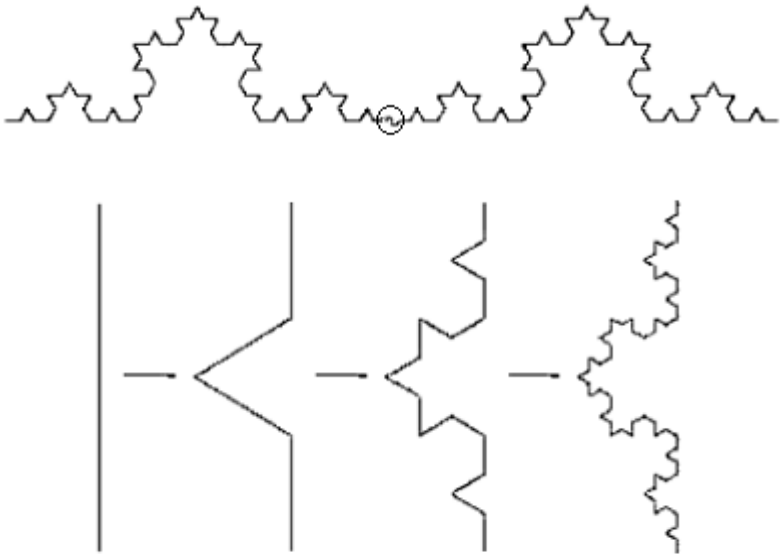

Figure 1. Fractal Designs

This fractal figure is built as follows: first line (length is z) is cut in 3 equal pieces z/3. In the middle the triangle is formed with same side lengths z/3 and same angles. This creates a single element template. This process is repeated with other segments in which sizes diminish 3 times (z/9), then again 3 times (z/27), and so on. A fractal antenna is created using fractal geometry, a self-similar pattern built from the repetition of a simple shape.

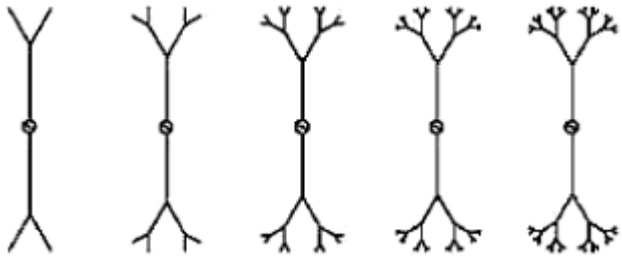

Figure 2. Fractal Dipole

The Fractal dipole as shown in Figure 2, is a recursive tree. Each of the new iterations multiplies the branches by two, in the process lowering the resonance frequency. By using many iterations, it is possible to use an antenna at lower frequencies without increasing the overall antenna size. Dipole antennas usually have narrow bandwidth, about 2.4% of the center frequency. If the 5th fractal iteration is used, then this parameter increases to 3.1%. If a 3D tree is used (when there are 4 branches used instead of 2) then this parameter increases 12.7%. Besides Dipole antennas there are resonant loop antennas used. Some typical loop fractal antennas built using Koch figures as shown in Figure 3 [7,8].

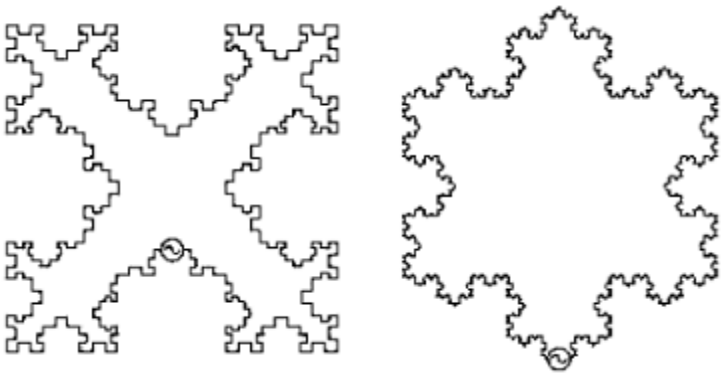

Figure 3. Fractal Loop Examples

RF MEMS could also be used in conjunction with fractal antenna structure as the basis of a new reconfigurable array antenna approach. The RF MEMS switches permit the connectivity of sections of the antenna's conductive parts, and therefore enhance the coupling between the fractal elements allowing multiple frequency operation with one antenna. Using this scheme a set-top antenna could be designed to change shape and/or size based upon which frequency (channel) the television was currently tuned to. The use of fractal shapes provides the multiband characteristic through the property of self similarity at equal or different physical scales. The electromagnetic performance of the RF MEMS switches is ideal for this application, and their placement is accomplished by small physical connections of the antenna's adjacent conducting pans [1].

Most fractal antennas, including the Sierpinski antenna, have been studied extensively over the last few years [3,4]. A modified Sierpinski antenna is shown in Figure 4. The centerline of the CPW [1] feed provides the RF input and dc voltage for MEMS switch actuation. Switches S1 and S1' actuate at a low voltage, switches S2 and S2' at a medium voltage, and switches S3 and S3' at a high voltage. Figure 5 shows the different states of the antenna. An alternate implementation could be for a bowtie antenna as shown in Figure 7.

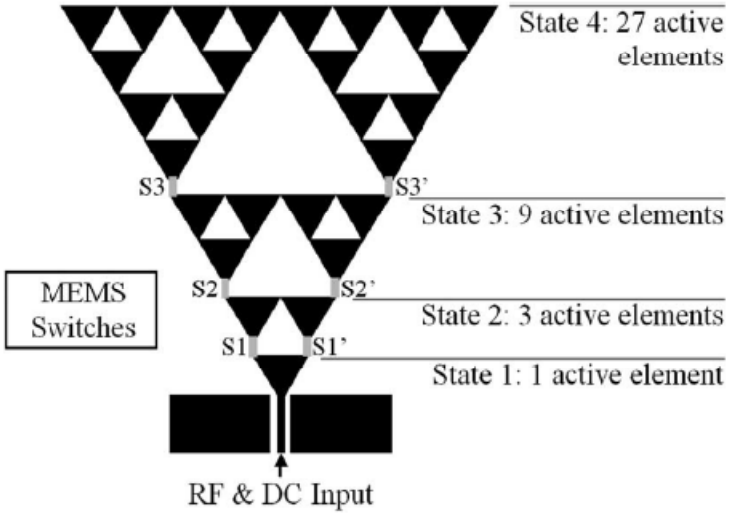

Figure 4. Illustration of a MEMS reconfigurable Sierpinski antenna.

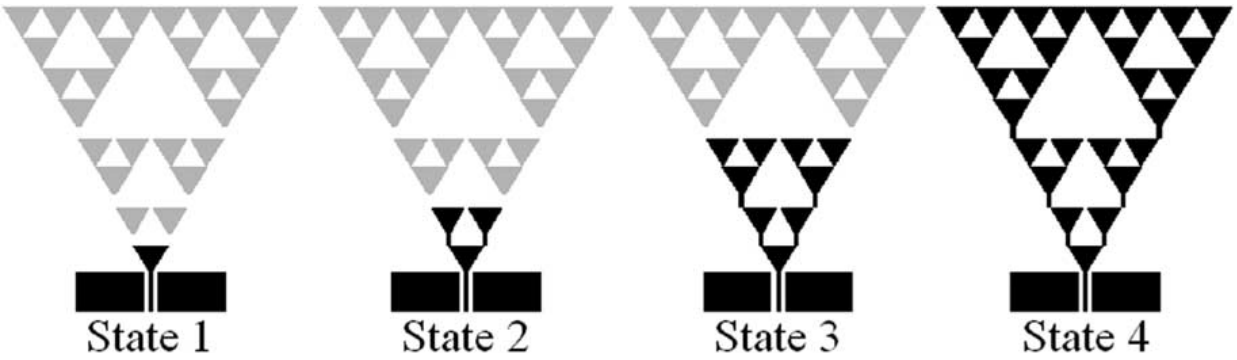

Figure 5. States of Reconfigurable Sierpinski Antenna

In most of the literature, integration has been accomplished on rigid and nonflexible semiconducting or organic polymer substrates such as silicon and FR-4. The idea of integrating RF MEMS switches into a multiband self-similar antenna was first implemented in [2], where the entire system, including the RF MEMS, the planar self-similar antenna, and the CPW–coplanar strip transition, was fabricated on silicon. The integration is achieved on a very thin and flexible liquid crystal polymer (LCP) substrate. Since the switches share a common dc feed, this technique provides reconfigurability

without the need for additional bias lines. This is advantageous since dc bias lines take up space, add loss, and reduce the bandwidth of a device. This technology is particularly useful for antennas where bias lines can have a pronounced effect on radiation patterns, and may be especially useful in the set-top application.

The implementation of a sequentially activated antenna is shown in Figure 5. All of the MEMS switches used are single supported (cantilever type) and ohmic. Regardless of the applied voltage, the triangular element that is closest to the RF/dc input is always active. When no dc voltage is applied, the antenna radiates at its highest frequency. When a low dc voltage is applied to the signal line, the first set of MEMS switches (S1 and S1') actuate, and this activates the second level of triangular elements. The antenna now radiates at a lower frequency. Since all of the switches are ohmic, the low voltage is also present at the membrane of the next set of switches (S2 and S2'). However, these switches are designed to actuate at a higher voltage so they are unaffected by the voltage present. When a higher dc voltage is applied, the first set of MEMS switches (S1 and S1') remains in the "ON" position while the second set of switches (S2 and S2') actuates. This activates the next iteration, consisting of six additional radiating elements. Again, this higher voltage is present at the next set of switch membranes (S3 and S3'), but the electrostatic force created is not sufficient for actuation. Finally, when the voltage is increased to its highest value, the first two sets of switches (S1 and S1' and S2 and S2') remain in the "ON" position while the remaining set of the switches (S3 and S3') actuates .

Thus, the voltage "cascades" from one state to the next like a sequence of overflowing buckets. This technique could not be used if the switches were capacitive since they do not pass dc voltage. The four different states are illustrated in Figure 8, where all of the activated regions for different voltages are dark in color. This biasing technique allows for direct actuation of the electrostatic MEMS switches through the RF feed structure. Since only the RF feed is dc grounded, the switches actuate with the use of a floating ground. That is, the signal pin of the CPW feed is connected to the dc cathode, and the ground pins are corrected to the anode of a bias tee. The electrostatic charges that are created during switch actuation can dissipate through the substrate and be removed by the dc-grounded RF feed when in the "OFF" state. This method has been successfully documented in [5]. The reduction or elimination of bias lines is highly advantageous because they can significantly distort the radiation patterns and they can introduce additional unwanted resonances. To change the actuation voltage of a MEMS switch, there are four parameters that can be changed.

1) *Membrane material:* Switch membranes are almost always made of metal. This is due to their pliable nature. Stiffer metals (that is, those with a high Young's Modulus*, E*) will have a higher actuation voltage than those with a lower *E*.
2) *Bridge thickness:* The thicker the bridge, the stiffer the membrane, resulting in a higher actuation voltage.

3) *Bridge height:* The higher the bridge, the larger the gap between the metal layers, resulting in decreased the electrostatic force and increased actuation voltage.
4) *Membrane geometry:* Springs can be designed into the shape of the membrane to lower the actuation voltage.

Of these parameters, only the fourth does not require any fabrication changes. Making changes to a fabrication process can be a costly endeavor and may create additional variables of concern.

LCP was chosen as the substrate for its many advantages. LCP is a thin (100 μm), flexible, low-loss (tan $\delta \approx 0.004$), low-moisture absorbing material with low permittivity ($\varepsilon r \approx 3$) [9]. Since the material is a polymer, there are additional packaging and cost advantages. All of these characteristics make it an ideal substrate for antennas, particularly at high frequencies. With respect to the geometry, the antenna elements have a 60◦ flare angle and maintain the resonant structure's self similarity with a log-periodicity of $\delta = 2$. The antenna is fed through a 6-mm-long CPW transmission line with a 50-μm gap, a 1.3-mm signal conductor width, and a 1.5-μm-thick aluminum layer. The overall size of the antenna, including the feed, is 20 × 25 mm. The CPW feed was chosen to facilitate the measurement setup. This reconfigurable antenna operates at four different principle frequencies. For each frequency, the antenna maintains its multiband performance. It was verified that the antenna has a different first resonant frequency for each of the four states. Since the antenna is self-similar with a log-periodicity of 2, each time the antenna transitions to the next state, the frequency should be halved. That is, the resonant frequency of state 2 should be half that of state 1. This is shown in Figure 6.

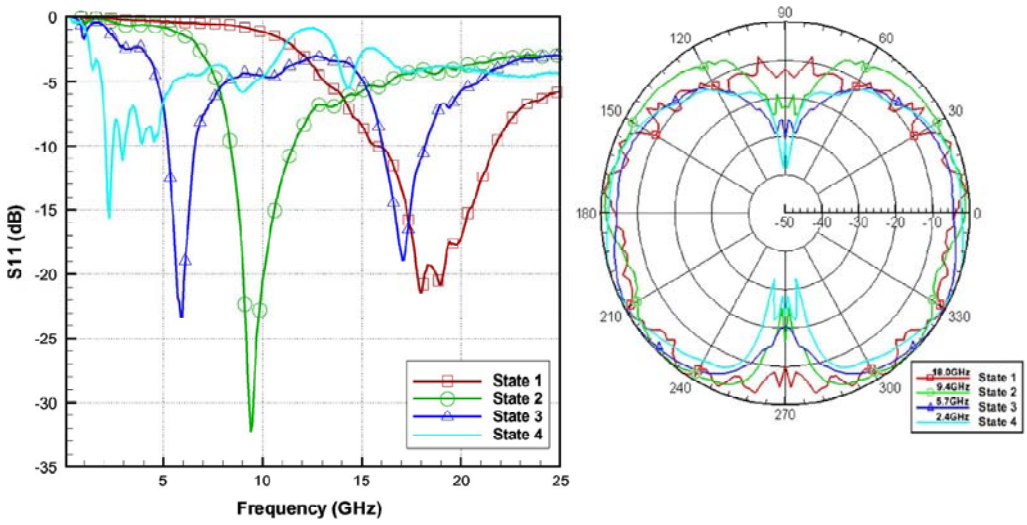

Figure 6. Measured Results of Built antenna for S11 and pattern

Fractal Antenna with RFID-MEM's

The general problem with using MEMS in a fractal antenna is how to power them. This was accomplished by putting DC on the RF of the feed of the antenna with a floating ground in the last section. If the goal is a dipole antenna as shown in Figure 7, then the floating ground would become a problem. One possible solution for this difficulty is known as "RFID-MEM's." The RFID could power the MEM to switch a section on and off. It would be controlled with a reader placed close to the antenna. If the television sends a digital signal back on the coaxial line that has information on what channel is currently tuned, then this information could be used by the reader to activate the correct switches to optimize the antenna for the best reception on the tuned channel. The RFID would need to operate either below the television spectrum, such as 13.56MHz, or above it, such as an UWB RFID. This system should have minimal effects on the antenna pattern of the bowtie antenna and could cover the entire VHF and UHF bands.

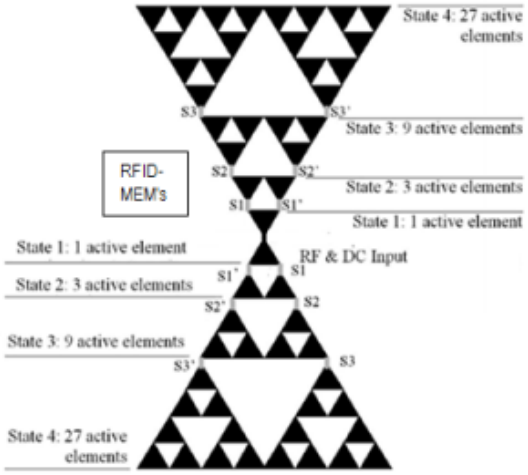

Figure 7. Bowtie Antenna

Fractennas

There have been some commercially available fractal/self similar antennas made by Fractal Antenna systems Inc. [10]. Fractal Antenna Systems has fabricated a wideband dipole as shown in Figure 8. The antenna has a self similar geometry present at multiple resolutions. Along two of the axes there is a substantial mirror image. Along the center there is a thin dipole that runs all the way through the antenna. The long thin dipole geometry creates a loading effect rather than predominately providing the function of radiating electromagnetic energy, which instead is provided by the more distinct V shaped dipole as shown in Figure 9. This antenna is claimed to radiate energy between 400 MHz and 6000MHz and are fabricated using deterministic fractal geometry.

2.10 Retrodirective Arrays

2.10.1 Summary

Retrodirective antennas are self-adapting systems that transmit a signal or direct their beam in the direction of an incoming signal without any prior knowledge of the signal's angle of arrival or intensive signal processing to determine the direction. Two types of retrodirective antennas have been developed, the Van Atta (VA) array and the Phase Conjugating (PC) array. The VA array is a fundamentally a passive, planar structure (although active VA arrays exist as well). The PC array is an active antenna that can be fabricated on a non-planar surface. Thus, the VA array generally is simpler and, consequently, easier to design and fabricate. Retrodirective systems are attractive candidates for the set-top television antenna.

While existing retrodirective systems typically operate at frequencies well above the television band, the technology is advancing rapidly and much of it at this time or in the short-term future likely will be applicable to set-top antennas. This section describes several state-of-the-art implementations, mostly for VA systems, but some for PC systems. It also describes an important development in conformal PC array design using genetic algorithm optimization that allows a retrodirective array to be designed for a specific surface shape. Finally, some new work on near field scatterer effects is discussed that shows how a retrodirective antenna can mitigate near field phase distortions in environments such as the interior of a building (a typical set-top environment).

(a) Retrodirective Concept

A retrodirective antenna is conceptually similar to an optical corner reflector, three plane reflecting surfaces intersecting at right angles. A light beam incident onto the corner reflector, also known as a retroreflector or cataphote, is automatically reflected back along the direction from which it came. The basic retrodirective array concept is shown schematically in Figure 1. There are two basic structures: (1) the Van Atta array, and (2) the Phase Conjugating array. The VA array is simpler than the PC array because it does not require active devices, whereas the PC array does. VA and PC arrays operate differently, but both systems achieve the same goal of directing the antenna's beam in the direction of an incoming signal. Without any knowledge of the signal's direction of arrival, a retrodirective antenna is able to transmit a signal back toward the transmitter along the direction of that incoming signal without using phase shifters.

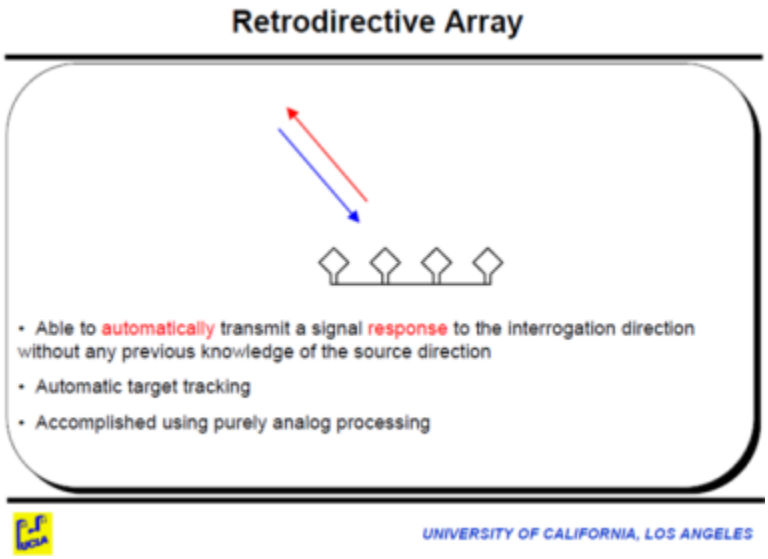

Figure 1. Basic retrodirective concept (reproduced from [1].

(b) Van Atta Array

The VA concept [2] is shown in Figure 2. Pairs of antenna elements, which can be any type of radiator (in this case horns), are equally spaced about the array's center point and interconnected with waveguides (or transmission lines) that have equal length or are multiples of a wavelength. Each antenna element acts as both a receiving antenna and a transmitting antenna. The incident field received by each element is reradiated by its paired counterpart after propagating along the interconnecting transmission line or waveguide. The effect of the resulting propagation delay is to reverse the phase of the reradiated field distribution relative to the received field distribution, causing the reradiated field to be directed back along the line of sight of the incident field. While Van Atta's original antenna was strictly a passive retroreflector, active systems have been developed that utilize the basic Van Atta structure [3,4,5]. Figure 3 provides a schematic illustration of the Van Atta concept for passive and active implementations.

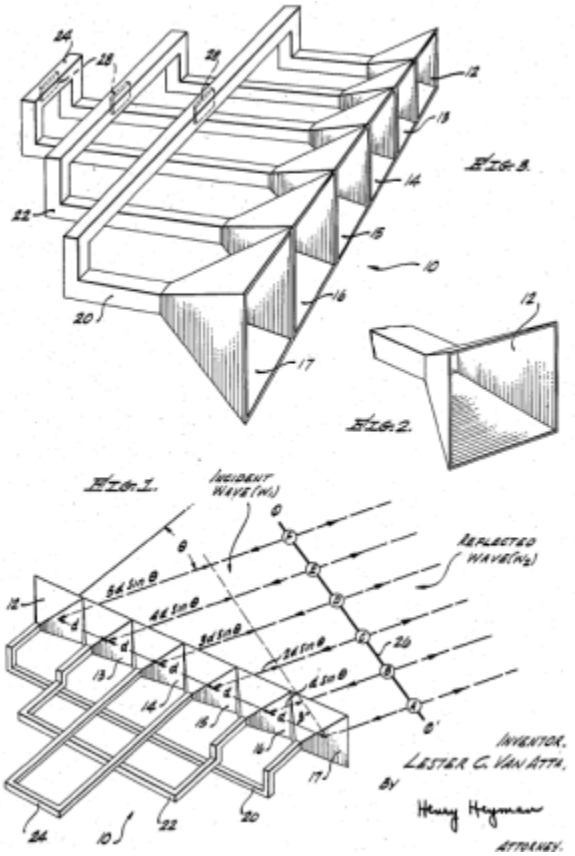

Figure 2. Van Atta retrodirective array (reproduced from [2]).

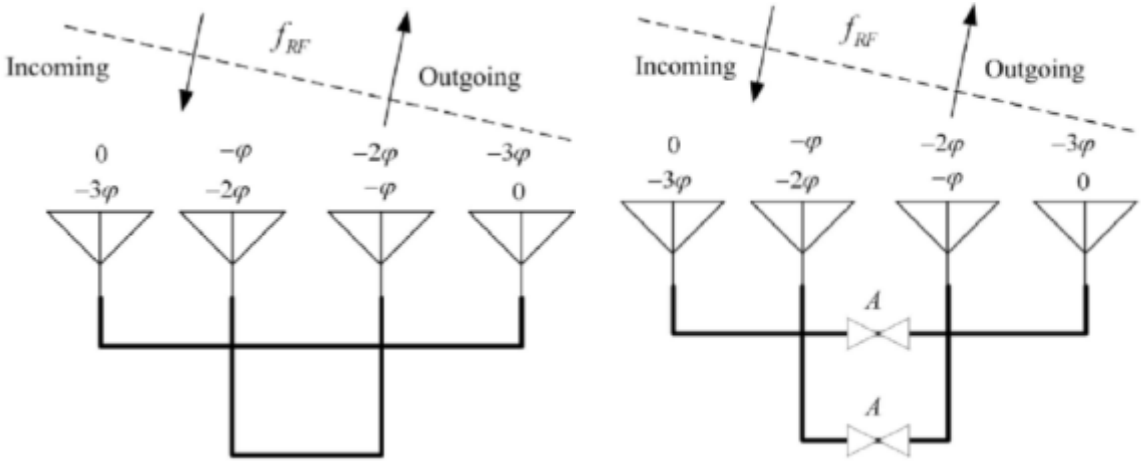

Figure 3. Passive (a) and active (b) Van Atta array phase front (reproduced from [3]).

(c) Phase-Conjugating Array

Unlike the Van Atta array, the PC retrodirective array requires active elements because its operation relies on actively changing the relative phase of its elements. The direction of an emitted signal, or, by reciprocity, the maximum directivity for received signals, is controlled by the relative phase and amplitude of the individual radiating sources or receiving elements in a multi-element array as shown in Figure 4. By operating a local oscillator (LO) at twice the received signal's radio frequency (RF), mixing the LO and RF signals results in a lower sideband product whose frequency is the same as the incident signal's but whose phase is conjugated (reflected about the real axis as shown in Figure 5).

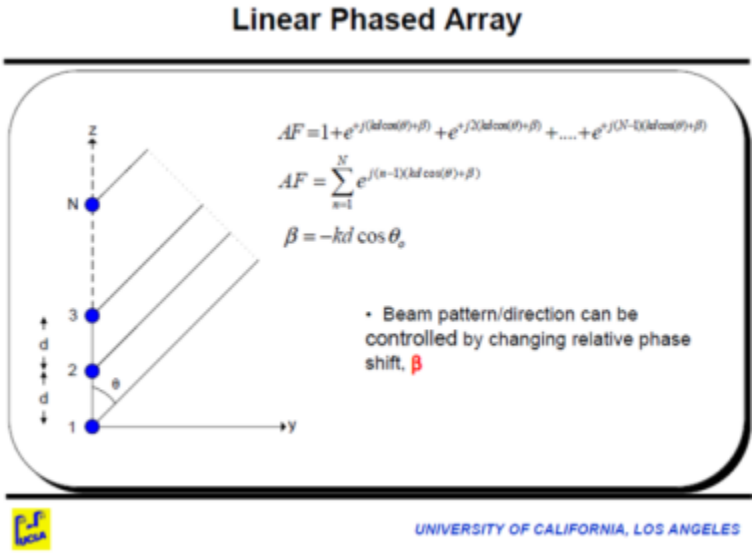

Figure 4. Beam direction control (reproduced from [1]).

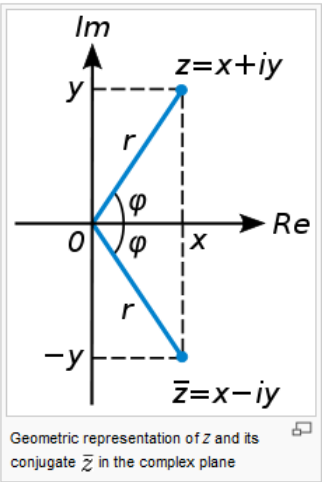

Figure 5. Phase conjugation.

Conjugating the phase for each antenna element steers the antenna beam back along the direction of the incoming signal as shown in Figure 6. If the antenna is used for transmitting, then the radiated signal is transmitted along back along the direction of the received signal. If the antenna is used for receiving, then the radiation pattern is steered with is maximum directivity in the direction of the received signal.

A conjugating retrodirective antenna, whether VA or PC, could be very useful as a set-top television antenna because it provides optimal gain in the direction of the received signal regardless of its incidence direction. A retro receive antenna would automatically adapt itself to the signal environment allowing a fixed antenna to provide maximum response to signals from any direction. The following sections describe some state-of-the-art implementations that may be applicable in the set-top television environment.

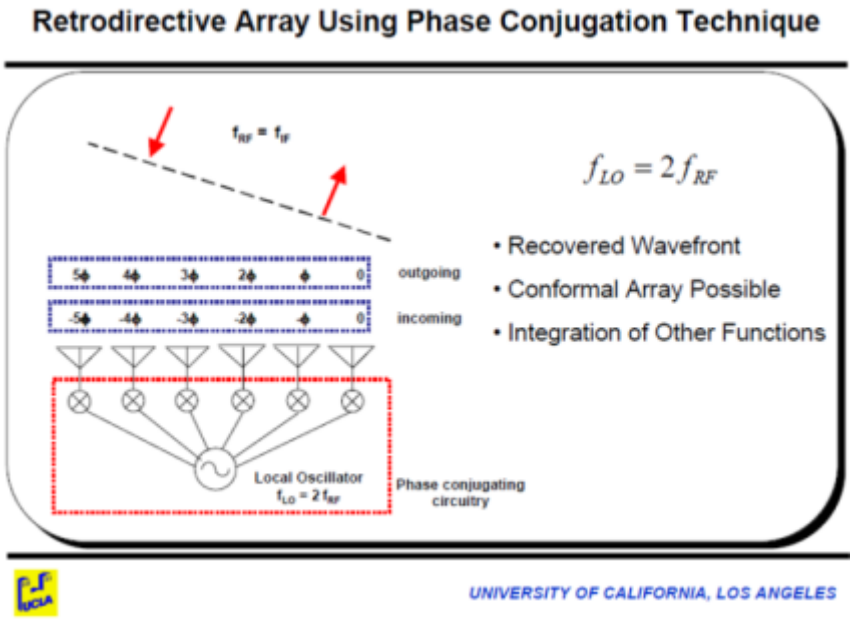

Figure 6. Retrodirective phase conjugating architecture (reproduced from [1]).

(d) Retrodirective Array Implementations

Broadband Van Atta Array. Figure 7 shows the schematic diagram for a frequency-offset broadband Van Atta array [6]. While the VA architecture is inherently more broadbanded than PC arrays because bandwidth-limiting LO and phase conjugation mixers are not required, there nevertheless are active-element implementations that improve performance while maintaining substantial bandwidth as shown in the figure. In this particular application, the antenna is used for two-way communication, which is why optional amplifiers that increase effective radiated power are included and dual-polarized antennas are used (orthogonal polarizations for transmission/reception to increase isolation).

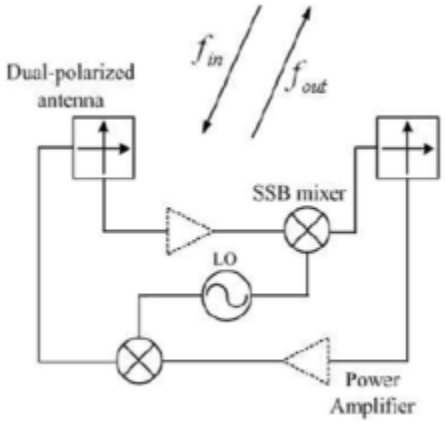

Figure 7. Diagram of broadband two-way Van Atta array (reproduced from [6]).

Figure 8 shows the structure of the prototype broadband VA array antenna. A patch radiator is fed by two excitation slots at right angles to provide orthogonal polarization. Microstrip feed lines excite the apertures and are deposited as shown the opposite side of the aperture substrate. The reflecting plane is included to improve front-to-back ratio. Two such antennas comprise the prototype array which operates from 2.8 to 3.4 GHz. The antenna as fabricated is shown in Figure 9. The patch antennas are evident on the surface of the front circuit board substrate, while the separate SSB mixer circuit boards are seen in the background. This antenna achieved beam steering over approximately ±30º from the broadside direction (perpendicular to the plane of the antenna patches). This active VA array shows that substantial retrodirectivity can be achieved even in a simple two-element array. It perhaps points the way towards retrodirective set-top antennas based on the same or similar architecture that utilize different antenna elements, such as dipoles or bow-ties, that are better suited to the lower television frequencies.

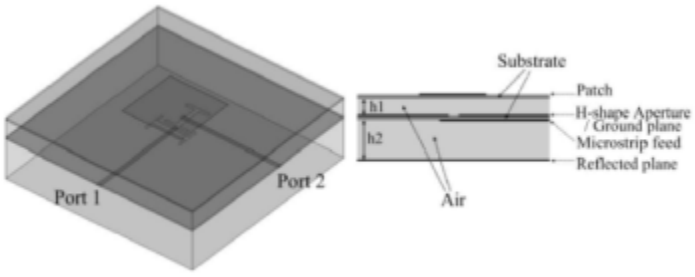

Figure 8. Broadband two-way Van Atta array antenna element (reproduced from [6]).

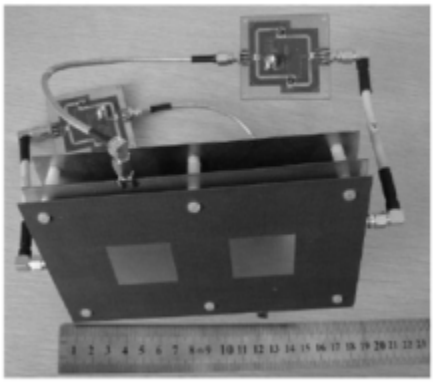

Figure 9. Broadband two-way Van Atta array as fabricated (reproduced from [6]).

Passive Array with Hybrids. An interesting example of a passive VA array implementation involves using 90º hybrid couplers as the phasing elements [7]. This design relies on a clever use of hybrid couplers whose incident and reflected signals' phases are reversed when the coupler is terminated with loads having the same reflection coefficient. Figure 10 shows how a phase difference $\Delta\phi$ between signals into ports 1 and 2 (input/isolated ports, respectively) is transformed into a phase difference of $-\Delta\phi$ between the reflected signals at those ports as long as ports 3 and 4 (direct/coupled, respectively) are terminated with the same reflection coefficient. In practice, these ports simply float unterminated because Γ then is the same for each (~1).

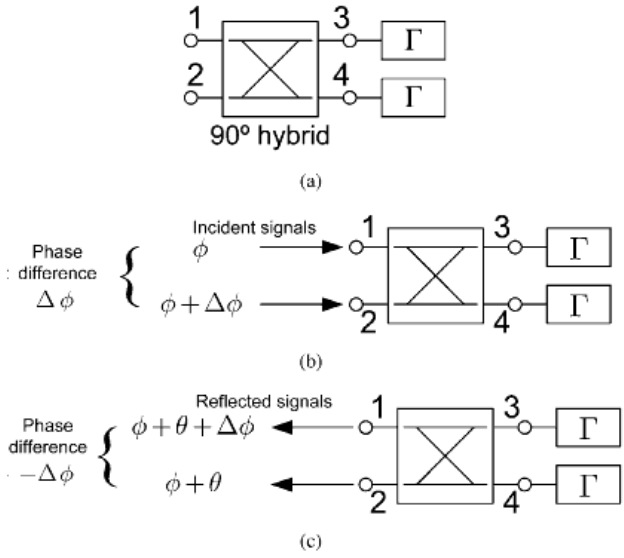

Fig. 2. (a) A terminated 90° hybrid with (b) and (c) to illustrate the phase difference reversal characteristics of the input signals and the reflected signals.

Figure 10. Passive VA array using hybrid couplers (reproduced from [7]).

A particularly attractive feature of this design is ease of implementation. Figure 11 shows 3-, 4- and 6-element retrodirective array circuits fabricated on 1.6 mm thick FR4 substrate using planar 90º microstrip branch line couplers. It is significant, too, that this retrodirective design does not require an even number of array elements as does the basic Van Atta design. The prototype array was fabricated with 2.9 GHz patch antenna elements on the same type substrate spaced 0.48λ. Measurements showed effective beam steering over a range of ±40º. This type of retrodirective antenna may be particularly attractive for the set-top application because of its simplicity.

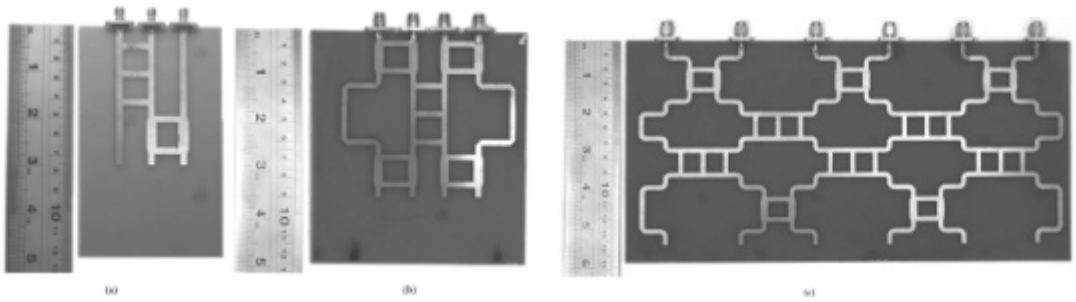

Figure 11. Passive 3/4/6-element VA array circuits as fabricated on PCB (reproduced from [7]).

Feed Systems for Van Atta Arrays. Two interesting and potentially useful VA array designs are described in [8]. Two planar VA arrays were designed and simulated using commercially available electromagnetic modeling software (ANSOFT HFSS). The first antenna (Figure 12, (a)/(b) left) used a microstrip line edge-fed patch at 7.58 GHz as the antenna element (overall dimensions ~13 x 30 mm). This element was arrayed in a two-dimensional 4x4 grid and evaluated for bandwidth and radiation characteristics. The second antenna comprised aperture-coupled microstrip patch antenna elements operating at 9 GHz also arrayed in a 4x4 2-D grid (Figure 12, (a)/(b) right). The second design was found to be superior because it could be more easily fabricated using both sides of the substrate and it provided better beam steering (±80º @ -10 dB). This simulation shows that very effective designs with small footprints are possible at very short wavelengths. This technology may be applicable directly or with modification or extension to set-top antenna requirements.

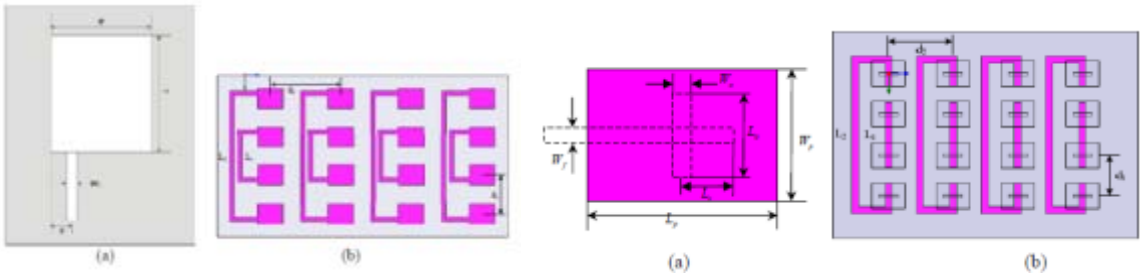

Figure 12. Planar edge-fed VA arrays (reproduced from [8]).

A Fractal VA Antenna Element. Dual-polarized Van Atta array antenna elements provide advantages over singly polarized elements, in particular increased transmit/receive (T/R) isolation on two-way links, multipath mitigation, and polarization diversity. While T/R isolation is not a consideration in the set-top television antenna, the other factors are. Additionally, size is a concern, and newer antenna element designs emphasize small size. An interesting fractal-based element is reported in [9] that may be useful for set-top VA arrays. Figure 13 shows the overall antenna in perspective and plan views. There are two square (40 mm) 1-mm thick material dielectric substrates, the top one being PTFE material ($\varepsilon_r = 2.65$), and the bottom FR3 ($\varepsilon_r = 4.4$). The First Minkowski fractal patch is shown on the right with the vertical and horizontal polarization feed ports marked V and H, respectively.

Details of the patch, which is designed to operate from ~4.4 to 5 GHz, appear in Figure 14. Its overall size is quite small at 21 x 16.8 mm, and it provides similar electrical performance to a square patch that is about 20% larger. Figure 15 shows details for the H-shaped slots that function as aperture coupling structures to excite the fractal patch. It is evident that, once dimensions are specified, the components are readily fabricated and easily assembled, which are very desirable characteristics for the set-top television antenna.

Computed data show that the antenna element exhibits H-polarization VSWR < 2 from ~4.82-5.17 GHz with 16.8% impedance bandwidth. The corresponding V-polarization figures are ~4.27-5.2 GHz, bandwidth 19.8%. Measured results confirm the modeling with bandwidth figures of 19.7% and 20.5%, respectively, which is good agreement. Directive gain is ~8 dB with >20 dB front-to-back ratio. These results clearly show that the microstrip Minkowski fractal antenna element is useful in VA arrays at microwave frequencies, and that it well may provide excellent performance for the higher television bands as well.

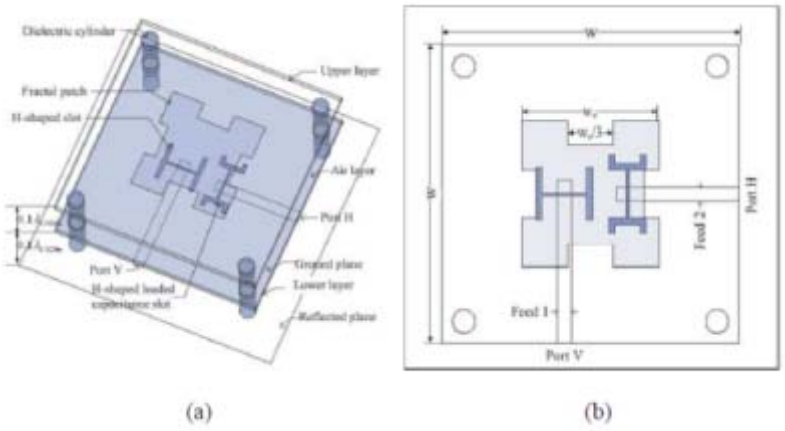

Figure 13. Proposed microstrip fractal antenna element (reproduced from [9]).

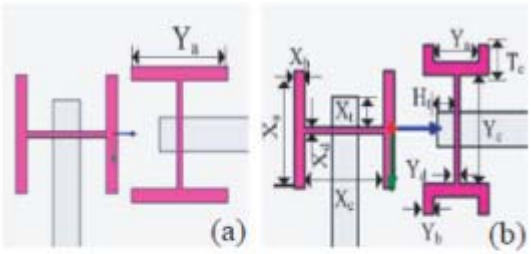

Figure 3. The aperture-coupled structures. (a) Double H-shaped slots, (b) H-shaped and H-shaped loaded capacitance slots.

Figure 15. Aperture details (reproduced from [9]).

Dual-Ring Antenna Elements. The dual-ring antenna element proposed in [10] is another novel device that can be used in retrodirective Van Atta arrays. Inner and outer concentric rings form an inherently two resonant-frequency structure. Each of the rings is parasitic with the other ring excited, and by properly choosing dimensions fairly widely separated resonance points can mark the upper and lower limits of a fairly flat response curve. The structure of the dual-ring element is shown in Figure 16. It is implemented in a two-layer microstrip structure with the rings deposited on the outer surface of an upper substrate underlain by a transmission line for feeding and a ground plane as shown. Element dimensions were optimized using HFSS modeling software, and the fabricated element tested. The measured bandwidth (-10 dB) was just under 34% (31-42.8 GHz), which agreed quite well with the predicted value of 34.3% (30-42 GHz). Between 30 and 40 GHz the average measured gain was ~4.5 dBi.

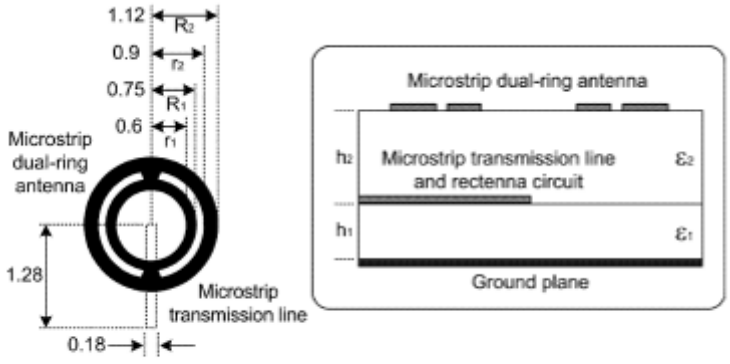

Fig. 3. Geometry of the broadband proximity-coupled dual-ring antenna and the two-layer dielectric structure. All dimensions are in mm.

Figure 16. Dual ring antenna element (reproduced from [10]).

The Van Atta array implemented using dual-ring elements was fabricated using 8 sub-arrays comprising 16 dual-ring elements in a 4 x 4 2-D grid. Figs. 17 and 18 show the sub-array and complete array structures, respectively. Measurements confirm the new array's predicted performance, which shows excellent beam steerability out to about

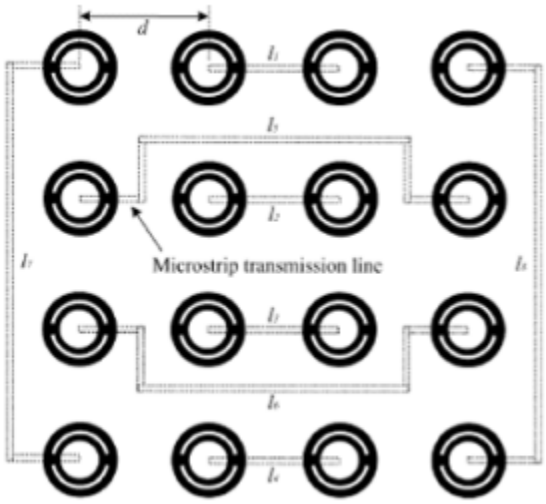

Fig. 5. Geometry of the 4x4 retrodirective sub-array where the dash-lines are the microstrip transmission line networks.

Figure 17. Dual ring element sub-array (reproduced from [10]).

±45º. The large array exhibits a very narrow main half-power beamwidth on the order of ~2º that is very stable between 32 and 49 GHz. Of course, this prototype antenna operates far beyond the highest television operating frequency, but its technology may be applicable to the TV set-top antenna with appropriate modifications.

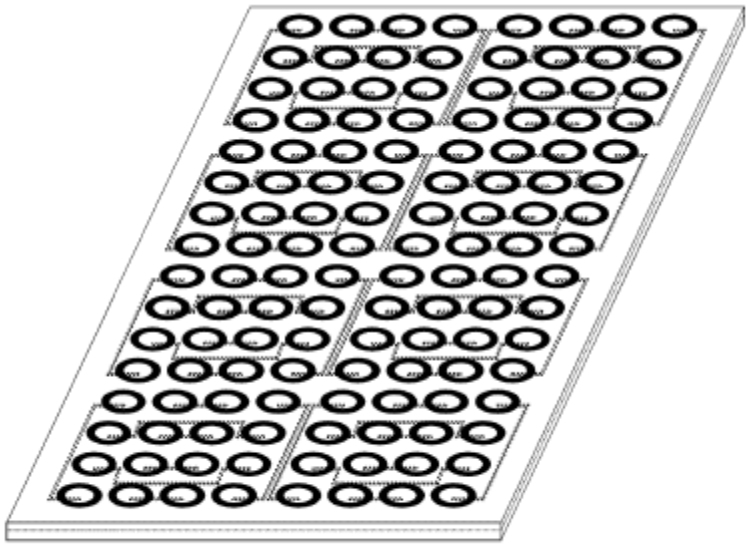

Fig. 6. Geometry of the 8x16 retrodirective array that consists of eight 4x4 sub-arrays.

Figure 18. Retrodirective array of dual ring elements (reproduced from [10]).

Conformal Retrodirective Arrays. In some cases it may be desirable to deploy a retrodirective antenna on a non-planar surface (the systems described above all utilize planar structures). Unfortunately the simpler Van Atta design cannot be used in such cases, so that Phase Conjugating systems are required instead. An interesting example of a genetically optimized, thinned PC array is described in [11]. The array's schematic representation appears in Figure 19, and its final physical configuration in Figure 20.

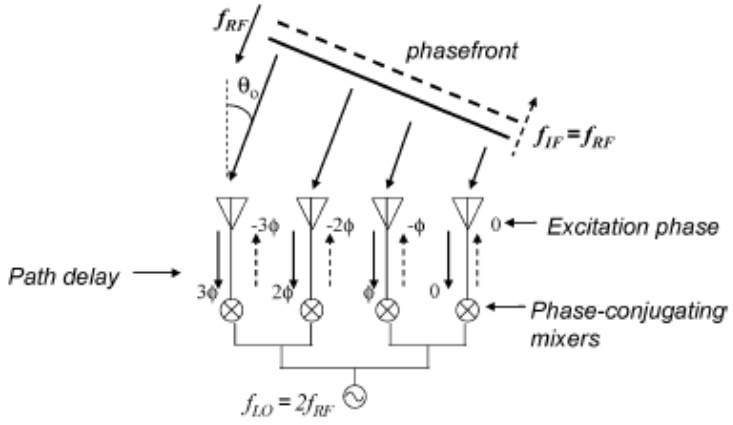

Fig. 1. A retrodirective array using heterodyne technique [5].

Figure 19. Conformal PC retrodirective array schematic diagram (reproduced from [11]).

In this example, the array was thinned to a total of 16 elements whose positions were optimized to achieve reasonable sidelobe levels over a scanning range of ~±120º. The shape and size of the optimized array aperture cannot be determined analytically, but a suitable optimization algorithm permits design of conformal PC arrays. This type of structure could be important in the set-top environment as a space-saving measure, but it would incur the additional expense and complexity associated with active PC arrays compared to the simpler passive Van Atta design.

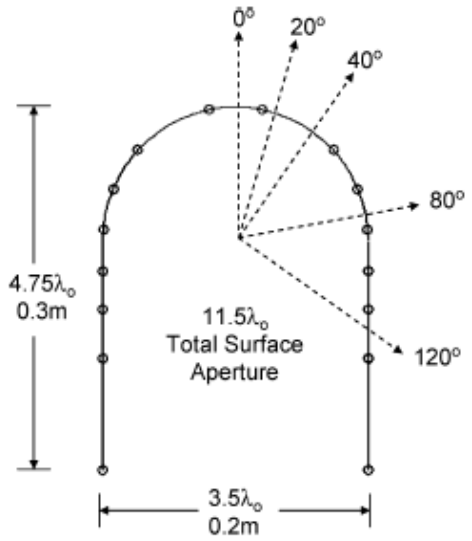

Fig. 2. The shape and the physical size of the aperture [4].

Figure 20. Conformal PC array structure (reproduced from [11]).

Near-Field Effects. Retrodirective antennas typically operate primarily in free space or near-free space environments, so that near field obstructions are not a factor in antenna performance. This typical environment is quite different from the set-top environment in which nearby objects and structures will definitely be in the antenna's near field and consequently a potential source of interference. Near field effects were studied in [12] in order to investigate these effects. Figure 21 shows the experimental antenna in an anechoic chamber and typical measured data. Three different near field scatterers were studied: (a) straight wire grid; (b) partially obscuring low loss MDF (medium density fiberboard); and (c) partially or totally obscuring concrete blocks.

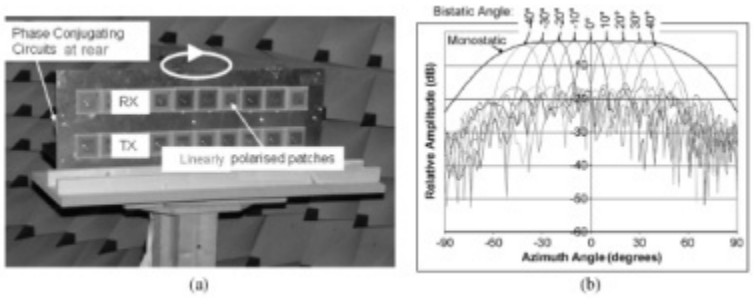

Figure 21. Measurement system for near field effects (reproduced from [12]).

Measurements were made at 2.4 GHz using a 10-element retrodirective array scanning ±40º with a half-power beamwidth of ~12º. The retrodirective antenna performed quite well in the presence of obstructions. For example, using gapped concrete block scatterers, it was able to fully compensate for phase distortions that reduced a basic reference antenna's gain by 11 dB. This study was the first to demonstrate that retrodirective antennas offer demonstrable performance advantages over other antennas in difficult propagation environments such as the interior of a building. This finding is an important reason for exploring retrodirective technology as it might be used in a television set-top antenna.

3.0 Conclusions and Design Recommendations

Upon consideration of Table 1-1 at the end of Section 1 of this report we have concluded the following:

- There have been significant and potentially useful antenna design methods and actual hardware developed over the past 15 years that will improve the performance of low-profile, compact indoor/set-top DTV antennas.
- In the area of electro-magnetic computational and design optimization methods Genetic Algorithms (GA) and the Central Force Optimizer (CFO) have proven themselves as powerful tools in the design of broadband, compact antennas.
- Using the above, we have included an example of an advanced antenna technology, specifically the Fragmented Antenna as part of this project. We submit that it would be nearly impossible for a human to replicate its design and performance.
- The Non-Foster active broadband matching technology and its required semiconductors have matured to the point where they could be incorporated into a commercial indoor/set-top design to provide a matched antenna where it is considered as being electrically small. In the example shown below it would be used to provide acceptable performance with the Fragmented dipole within the 54-88 MHz band. Other element geometries are also possible.
- Many of the other advancements listed in Table 1-1, specifically 2.4 through 2.6, require a CE-909-A type interface with the DTV receiver, and while potentially useful if and when manufacturers start adding this feature to their products they offer no practical improvement for the near term.
- The technologies designated as 2.7 through 2.10 while interesting are either too embryonic (2.7 & 2.8), too complicated and too large (2.10) or not well vetted (2.9) to be considered in the near term.

Considering the above it is recommended that the NAB give consideration to further developing a computer generated/optimized broadband dipole antenna element, such as a Fragmented Planar Dipole with/without a Non-Foster Matching circuit in order to demonstrate that it is feasible to design a VHF/UHF antenna system that is both simple, have positive gain, be of reasonable size and weight and not require a CE-909-A interface with the DTV receiver.

As an example, a fragmented planar antenna was optimized for 54-698 MHz to cover all three DTV television bands. The antenna has dimension of 13” x 13” across the VHF and UHF bands, a block diagram of the proposed antenna system is shown in Figure 1. The computed directivity, after optimization, along the horizon is good at all DTV frequencies as shown in Figure 2. The antenna shows a good match at UHF frequencies, but as shown in Figures 4 and 5 some matching, using a simple L-C passive network of SMT components and Non-Foster Matching circuitry at the feed-point would be necessary for good performance in the high and low VHF bands respectively.

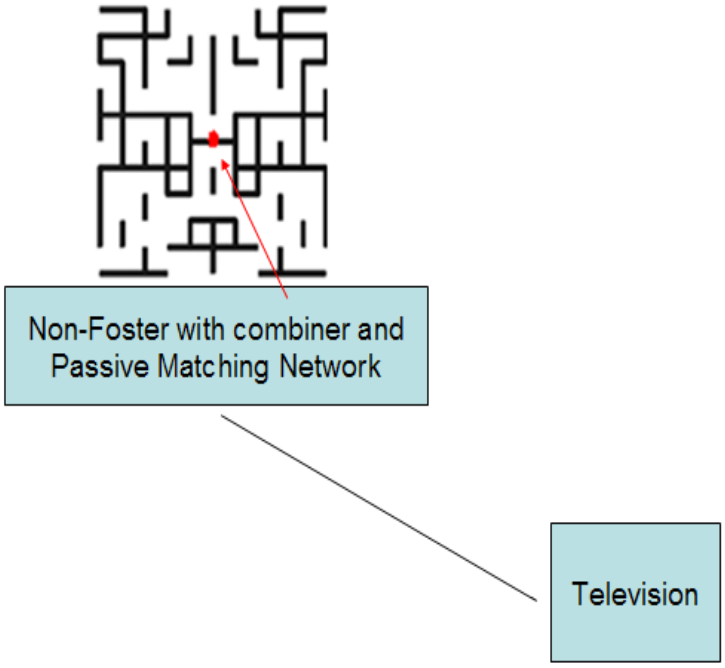

Figure 1. Fragmented Antenna Example, 13”x13”

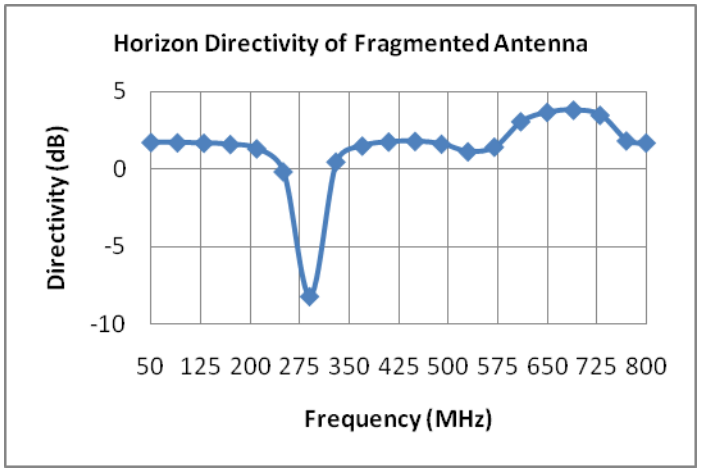

Figure 2. Directivity Along Horizon for Fragmented Antenna

The pattern of the antenna as currently designed is a “figure eight” dipole pattern at all frequencies, as shown in Figure 3. Figure 6 indicates that without any matching, a very low VSWR across the UHF 470-698MHz band.

***Abstract*—In this paper, a unique process for fabricating microstrip patch antennas with flexible graphene-based conductors is presented. In particular, this manufacturing process uses a commercially available micro-cutter to cut the outline of the patch antenna from the flexible graphene-based conductors, and then this piece is attached to a grounded FR4 substrate using adhesive to create a unique printed antenna. The design was modeled using a commercial simulator, and a prototype was fabricated and measured. Overall, it was shown that the S-parameter simulations agreed fairly well with measurements, and that this manufacturing process has the potential to develop more complicated designs, such as meander-line dipoles for example, that are difficult to cut-out manually.**

***Index Terms*—Patch antenna and graphene-based conductors.**

I. INTRODUCTION

Modern wireless communication systems are being required to operate in evermore complicated environments. This is because these systems are being applied to problems that (1) involve surfaces that change shape with time, (2) include wearable networks and/or (3) are subjected extreme environmental temperature/pressure changes [1]. Because of the wireless nature of these systems, the antenna is a major part of the design and conformal antennas have the potential to overcome some of the aforementioned difficulties. However, one drawback of using a traditional conformal antenna can be the copper conductors. This is because of the weight and the potential for copper failure due to repetitive bending deformations, which was noticed in the work reported in [1]. To mitigate some of these issues, a flexible graphene-based conducting material [2] is being explored as a possibility of replacing the etched copper in a conformal antenna. A picture of the material is shown in Fig. 1(a). However, an efficient manufacturing process for fabricating complicated antenna designs based on this material is required. Thus, the objective of this paper is to present a suitable manufacturing process and introduce the graphene-based microstrip patch antenna shown in Fig. 1(b). This provided a standard design that has been well understood and was marginally complicated.

An initial investigation on graphene patch antennas at microwave frequencies was reported in [3] and later discussed in [4]. The authors of these papers summarized the benefits of graphene as a mono-atomic structure, whereas the presented work builds on these ideas and explores the potentials of using graphene-based conductors that are commercially available and much thicker than a single layer for printed antenna purposes.

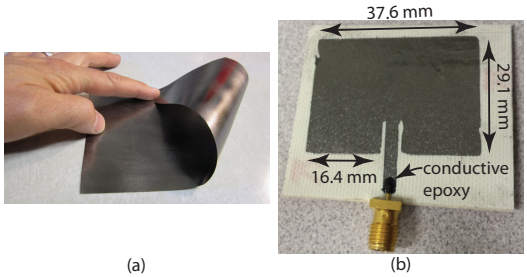

Fig. 1. Photograph of the commercially available flexible graphene-based conducting material and (b) a photograph of the prototype (with dimensions) of the fabricated graphene-based patch antenna.

II. THE MANUFACTURING PROCESS

Several steps are required to prepare the graphene-based conductor material in Fig. 1(a) for manufacturing. Initially, the temporary spray adhesive (Sulky KK 2000 [6]) shown in Fig. 3 is applied to the top surface of a 100 μm thick sheet of paper and bonded to the bottom surface of the graphene-based conducting material (Fig. 2). Next, the same spray adhesive is applied to the bottom surface of a 100 μm thick transparency film and bonded to the top surface of the graphene-based conducting material (also shown in Fig. 2). As a result, the three layers are bonded together for manufacturing, giving the 3-layer structure shown in Fig. 2. The 3-layer structure is then placed on the adhesive cutting mat shown in Fig. 3. The graphene-based conducting layer is now ready for cutting out the shape of the microstrip patch. It should be noted that the three layers were pressed together by hand and the temporary adhesive was cured at room temperature for 2 - 3 minutes before cutting. This allowed for the separation of the three layer after the cutting process was completed. Finally, the layout of the patch is defined in the software included with the micro-cutter, which is discussed in the next section.

Fig. 3. Photograph of the commercial micro-cutter [5] and the temporary adhesive spray [6].

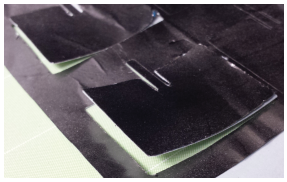

Fig. 4. Fabrication step to separate the flexible graphene-based conducting layer of the patch from the protected layers.

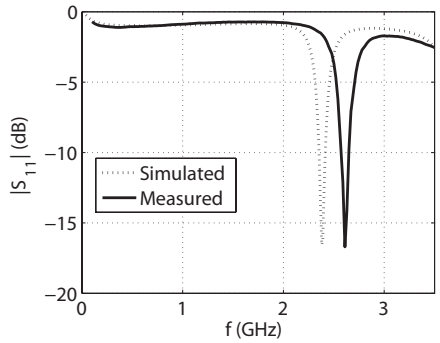

Fig. 5. Measured and simulated $|S_{11}|$ values of the prototype graphene-based antenna.

III. Design and Evaluation of the Prototype Microstrip Patch Antenna

To develop the patch antenna in Fig. 1, the conductive properties of the graphene-based material [2] were determined by measuring the S-parameters of a known printed microstrip transmission line that used the graphene-based conductors instead of copper. The conductivity was determined to be σ = 1.94×10^5 S/m for a thickness of 25 μm. Next, this thickness and conductivity were used in the commercial simulation software ADS [7] to determine the geometry of the patch antenna shown in Fig. 1(b). The simulated S-parameters are shown in Fig. 5. The resonant frequency was predicted to be 2.4 GHz and the grounded FR4 substrate was 1.5 mm thick with ε_r = 4.5 (the bottom layer of the FR4 was 0.5 oz copper). Then, this geometry was drawn in the software included with the micro-cutter and used to cut out the graphene-based conducting layers shown in Fig. 4. As a final step, the graphene-based conducting patch was removed from the 3-layer structure and attached to the FR4 substrate. The result was the prototype shown in Fig. 1(b). The center conductor of the SMA connector was attached to the patch with conductive epoxy. Next, the $|S_{11}|$ values of the prototype were measured in an anechoic chamber and are shown in Fig. 5. The resonant frequency was 2.6 GHz.

Several comments can be made about the results in Figs. 1(b) and 5. Closer observation of the edges in Fig. 1(b) shows that the micro-cutter blade tends to wobble slightly during cutting, which may be the cause of the differences in the S-parameters in Fig. 5. This behaviour could be due to the blade depth setting and further exploration is planned in the near future. On the other hand, the results in Fig. 5 show that a new patch antenna can be developed using this flexible graphene-based material, which may be difficult to otherwise manufacture with the existing PCB techniques.

IV. Conclusion

An initial investigation of a new patch antenna that uses flexible graphene-based conductive material was introduced in this paper. Additionally, a unique process of manufacturing these patch antennas with the graphene-based material was presented. The design was simulated in ADS using extracted material properties, and a prototype was fabricated and tested. Overall, fair agreement between the $|S_{11}|$ values was observed and it was demonstrated that moderately complex geometries could be manufactured using a simple and cost-efficient commercially available micro-cutter.

BUILD A SHORTWAVE ANTENNA

"The Search For The Perfect Shortwave Antenna"
by N4UJW Webmaster Hamuniverse.com

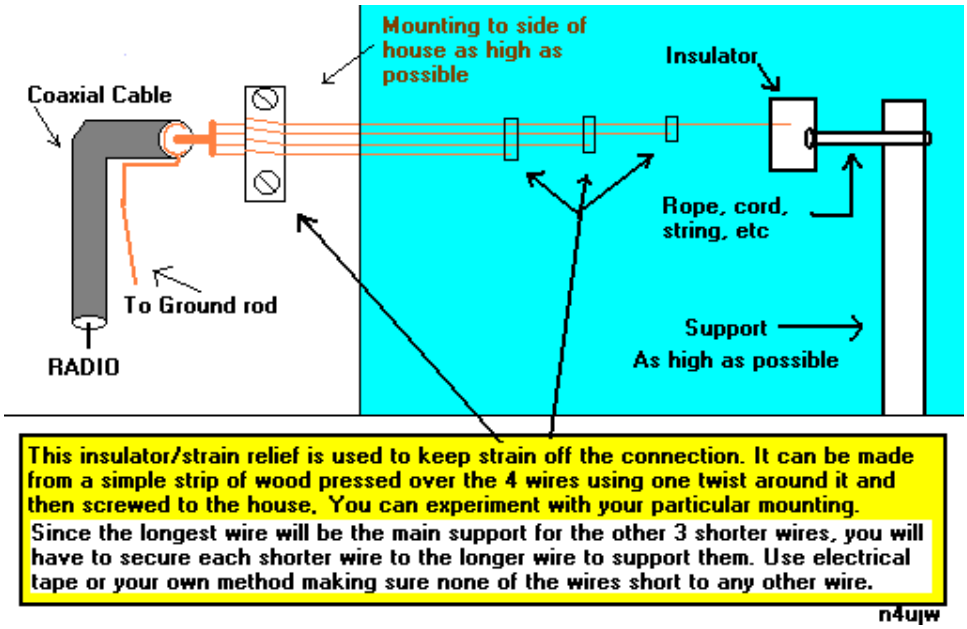
THE MULTIBAND LONG WIRE SHORTWAVE ANTENNA

A Much Better But More Complicated Antenna

This antenna is end supported and designed to receive the major shortwave bands between 90 meters and 16 meters. It uses only 4 wires and a unique antenna property called harmonics to get 8 bands using only 4 wires! Again, it is a compromise but an excellent performer....the perfect antenna does not exist. We "Hams" are working on it constantly!

After construction, this shortwave antenna should be stretched out in a straight line as high as possible as in the long wire antenna above, and about 140 feet straight out from the house! Don't fret! If you cant', you can't. Utilize your existing space. More supports may be required for a zig zag layout but performance may suffer a bit. Don't worry, it will certainly outperform that built in poor excuse for an antenna!

It consists of 4 separated insulated wires, (measurements below), all connected (soldered) on one end, leaving the opposite end unconnected and insulated at the support. If you do not know how to solder, then scrap all the coating from the wire down to bare copper and tie the ends together using several knots. You really should learn to solder though!. This will make for a more permanent and much better electrical connection.
The soldered end must be between an insulator and the radio for mechanical strength.
You don't want much stress on the soldered connection other than the coax leading to the radio. The end that has all wires connected should be soldered to the center wire of a suitable length of 50 - 75 ohm coaxial cable leading to the short wave radio with a suitable connection. A ground wire is soldered to the shield only of the coax at the same end that you soldered all the wires together and attached to a ground rod driven into the ground near the house. Seal and tape all outdoor connections from the weather. This antenna is called an end fed half wave antenna.
See picture, formula and wire measurements for bands below:
(The lengths are not extremely critical, but try to get them as close as possible.)



Note: In the instruction box above, the last sentence refers to the long portion of the wires, not at the connection point to the coax feed line to the receiver. All wires are connected together at the connector center conductor wire!

(frequencies shown below are approximate shortwave band centers):

Wire 1 (LONGEST WIRE) 3.25 MHz (90 meter band) 09.75 MHz (31 meter band 3rd harmonic)
468 ÷ 3.25 = 144' 0"

Wire 2 3.95 MHz (75 meter band) 11.85 MHz (25 meter band 3rd harmonic)
468 ÷ 3.95 = 118' 6"

Wire 3 5.10 MHz (60 meter band) 15.30 MHz (19 meter band 3rd harmonic)
468 ÷ 5.10 = 91' 9"

Wire 4 (SHORTEST WIRE) 5.90 MHz (49 meter band) 17.70 MHz (16 meter band 3rd harmonic)
468 ÷ 5.90 = 79' 3"
The number 468 divided by the frequency above is the formula for calculating a half wave antenna length used all the time by Amateur radio operators in building many different kinds of antennas.
You'll need about 435 feet of wire for this antenna plus appropriate length of coaxial cable.

The wires are spread 3-4 inches apart, held in place with simple non-conductive spacers.
Just cut a few pairs of the acrylic, Plexiglas, plastic strips or other non-conductive material that will not be damaged by moisture long enough to attach the wires keeping the spacing about 3 to 4 inches or further if you want.

OUTDOOR CENTER FED MULTIBAND (FAN) DIPOLE SHORT WAVE ANTENNA

NOTE: For use with the higher quality table model communications receivers that have standard antenna connectors capable of using direct coaxial cable connectors.

This antenna type is used by many Ham Radio Operators worldwide and is very popular but the lengths for the Ham bands are entirely different.
The entire length of the antenna is about the same as the one above and the coaxial cable is connected in the center of the span with the center conductor connected to one side of the antenna and the shield connected to the other side then at the other end, to the receiver.
The formula used for this antenna is the same as the Multiband Long Wire above:

468 / by frequency in mhz = total length in feet. This resulting length is cut in half!

One antenna per band stacked.

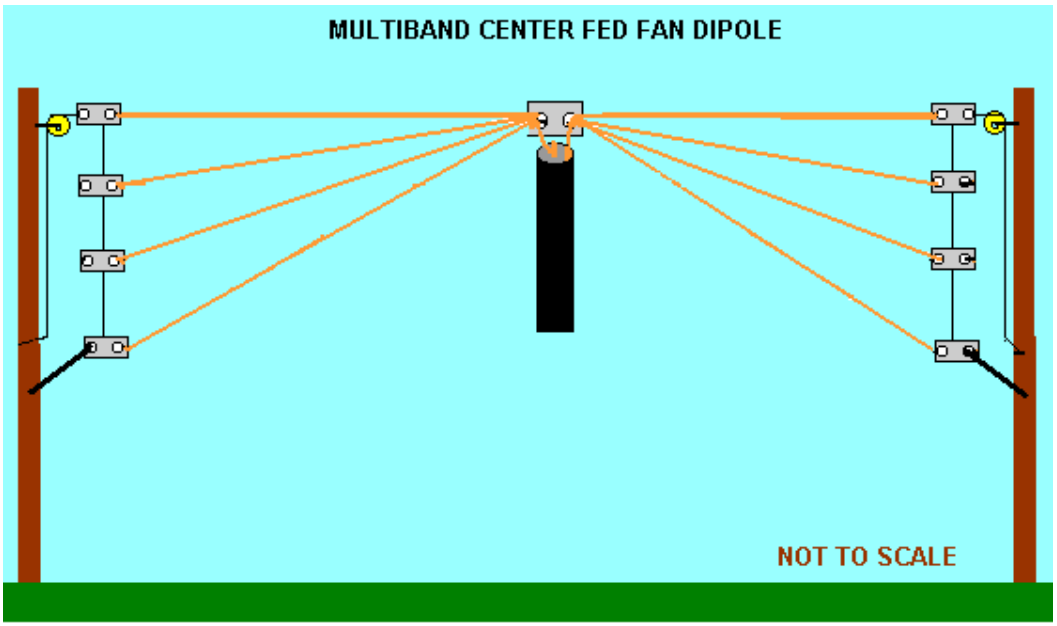
It is somewhat more complicated in construction due to the center connection and requires support in three places....each end plus the center. The preferred method for using this antenna is drawn in the picture below with the wires "fanned" apart with at least a foot of separation between the ends.
All of the wire elements can be close spaced but some interaction will occur. Insulated wire is best so the individual wires do not connect on the longer lengths of the antenna.

Choose the antenna of your choice depending on your constructions skill and needs.
Either way, they both will be much better than the little telescoping antenna that comes with most portable receivers.

The center fed multiband dipole antenna (drawn below) consists of 2 separate sections of 4 wires on each side of the center connection at

the support consisting of 4 wires connected to the center conductor of the coax and the other 4 connected to the shield.

In this arrangement, one half of the antenna is feeding the center conductor and the other half is feeding the shield. Each side must be insulated....not connected....to the other side. The other end of the coax is connected to the radio with the appropriate connector.
Use lengths in the above multiband antenna with total length split in half using the formula....half on one side and half on the other for each wire length per band. The coax can be anything from 50 ohm to 75 ohm.
Not critical on receive!



Shown supported between two wooden poles. Gray rectangles are insulators.
Yellow circles are pulleys.
Orange lines are dipole elements.
Heavy black vertical line in center is coax leading to radio.
Note that one side of antenna is connected to center of coax, shield to the other side.

The final assembled antenna can be installed with the center section higher than the ends, making it look like an inverted V, like this /\ .
Make the angle of the V about 90 degrees or more.
Or it can be horizontal to the earth or anywhere in between.
The inverted V configuration is more omni-directional, (all directions), than the horizontal method which tends to receive best, broadside to the wire. Less real estate is required for the inverted V method. Center supporting also has less tension on the antenna so smaller wire size may be used to save money.

Choose the antenna of your choice above depending on your constructions skill and needs. Either way, they both will be better than the little telescoping antenna that comes with most portable receivers. Enjoy!

INDOOR MULTBAND SHORTWAVE ANTENNAS

Attic Antennas

To begin with building and installing an attic antenna that helps your reception, you need to take stock of your attic's measurements, particularly the length of the attic at it's longest distance that you have easy access and your radio's location.
One of the more common house sizes is about 50 to 60 feet long and about 25 to 30 feet wide at the ground level. Your house or home may be entirely different. The accessible attic space usually is much less than this. You will have to really compromise with an attic antenna as far as the band coverage is concerned for a short wave antenna to perform adequately. Use the dimensions of your attic and compare them with the lengths of the long wire and dipole type antennas in this article above and choose the one that you can "fit" into the attic. You may not be able to use lengths for all the bands, but again, no matter what length your end result is, it will certainly outperform that little pip squeak of a poor excuse for an antenna that came with the radio! Just utilize the space that you have and don't worry about the length. Just use as much wire as you can and forget about that "perfect antenna". It still does not exist up to this point in this article! Hams are still working worldwide on it!

The best place to mount or attach the antenna is against the peak or highest part of the roof thereby keeping it away from ductwork, AC and heater systems, telephone and all the other metallic environment that exists in most attics. Once you have the location selected, then build the antenna while keeping in mind that the coax or wire will have to get to the radio. If you're working up on the roof, get a helper to assist, an adult, not children! Be careful on those ladders!
You can push most small coaxial cable under the space where the carpet and wall come together and wire should be no problem, then to the nearest closet, up the wall and into the attic. You can work from the attic down or radio up....your choice. Lots of variables here too so you will have to choose your own route and method of installation. If you have to drill into a wall to feed the wire, use caution and don't drill into electrical wires! It may be the last time you do!

IN ROOM ANTENNAS!

In those cases where you can't put an antenna outside or up in the attic, then you can install it in the same room with the radio! They won't be as effective as those up in the attic or outside but will still get more signal to your radio which is what you want.
Simply use your own method to attach a random length wire, up next to the ceiling against the walls...around all sides of the room if possible. One other choice is to push a random wire between the carpet and the baseboard around the walls of the room. You will be surprised at the difference compared to that telescoping antenna that came with your radio. Just attach the antenna to the telescoping rod...don't forget to remove the insulation on the wire at the attachment point!

A Metamaterial-inspired Approach to RF Energy Harvesting

C. Fowler (cfowler@mail.usf.edu) Department of Physics, University of South Florida, 4202 E. Fowler Avenue, Tampa, FL 33620

J. Zhou (jiangfengz@usf.edu)* Department of Physics, University of South Florida, 4202 E. Fowler Avenue, Tampa, FL 33620

Abstract

We demonstrate an RF energy harvesting rectenna design based on a metamaterial perfect absorber (MPA). With the embedded Schottky diodes, the rectenna converts captured RF waves to DC power. The Fabry-Perot (FP) cavity resonance of the MPA greatly improves the amount of energy captured. Furthermore, the FP resonance exhibits a high Q-factor and significantly increases the voltage across the Schottky diodes, which improves the rectification efficiency, particularly at low power. This leads to factor of 16 improvement of RF-DC conversion efficiency at ambient intensity level.

Introduction

Low-power RF energy harvesting has become a field of interest due to the need to acquire power in situations where the use of wires and/or batteries is impractical such as in the cases of expansive sensor networks and structural health monitoring. The recent proliferation of RF signals due to cell phones, Wi-Fi networks, and GPS has produced readily available ambient power sources (although of low power density) for scavenging energy. Historically there has been difficulty with creating omnidirectional electrically small energy harvesting antennas at RF frequencies that efficiently collect energy[1]. There is further difficulty with efficient AC to DC rectification in cases of low input power[2]. In this paper we demonstrate the potential of metamaterial-based energy harvesting antennas to address both of these issues[3].

Research in metamaterials is a relatively new and unexplored field of study with objectives for constructing materials with customized optical, mechanical, or electrical parameters that would otherwise be difficult or impossible to obtain with ordinary materials[4,5]. Metamaterials are constructed by building a 2-D or 3-D array of structures within a substrate. The choice of the structures used in the array is the primary determinant of the properties of the bulk metamaterial. Thus the bulk properties of the metamaterial can be tuned by altering the shape, spacing, size, etc. of the structures that the metamaterial is composed of. Provided that the size of the structures is sufficiently smaller than the wavelength of the incident electromagnetic waves, the waves interact with the structures in a fashion analogous to the way that optical light or x-rays interact with the atoms and molecules of ordinary materials. There are a multitude of potential applications for metamaterials such as the construction of negative index materials[6,7], cloaking[8], perfect lenses[9], and energy harvesting[10] (which will be the focus of this paper).

A big limitation of metamaterials is that they will typically only function as intended within a limited bandwidth. The structures used to make a metamaterial typically resonate such that the metamaterial exhibits the desired properties only at its resonance frequencies. Thus the metamaterial

functionality is often confined to a relatively small bandwidth surrounding each resonance peak, the

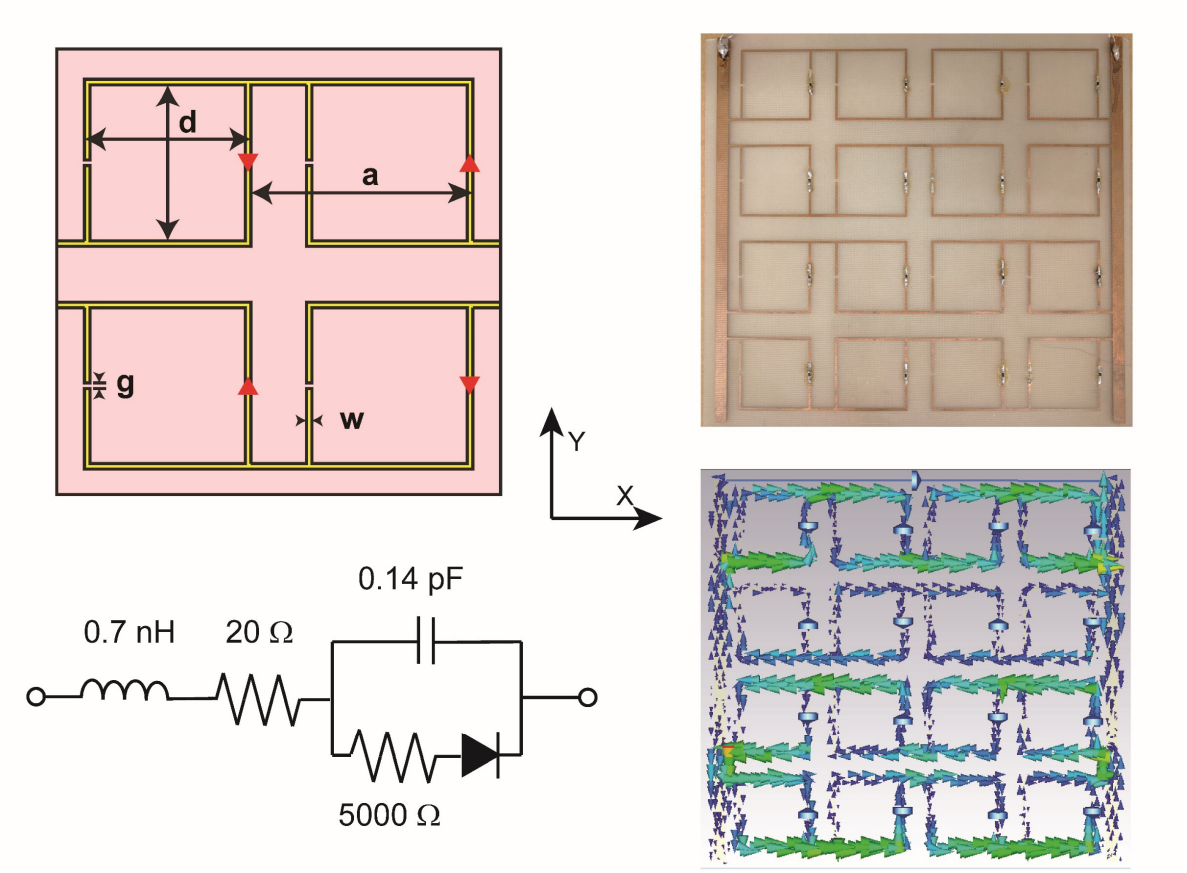

Figure 1 - Rectenna sample design with the dimensions of the unit cell and the equivalent circuit model used for the Schottky diodes in simulations. Diodes are indicated in the unit cell by red triangles pointed in the direction of current flow. d = 30 mm, a = 20 mm, g = 1mm, w = 1mm, t = 0.8128 mm (thickness of FR4 substrate), s = 0.0178 mm (thickness of copper ring layer). The incident wave is perpendicular to the plane of the rectenna and polarized in the x-direction. The surface current modes activated at the resonance frequency (908 MHz) are shown on the sample.

performance of which depends on the Q-factor of the resonance.

An antenna constructed out of an appropriately designed metamaterial that incorporates a means of rectification can operate as an efficient energy harvesting system that can be used to convert power captured from RF sources (or possibly other regions from the electromagnetic spectrum) to useful DC power [11,12]. Optimal RF energy harvesting occurs when the metamaterial is constructed such that a high Q-factor resonance occurs at the same frequency as the external radiation source. For ambient RF energy harvesting, these frequencies will usually be found in the ISM band (particularly those from 800 MHz to 6 GHz) from sources such as cell phone signals, GPS, and WI-FI. References [13-15] provide measurements of power density levels that one might expect to find in urban environments. The greatest power density measured was 6.4 $\mu W/cm^2$, but average values typically ranged from 1-50 nW/cm^2 depending on the frequency, time of day, and proximity to RF sources.

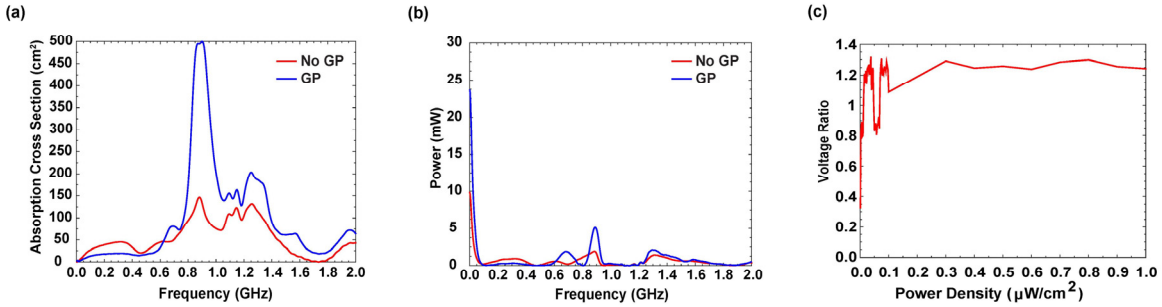

Figure 2 - (a) Comparison of simulated rectenna absorption with and without the ground plane. The absorption peak narrows and increases, indicating an increase in the Q-value of the resonance. (b) Simulated power delivered to the load from a Gaussian pulse. The DC component of the power delivered to the load is the largest component, suggesting good rectification efficiency. The DC component is also strongly enhanced by the ground plane. (c) Oscilloscope measurement of the DC voltage across one of the Schottky diodes. The presence of the ground plane enhances the voltage, which makes it easier for the diode to activate (particularly at low power) and thus improves energy harvesting efficiency.

Reference [16] gives a nice summary of past attempts at developing high efficiency low-power energy harvesting systems for various power densities and frequencies. As mentioned by the authors, the results between groups are not directly comparable due to differing frequencies, definitions of efficiency, and power densities. Nevertheless, they provide a reference point for evaluating the results presented by this paper. Other efficiency benchmarks are presented by references[17,18]. The results of our measurements on the energy harvesting efficiency of the metamaterial sample described in figure 1 are presented in this paper. Upon examination of the results presented by other groups, we believe these results to be the most efficient over the power densities and frequencies investigated.

Results

The absorption cross section obtained by simulation of the rectenna (figure 2a) predicts a peak energy harvesting frequency around 0.8 GHz. Adding the ground plane causes the peak to become somewhat narrower, but much larger (an increase in Q-value). As seen in figure 2b, the power delivered to the load is primarily from DC, while power from AC signals is much smaller. When the ground plane is incorporated, the DC power is much higher. A rough oscilloscope measurement of the voltage across one of the diodes shows the voltage-enhancing effect produced by inclusion of the ground plane (figure 2c).

Efficiency measurements for relatively high power densities (figure 3) indicate that the maximum energy harvesting efficiency occurs at 0.9 GHz, which is comparable to the frequency predicted by the absorption cross section. The power density range is well above what would typically be expected to be available from ambient RF signals and thus would only be found within close proximity (<100m) to a strong RF source such as a cell phone tower or right next to a weak RF source. In general, the efficiency of the sample increases with incident power density. However, when the ground plane is present, there is a point where the efficiency begins to diminish with increased power density (the red curve in figure 3f). When the ground plane is placed at the optimum distance (4cm), the energy harvesting efficiency improves considerably (compare figures 3a-3c with 3d-3f) and goes well over 100% at times. This indicates that the ground plane has caused the effective area of the rectenna to become larger than its geometric area.

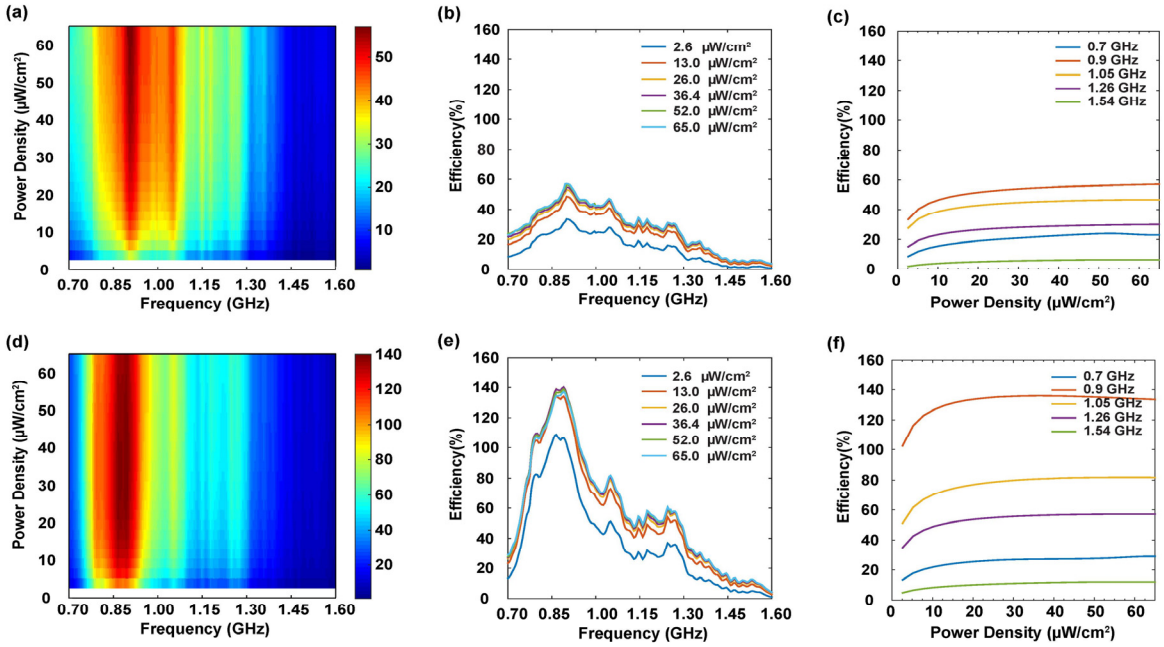

Figure 3 - Experimental measurements of energy harvesting efficiency as a function of frequency and power density. (a)-(c) are measurements without the ground plane. (d) - (f) are measurements with the ground plane.

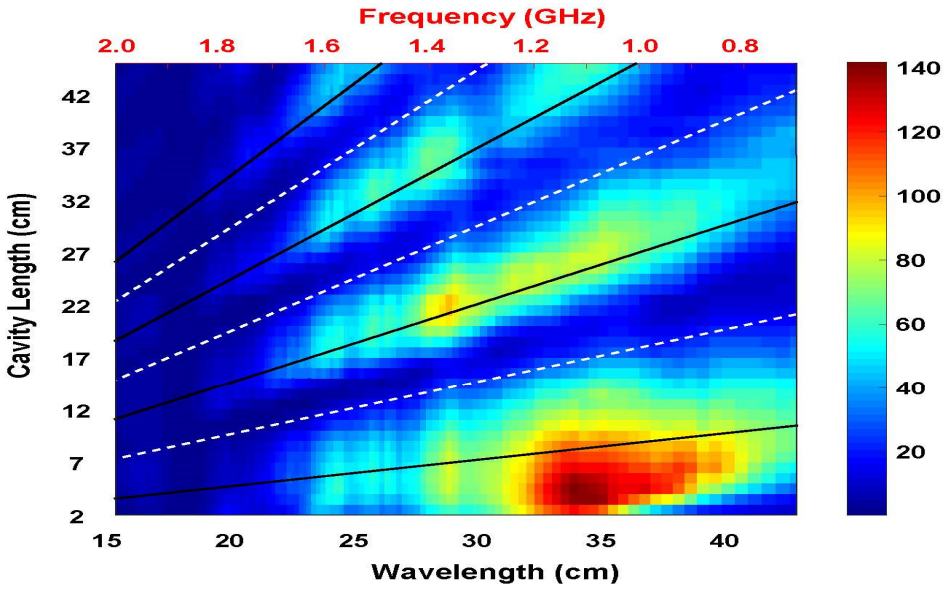

Figure 4 - Measurement of the effect of Fabry-Perot cavity length on energy harvesting efficiency at fixed power density (30 μW/cm²). Solid Lines indicate the theoretical prediction where maximum energy harvesting efficiency would occur for a vacuum-filled cavity with half-open boundary conditions. Dashed lines indicate where energy harvesting maxima would occur for a vacuum-filled cavity with closed boundary conditions. The metamaterial perfect absorber rectenna behaves similarly to a half-open FP cavity. The shortest observed resonance length (λ/8) is less than predicted (λ/4), because the effective index of refraction of the metamaterial surface is larger than one.

Figure 4 demonstrates the efficiency-enhancing effect of the Fabry-Perot cavity created by the rectenna and the ground plane. Examining the relationship between the efficiency, ground plane distance, and RF wavelength reveals standing wave patterns resembling that of a resonating cavity with one side closed (ground plane side) and the other side open (rectenna side). In the figure, the standing wave pattern is compared to the theoretical predictions of vacuum-filled Fabry-Perot cavities with half open (solid black lines) and closed (dashed white lines) boundary conditions.

Figures 5a and 5b show the energy harvesting efficiency measurements at power densities that are comparable to what can be found from ambient sources (up to 1.0 $\mu W/cm^2$). The power density levels presented were chosen to correspond to what can be found within relatively short distances from a commercially available high-power (100 mW) omnidirectional WIFI antenna with a maximum gain of 3/2. Now the efficiency is clearly much lower than it was for the high-power measurements. However, the presence of the ground plane increases the efficiency by a large factor (up to 16) in this case. A plot of the ratio of the efficiency with the ground plane to the efficiency without the ground plane, which will be referred to as the enhancement factor, is shown in figure 5c. The presence of the ground plane produces the largest enhancement factor at very low powers (about 0.01 $\mu W/cm^2$, which is at a typical ambient level), but unfortunately the overall efficiency at this level is still very low (only about 1%). At the lowest power density levels the efficiency is no longer enhanced much.

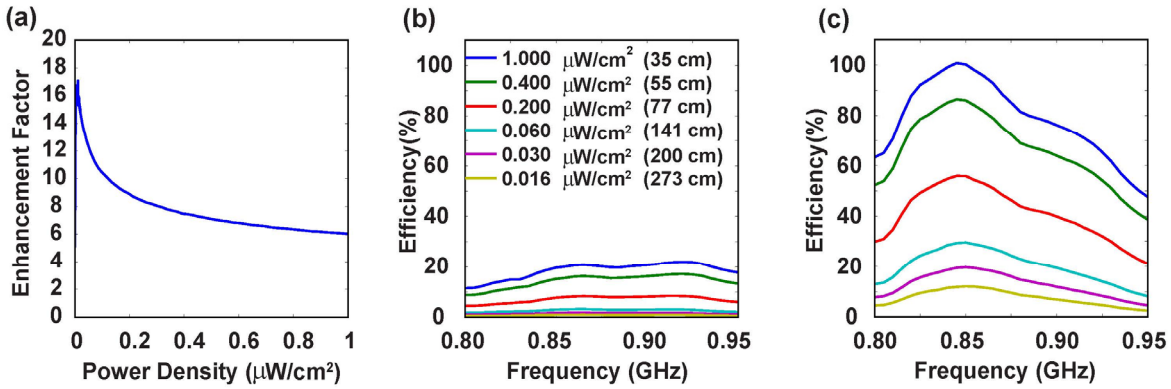

Figure 5 - Measurements corresponding to power densities that would be available at the specified distances from a 100 mW source possessing a transmitting antenna with gain of 3/2. (a) No ground plane. (b) Ground plane present. Same legend as 5a. (c) Enhancement factor; defined as the ratio of power harvested with the ground plane to power harvested without the ground plane. Measured at 0.85 MHz. The peak frequency is slightly different than before because of slight differences in the angle of incidence of the rectenna between measurements.

Discussion

The data indicates several advantages to basing an energy harvesting antenna off of a metamaterial perfect absorber. First, building the diodes into the metamaterial surface results in highly-efficient rectification at the resonance frequency as determined in both the simulated results (figure 2) and the experimental results (figure 3). Alignment of the FP resonance with the natural resonance of the metamaterial surface leads to the best results. Second, the tunability of the metamaterial's dielectric constant allows the rectenna to be designed such that it is impedance-matched to free space, and hence has a reflection coefficient near zero. This improves the absorption and has the added advantage of allowing for a smaller rectenna. Since the surface behaves closely to an open-boundary for the FP cavity,

the resonance length is shorter than for a closed boundary cavity (λ/4 compared to λ/2). The measured FP resonance peak occurred at a wavelength of λ/8 instead of λ/4 (figure 4), because the index of refraction of the material is not quite equal to 1. Third, as evidenced by the measurement in figure 2c, the conducting ground plane increases the voltage across each of the diodes in the rectenna. The effect gets stronger at low power (figure 5c) since it can provide enough of a voltage boost to activate the diodes when the diode threshold voltage would not ordinarily be attained. Once the power gets too low, then the diode threshold can not be met even with the ground plane present. If the power is too high (well above ambient levels), the diodes reach their breakdown voltage and efficiency decreases as shown in figure 3f. Fourth, the ground plane increases the directivity of the antenna (and thus also the effective area) for angles of incidence for which the metamaterial surface is located between the ground plane and the source. However, this comes at the cost of directionality since the ground plane will reflect away any signals coming from angles of incidence for which the ground plane is located between the rectenna and the source.

The point about the ground plane increasing the directivity is important, because it may not be feasible to build an omnidirectional energy harvesting device capable of collecting enough ambient RF power to operate practical devices. Energy harvesting efficiency is proportional to the effective area, which is a function of wavelength and directivity. Since the wavelength will be pre-determined by the source from which energy is being harvested, the only way to increase the effective area is by increasing the directivity. However, it is impossible to simultaneously increase the directivity in all directions because an increase in directivity for some directions necessitates a decrease in others. To demonstrate the difficulty of energy harvesting with a low-directivity antenna, consider a perfectly efficient short dipole antenna with a directivity of 1.5; a well-known omnidirectional antenna. The total amount of energy that can be harvested at 900 MHz with a relatively high incident power density of 0.1 $\mu W/cm^2$ is about 13 μW. This is well below the 100 μW threshold that might be needed for typical devices as suggested by Visser[19]. In circumstances where the location of the ambient radiation source is known, it would be beneficial to instead use a highly directive receiving antenna aimed at the source to maximize the effective area.

Future improvements in the design will be aimed at increasing the effective area, and improving the rectification efficiency of the antenna. The effective area may be improved by considering alternate structures and geometrical arrangements. Alternate structures could allow for polarization-independent energy harvesting. It's possible that the SRRs in the sample may be placed too close together such that the capturing areas of adjacent rings overlap and thus reduce the amount of power captured by each ring. A higher amount of power captured per ring should make it easier for the diodes to activate. Array theory for antennas suggests that the SRR's should be placed about half a wavelength apart for optimal power capture. To improve rectification efficiency, it may be worthwhile to replace the Schottky diodes with spin diodes[20] due to their superior zero-bias resistance. Another possibility is to replace the diodes with more complicated rectifying circuits that will increase DC voltage such as the Greinacher circuit[17].

Conclusion

Designing RF harvesting rectennas based off of metamaterial perfect absorbers is a promising solution for collecting ambient RF energy in low power density environments because they are tunable, highly efficient, and electrically small. However, to operate practical devices, the efficiency needs to be improved further, particularly in regards to overcoming the zero-bias resistance to activate the diodes. The reflecting ground plane component of the metamaterial rectenna dramatically improves the RF-DC conversion efficiency, especially for lower available power densities, by helping to overcome the zero-bias resistance and by increasing the effective area of the antenna for certain angles of incidence. The

biggest disadvantage of the ground plane is that it precludes omnidirectionality, although this may be unavoidable for effective energy harvesting.

Method

Fabrication

The metamaterial samples are fabricated using photolithography techniques. First, a mask that outlines a copper ring structure containing two gaps is designed and created. The dimensions of the unit cell and the design of the complete sample are shown in figure 1. The mask is placed on top of a copper-plated piece of printed circuit board composed of FR4 substrate which is then placed under an exposure lamp for 10 minutes. The mask is removed and the sample is washed with a diluted developer solution and then bathed in ferric chloride until any copper that was not shielded by the mask has been removed. After the excess copper has been removed, Skyworks SMS 7630 Schottky diodes are soldered across the right-hand gap of each ring with the orientations indicated by the red triangles on the unit cell shown in figure 1. The copper rings in the metamaterial capture RF waves, which are rectified by the diodes to deliver DC power to a load. The configuration of an antenna with a built-in rectification circuit is commonly referred to as a rectenna.

It is important to note that the rectenna sample is very sensitive to the polarization and angle of incidence of incoming RF signals. Since the sample is composed of an array of copper loops, electrical current can be driven by both the electric and magnetic fields. The orientation of the fields with respect to the sample determines which resonance modes will be excited and at which frequency they will occur. As such, deviations in the angle of incidence and/or polarization affect both the amount of energy harvested and the optimum frequency.

Experimental Setup

A signal generator produces a sinusoidal RF signal and sweeps both frequency and output power with frequencies ranging from 0.7-2.0 GHz. The signal is sent to an amplifier which increases the signal strength by about 45 dB (depending on the frequency). A small fraction of the amplified signal is extracted with a coupler, and then measured with a signal analyzer to determine the strength of the amplified signal. The amplified signal is transmitted by an SAS-570 horn antenna at normal incidence to the rectenna sample located about 380 cm away from the transmitting antenna. A metal ground plane is placed behind the sample with the purpose of creating a Fabry-Perot cavity to increase the amount of captured RF radiation. The experiment takes place within an anechoic chamber to isolate the rectenna sample from multi-path interference and outside signals. The rectenna sample is connected to a decade resistor box, which is used as a proxy for a device that DC power will be delivered to.

Theory

The DC power (P_{DC}) harvested from the sample can be determined simply by measuring the DC voltage (V) across the load with a multimeter and applying the well-known equation $P_{DC} = V^2/R$. A program written with LabVIEW is used to sweep over the appropriate frequency and power ranges while recording the voltage across the load to measure the efficiency (η) as described below. The efficiency is measured by taking the ratio of the rectenna's effective area to its geometric area. Effective area is

defined as the ratio of the power absorbed at the load divided by the Poynting vector at the location of the rectenna and is given by[21]:

$$\frac{P_{DC}}{S} \tag{1}$$

To determine the poynting vector at the location of the rectenna sample, the following equation from antenna theory is used[21]:

$$S = \frac{P_t \times G_t}{4\pi D^2} \tag{2}$$

P_t is the power radiated from the transmitting antenna, G_t is the linear gain of the transmitting antenna, and D is the distance between the transmitting antenna and the sample. The gain of the transmitting antenna was determined by using the standard 3-antenna technique for gain measurements[21].

Putting this all together leads to the following definition which will be called the energy harvesting efficiency:

$$\eta = \frac{\frac{V^2}{R}}{S \times A_{geo}} \times 100\% \tag{3}$$

This is actually the same way that aperture efficiency is defined for aperture antennas. For aperture antennas the efficiency will always be less than 100%, but for non-aperture antennas the effective area can be larger than the geometric area (a classic example of this is a dipole antenna). In such cases this definition of efficiency can yield results greater than 100%. It is important to recognize that this would not imply that the receiving antenna is capturing more power than is incident on it.

To characterize the efficiency of an energy harvesting system completely, the RF to DC conversion efficiency ($\eta_{RF\text{-}DC}$) should also be determined. $\eta_{RF\text{-}DC}$ indicates how much of the captured energy was successfully converted to DC power. This is the ratio of the DC power harvested to the RF power captured by the antenna.

$$\eta_{RF-DC} = \frac{P_{DC}}{P_{RF}} \times 100\% \tag{4}$$

Due to the nonlinearity of the diodes contained within the rectenna, a way to determine P_{RF} has not been determined, and so the focus of this paper is only on measuring the energy harvesting efficiency, η. Methods for determining P_{RF} will be explored in future experiments.

Experimental Concerns

There are a few considerations concerning the accuracy of the data. First, standing waves are generated between the transmitting antenna and the sample. This will result in higher power transfer at some frequencies and lower power transfer at others for a given distance between the sample and the transmitting horn antenna. It's estimated that this affects the power received by the sample varying by as much as ±10%. However, this effect is minimal at the frequency for which the power transfer is most efficient, since this is when the sample's reflection coefficient is at its smallest. Hence, the measurements taken at the frequency of peak efficiency will be the most accurate. Second, there is some power transmitted to the sample due to a second harmonic generated by the amplifier used for the transmitting antenna. The harmonic transmits a maximum of 5% of the total power radiated from the transmitting antenna, which occurs at the largest power densities that can be produced by the system. However, the harmonic signals are of frequencies that are inefficiently absorbed by the sample and thus are a very small contribution to the absorbed power. This effect is essentially negligible even at the highest measured power densities. Lastly, the precision of the transmitting system is not as good at high power due to limitations of the power settings of the signal generator. This results in some efficiency measurements appearing artificially lower than they should be. This effect is negligible when the power density is under 35 $\mu W/cm^2$. It is also negligible for power densities up to 50 $\mu W/cm^2$ while the frequency is less than about 1.3 GHz.

Some simplifications to this experiment have been made that slightly reduced the accuracy of the results, but greatly eased taking measurements. Firstly, since the impedance of the diodes is a function of both frequency and power, the impedance of the load should be adjusted accordingly for each measurement to maximize the power transferred to the load. We found that when the load was set to 1000 ohms, that the deviations from optimal efficiency were very small with changes in frequency and power. Secondly, the inclusion of a power management circuit might be necessary for real world applications to compensate for fluctuations in the signal being harvested. This is left out of the experiment so that we can focus on the energy harvesting efficiency of the rectenna alone.

Simulations

To supplement the experimental results, the absorption properties of the rectenna are simulated using CST Microwave Studio. Limitations in integrating circuit models into CST for plane wave simulations restricted us to using the Schottky diode model shown in figure 1, which is a simplified version of one used by Keyrouz et al[18]. The parameters for the model were obtained from the manufacturer's specifications. A broadband radar cross section monitor is used during a transient solver simulation of a plane wave to measure the absorption cross section (ACS) of the rectenna, which gives a rough indication of which frequencies the energy harvesting efficiency will be best. For the ACS calculation, the idealized diode in the equivalent circuit model is omitted to avoid generation of harmonics that interfere with the results. A surface current monitor is then used to identify the resonance modes of the rectenna at its peak energy harvesting frequency. Simulating the absorption cross section is primarily useful for estimating the peak frequencies for energy harvesting, but it is not good for predicting the correct proportionality for the efficiency across all frequencies. This is partly because of the limitations of the simple diode model used in the simulation. Another reason that the proportions may differ from measurements is that the absorption cross section includes energy losses in the rectenna, whereas the efficiency refers only to power absorbed in the load. As an additional test for energy harvesting capability of the sample, an incident Gaussian pulse was simulated and power delivered to a load was calculated. Although this technique will not indicate which frequency is best for producing DC power, it helps for getting an idea about how well the sample rectifies captured waves.

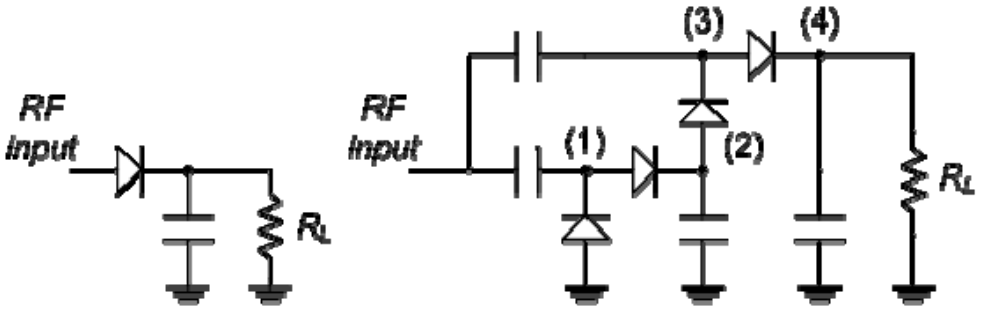
Rectenna Design

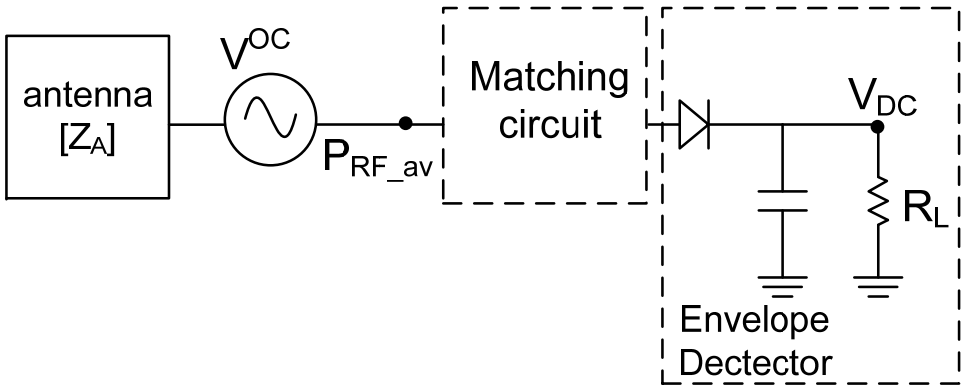
- Rectifier circuits: envelope detector, charge pump circuits
- Schottky diodes, low / zero barrier diodes



Reported UHF rectifier efficiencies for available input power levels in the order of 10 uW are near 20%, and increase to >50% for available power levels of 100uW.

Rectenna Design

- Rectenna optimization using the RECEIVE antenna Thevenin (or Norton) equivalent circuit



- Multiple goal harmonic balance for optimizing the RF-DC conversion efficiency

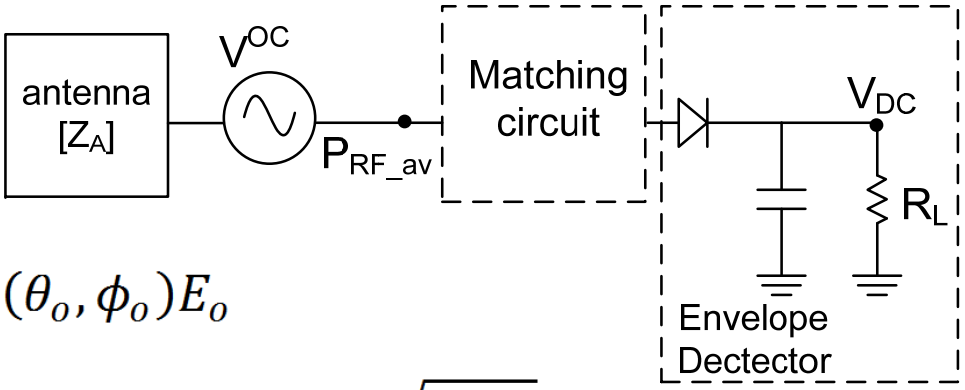
$$\eta = \frac{P_{DC}}{P_{RF,av}} = \frac{V_{DC}^2}{P_{RF,av} R_L}$$

Georgiadis, A.; Andia Vera, G.; Collado, A., "Rectenna design and optimization using reciprocity theory and harmonic balance analysis for electromagnetic (EM) energy harvesting," *Antennas and Wireless Propagation Letters, IEEE* , vol.9, no., pp.444,446, 2010

Rectenna Design

- Open circuit voltage maybe calculated using reciprocity theory

$$\eta = \frac{P_{DC}}{P_{RF,av}} = \frac{V_{DC}^2}{P_{RF,av} R_L}$$



$$V_{V,H}^{oc}(\theta_o, \phi_o, S) = \frac{4\pi}{jk\eta_o} F_{V,H}(\theta_o, \phi_o) E_o$$

$$E_o = \sqrt{2\eta_o S}$$

$$P_{av} = \frac{1}{4} V^{oc\,*} [Z_A + Z_A^*]^{-1} V^{oc}$$

$$\eta_o = 120\pi$$

- Harmonic balance for the optimization of the RF-DC conversion efficiency

Georgiadis, A.; Andia Vera, G.; Collado, A., "Rectenna design and optimization using reciprocity theory and harmonic balance analysis for electromagnetic (EM) energy harvesting," *Antennas and Wireless Propagation Letters, IEEE* , vol.9, no., pp.444,446, 2010

Rectenna Design

- The open circuit voltage *MAGNITUDE* can also be calculated using the antenna effective area

$$E_o = \sqrt{2\eta_o S}$$

$$V_{V,H}^{oc}(\theta_o, \phi_o, S) = \frac{4\pi}{jk\eta_o} F_{V,H}(\theta_o, \phi_o) E_o$$

$$A_e = \frac{\lambda^2}{4\pi} G \qquad P_{av} = A_e S$$

$$P_{av} = A_e S = \frac{\lambda^2}{8\pi\eta_o} G(\theta_o, \phi_o) E_o^2$$

HOW DO THEY COMPARE ?

$$V_{oc} = \sqrt{8 P_{av} R_A} = \sqrt{\frac{G(\theta_o, \phi_o) R_A}{\pi\eta_o}} \lambda E_o$$

Conclusion

- Multi-band rectennas allow wider application
- Reactive networks capable of minimizing rectenna efficiency sensitivity to load variation
- High PAPR leads to higher efficiency
- Spatial power combining for WPT transmitters

A Rethinking of RF Wireless Power Transfer: How to Re-Green the Future Networks?

Ha-Vu Tran[1] and Georges Kaddoum[1]

arXiv:1711.01320v1 [cs.IT] 3 Nov 2017

***Abstract*—Green radio communication is an emerging topic since the overall footprint of information and communication technology (ICT) services is predicted to triple between 2007 and 2020. Given this research line, energy harvesting (EH) and wireless power transfer (WPT) networks can be evaluated as promising approaches. In this paper, an overview of recent trends for future green networks on the platforms of EH and WPT is provided. By rethinking the application of radio frequency (RF)-WPT, a new concept, namely *green* RF-WTP, is introduced. Accordingly, opening challenges and promising combinations among current technologies, such as small-cell, millimeter (mm)-wave, and Internet of Things (IoT) networks, are discussed in details to seek solutions for the question with how to re-green the future networks?**

I. Introduction

Over past few years, green radio communication has drawn much attention from the research community, and it has strong impacts on various aspects, such as telecom business, wireless technologies, and natural environments. Specifically, the electricity cost and CO_2 emissions have been increasing due to wireless network operation. For instance, the number of base stations (BSs) is more than 4 million, and each BS consumes an average of 25MWh per year (estimated approximate 80 percent of the total network's power consumption). Bearing in mind the environmental perspective, generating sufficient power to supply the networks causes a significant amount of CO_2 footprint. Particularly, the overall footprint of information and communication technology (ICT) services, e.g., computer, cell phone, and satellite networks, is predicted to triple by 2020 [1].

Recently, towards a future green world, energy harvesting (EH) technique has the potential to deal with the problem of energy inefficiency [2]-[5]. The main advantages of this approach can be presented in two-fold. First, the EH techniques harnesses green energy from natural sources, e.g., solar and wind. Thus, it contributes to reducing the overall footprint in order to protect surrounding environments. Nowadays, the popularity of using conventional energy sources, e.g., diesel, still dominates the use of the green sources. However, although the overall implementation cost of EH solutions is higher than that of conventional ones, this cost might be compensated after several years of operation. Second, another main challenge in future networks is prolonging the lifetime of smart user devices. Given this concern, EH networks take a tremendous advantage in various specific applications. For instance, EH is an efficient solution for reducing battery replacement costs in wireless sensor networks. Also, it can recharge the devices working in areas where the traditional power supply is infeasible, e.g., robotic devices working in toxic environments. Nevertheless, the amount of harvested energy from natural resources, such as solar and wind, may vary randomly over time and depend on locations and weather conditions. In other words, harvesting energy from these sources is not controllable and sustainable. For instance, there exists insufficient sunlight at night to generate energy, or it is difficult for indoor devices to harvest solar energy. In this context, radio frequency (RF) wireless power transfer (WPT) might be a promising approach to overcome such a drawback.

In this paper, we provide a comprehensive review to address the mentioned question of regreening the future world. In more specific details, the main contributions of this paper can be summarized as follows. First, by rethinking the use of RF-WPT, a concept so-called *green* RF-WTP is introduced. Second, a vision of future green networks based on the platforms of EH and green RF-WPT is presented. Thus, we discuss potential scenarios with the purpose of bridging green resources to indoor energy-hungry devices in the networks. Third, applications of various interesting concepts, such as small-cell, mm-wave, internet of things (IoT), etc., networks are highlighted. Given this concern, the challenges on each concept are identified. Further, we discuss some attractive combinations of the existing concepts, such as a mixture of full-duplex, RF-WPT, and mm-wave, and investigate how the latter works together properly. To this end, promising trends in future are drawn to provide solutions for future re-greened networks.

II. Energy Harvesting and Green RF Wireless Power Transfer

In this section, an overview of EH models and a discuss on green RF wireless power transfer are shown.

A. EH Models

EH methodology might be described by harnessing energy from surrounding environments or thermal and mechanical sources, and then converting the latter into electrical energy. The generated electrical current can be used to supply devices

[1]Ha-Vu Tran and Georges Kaddoum are with University of Québec, ÉTS engineering school, LACIME Laboratory, 1100 Notre-Dame west, H3C 1K3, Montreal, Canada. Email: {ha-vu.tran.1@ens.etsmtl.ca, georges.kaddoum@etsmtl.ca.} This work has been supported by NSERC discovery grant 435243 - 2013.

by RF wireless power transfer. Generally speaking, EH models can be classified into two architectures with harvest-use, and harvest-store-use. In the first one, energy is harvested, and then is used instantly. Besides, given the second one, energy is harvested as much as possible and then stored for future uses. In the following, we discuss the characteristics of such models.

In the harvest-use architecture, the EH systems directly supply devices. To guarantee the operation of the devices, the power output of the EH systems should be higher than the threshold of minimum working requirements. Otherwise, the devices would be disabled because there is not enough power supplied. As a consequence, unanticipated fluctuation in harvesting capacity close to threshold yields the working devices to vacillate in ON and OFF states.

Further, the harvest-store-use model includes a component storing harvested energy and also powering the connected devices. Thanks to the storage, the energy can be harvested until sufficient for supplying the devices. Moreover, such energy might be stored for later uses when there is lack of produced energy or the devices need to increase the working performance. The storage component might include two parts of primary and secondary storages. In this context, the secondary storage can be seen as a backup one. In particular, the harvest-store-use system can make non-stable but foreseeable energy sources, such as solar and wind, more favorable in uses.

B. Green RF Wireless Power Transfer

Over the last decade, solar, wind, mechanical, and thermal energy can be considered as the most efficient resources generating green energy usable for wireless networks. However, the main drawback of such sources is the lack of stability. In the quest for an alternative solution, the research community has explored that radio signals belonging to a frequency range from 300 GHz to 3 kHz can be used to carry energy over the air [3], [6], [7]. On this basis, a transmitter can proactively recharge wireless devices by sending energy-bearing RF signals whenever it is necessary. This is the principle of a so-called RF-WPT technique.

In fact, it is well-known that EH is a green technique since it helps to reduce the footprint. However, in a shared vision, the RF-WPT technique seems to be harmful to surrounding environments because it costs electricity to generate RF signals, and causes electromagnetic pollution to the human body as well as interferences to data transmission. By rethinking the role of RF-WTP technique, we suggest that the RF-WTP can be seen as green *iff* (i) the RF signal carrying energy is generated using power harvested from green resources (for example, BSs are connected with outdoor energy harvesters to harvest-and-store green energy and then use such energy to wirelessly recharge to indoor devices using RF signals), and (ii) a tight restriction is applied for increasing the transmit power (i.e., following the equivalent isotropically radiated power (EIRP) requirement approved by Federal Communications Commission). In this work, the RF-WTP satisfying such two conditions is so-called the *green* RF-WTP. The characteristics of the green RF-WPT technique can be listed as follows

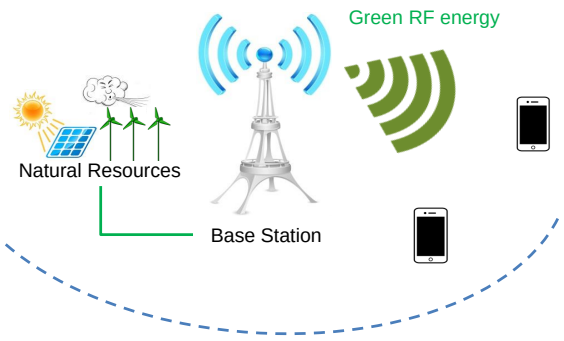

Fig. 1. Green RF-WPT.

- The green RF-WPT technique plays a role as a bridge between green energy sources and energy-hunger devices.
- The energy harvested at a receiver is foreseeable.
- The amount of harvested energy belongs to transmit power, propagation loss, and wavelength.

Indeed, it is expected that the green RF resource is one of the most interesting candidates for future applications.

III. A Vision of Future Green and EH Networks

A. A predicted model of future green networks with EH

Future networks, e.g., 5G, are expected to support multimedia applications to achieve 1000-fold higher throughput, 1000-fold higher mobile data per unit area, and 10-fold longer lifetime of devices over the fourth generation (4G) networks [4], [5]. To adapt this progress, the design of new cellular networks tends to a new form embracing a large-scale deployment of small-cells. Generally, the small-cells can be classified into distinct types including femtocell, microcell and picocell. Indeed, the multi-tier HetNet attains a promising gain in terms of spectral and energy efficiencies due to low power consumption and good ubiquitous connectivities [8].

On the other hand, nowadays, the development of wireless networks has broken the limits of power consumption, especially in cellular networks. Moreover, the energy cost and CO_2 emissions have been promptly growing due to the network operation. Specifically, this has inspired researchers with a challenging topic so-called future green wireless networks. As a promising solution, EH techniques exploit natural sources, and then contribute to reducing the overall footprint and extending the network lifetime. Nevertheless, the natural resources may not be always available to all devices. For instance, it is difficult for indoor devices to harvest solar energy. This yields another trend that BSs connected with outdoor harvesters which can harvest-and-store green energy when natural resources are available. Afterwards, BSs use such energy to wirelessly charge user devices using RF signals.

Another approach to future green networks is the concept of green IoT [10]. In fact, IoT is an emerging trend that billions of identified low-power devices, e.g., sensor nodes, are connected to each other without the need for human interaction. It can provide solutions to cut CO_2 emissions, reduce

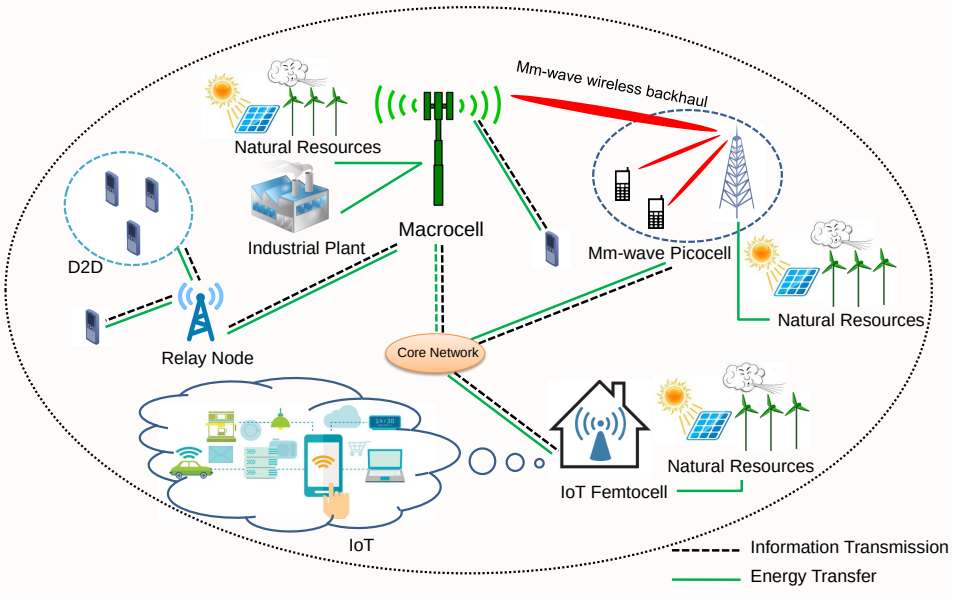

Fig. 2. A Future Green Network.

electromagnetic pollutions and improve energy efficiency. For instance, with tracking of motion sensors, the lights in rooms where there is no one inside would be turned off. Also, the green IoT technology can monitor energy usage in hi-tech buildings to reduce wasted energy. In fact, the green IoT is expected to enhance all technical, economical and environmental benefits. In particular, IoT network architectures mainly rely on the platforms of wireless sensor networks (WSNs), and cooperative networks to connect devices together [9]. In this concern, battery recharging for a large number of IoT devices is challenging indeed. Therefore, enabling the green IoT concept towards future networks requires advanced solutions of prolonging device's life-time, resource managements, and energy-efficient communication protocols.

Taking all the problems of interest into account, in the following, we further discuss several potential concepts towards green future networks as shown in Fig. 2. Specifically, challenges in implementing each concept are identified.

B. Green radio communications: Main concepts and discussions

1) Full-duplex networks: as mentioned, indoor devices which might not harvest green energy directly can be wirelessly powered by RF signals sent from BSs. Accordingly, this has inspired a combination of the full-duplex and simultaneous wireless information and power transfer (SWIPT) techniques. At the same time, the devices can receive energy in the downlink transmission while conveying information in the uplink connections to boost spectral efficiency.

Furthermore, we discuss two potential research issues of full-duplex SWIPT systems. First, the antennas at the full-duplex node are conventionally divided into transmit and receive sets. To improve the performance of SWIPT systems, an advanced form of the full-duplex technique that each antenna can simultaneously send information/energy and receive energy/information in the same frequency band is highly desirable. Indeed, this approach mainly depends on new hardware designs and new innovation of self-interference cancellation techniques. Second, full-duplex SWIPT small-cell base station can provide a promising approach regarding wireless backhauls in HetNets. In downlinks, the small-cell BS can receive information from macro-cell and transmit information/energy to users simultaneously. In uplinks, the small-cell BS can receive information/energy and send information to macro-cell at the same time. On this basis, the small-cell BSs do not require a separate frequency band of backhaul connections. Hence, resources and implementing costs are reduced.

2) Millimeter-wave networks: benefitting from mm-wave transmission, the overall electromagnetic field (EMF) exposure and power consumption per bit transmitted of networks are reduced due to a higher free-space attenuation at the mm-wave frequency, high directive antennas, and short distance links. Therefore, mm-wave communication has been considered as a primary candidate for green cellular networks in future. This approach is expected to achieve multi-gigabit data rates due to large spectrum resources at a ultra-high frequency band. Specifically, EH devices can extract energy from incident RF signals. Moreover, in mm-wave systems, many BSs are densely deployed to ensure proper coverage to ultra-high frequency networks. Thus, this can be attractive for the EH devices to potentially harvest sufficient energy.

In ultra-high frequency bands, the mm-wave signals mainly suffer from the propagation loss, such as poor penetration and diffraction. To make mm-wave networks more favorable for SWIPT, beamforming techniques can be a promising solution to increase the network coverage and system performance. Moreover, in mm-wave networks, although the small wavelength signals allow large antenna arrays to offer high beamforming gains, they require the alignment between transmit and receive beams to reach the highest possible

performance. In these concerns, there is a non-trivial problem of the beamwidth design. In practice, the length of beam-searching overhead is directly proportional to the number of beamformer candidates. The narrower beamwidth is, the more number of the beamformer candidates is, and then the longer overhead is. This leads the time of data transmission to be decreased. In constrast, the wider beamwidth means that it is easier for transmit and receive beams to be aligned, and the beam-searching process is sped up, however, the beamforming gain is reduced. Therefore, future works should consider the impact of beamwidth in various contexts to maximize the SWIPT system performance.

3) Wireless sensor networks: over the last few years, the trend for WSNs is one of the most attractive topics due to flexible installation and convenient maintenance. Accordingly, many standards such as WirelessHART, WIA-PA, and ISA100.11a have been proposed. Particularly, the IoT technology is mainly implemented on the WSN platform. With an integration of IoT with sensors, sensor devices can be interconnected with the global Internet in order to provide solutions for future networks, such as reducing wasted energy in hi-tech buidings.

Specifically, replacing or charging the batteries in IoT WSNs may take time and costs due to a large number of sensors, and this process becomes dangerous for humans in hazardous environments. As a result, the EH from natural resources and RF signals for WNSs have been considered as a promising solution to prolong the sensor's lifetime.

As the main distinction from conventional WSNs, EH-WSNs require new criteria in the fairness between information transfer and EH requirements. In fact, the network can fail to adapt the EH requirement while ensuring other system performances, such as throughput, delay or packet loss. As a result, leveraging between data transmission and EH is one of the critical concerns in designing EH-WSNs. Therefore, efficient resource allocation schemes should take such a problem into account to achieve high energy efficiency for EH-WSNs.

4) Cooperative relay networks: in recent, the cooperative relay network have been evaluated as one of the main core networks for the IoT technology where IoT nodes can communicate with each other and forward information and energy to the remote nodes. Up to now, many mature research works of cooperative communication have clearly shown that the relay can be implemented not only to extend the coverage range but also to improve the performance of wireless communications. Further, the concept of EH/WPT relay networks has been proposed and studied to enhance the lifetime of devices and overall performance of wireless networks. In cooperative EH/WPT relay networks, improving performance gain on the physical layer is one of the main research directions. Hence, most previous efforts attempt to design novel schemes regarding relay operation policies, power allocation, precoder optimization and relay selection.

Considering existing challenges, the enhancement for both spectral and energy efficiencies in cooperative relay networks with the green RF-WTP is remarkable. In this concern, full-duplex or two-way relaying methods might be a promising solution. Further, it is suggested that developed resource allocation schemes should consider the influence of incomplete channel state information (CSI) (e.g., the relay nodes have a partial user's CSI), and the energy status at the relay nodes and users (e.g., the available energy, current power consumption, predicted energy harvested from natural resources or RF signals, etc.) on system performance.

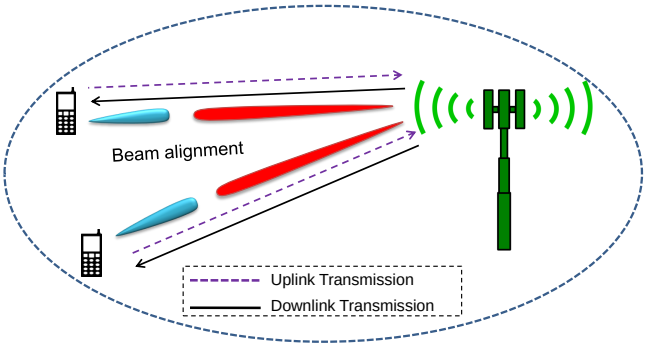

Fig. 3. Mm-wave SWIPT networks with full-duplex communications.

IV. Future Research Issues

In the prior section, several challenges of each concept have been presented. In future networks, since wireless communication systems are expected to be a mixture of various novel system concepts to enhance both the spectral and energy efficiencies, some interesting combinations of the existing concepts are discussed as follows.

A. When full-duplex communications meet mm-wave SWIPT networks?

A combination of mm-wave and full-duplex SWIPT systems, as shown in Fig. 3, seems to be interesting. Most of the recent research on full-duplex SWIPT systems mainly address the communications in conventional frequency bands. However, in mm-wave frequency bands, there are two main challenges need to be discussed. First, the practical implementation of mm-wave full-duplex SWIPT should be investigated with a bandwidth of several GHz. Second, in mm-wave networks, the communication is inherently directional. Therefore, at both the transmission and reception sides, the directional antenna should be used. As a result, the node structure should be re-considered according to the characteristics of mm-wave signals. To reduce the cost of antennas (i.e. about parabolic antennas), one of the efficient solutions is to employ transmit and receive beams to limit self-interference. Therefore, the future objectives should address:

- studying how the beamwidth affects the beam alignment, beamforming gain and beam-searching process,
- investigating the performance trade-off between self-interference and data transmission time,
- and then properly allocating available resources to optimize system performance.

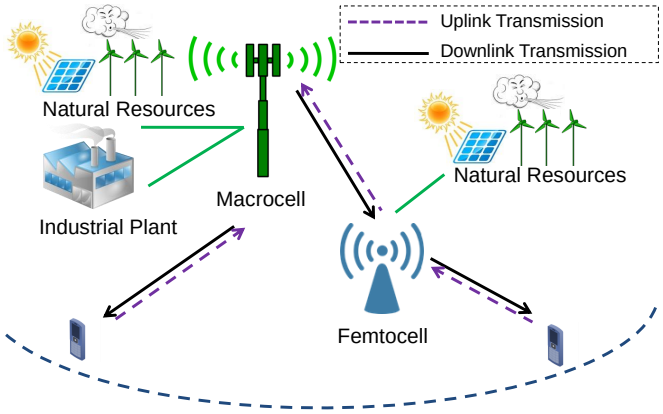

Fig. 4. SWIPT and EH HetNets with the full-duplex technique.

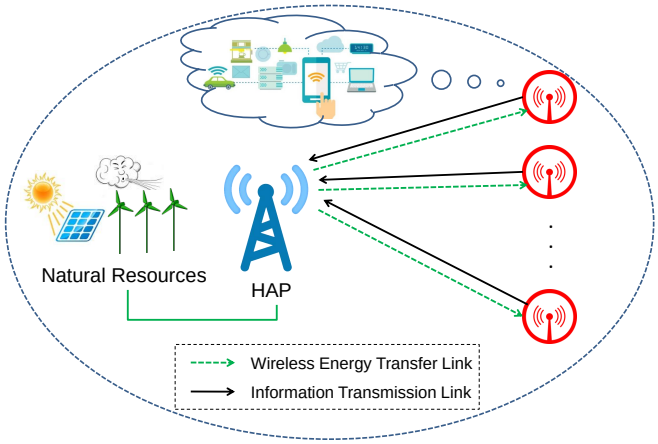

Fig. 5. RF-WPT Internet of Things networks.

B. What are potential scenarios for SWIPT and EH HetNets with the full-duplex technique?

Full-duplex EH-SWIPT HetNets may bring a bright, however, challenging approach. Given this concern, in Fig. 4, a macro-cell BS harvests energy from natural sources and then communicates with a small-cell BS. On the other hand, whereas the small-cell BS receives information from the macro-cell, it transmits information/energy to the users at the same time. In another case, the small-cell BS transmits information to the macro-cell while it receives information from the user simultaneously. Given these scenarios, the sytem benefits from an enhanced spectral efficiency, however, there appear a lot of interference sources, e.g., self-, inter-cell and intra-cell interferences due to full-duplex communications. Specifically, dealing with downlink-to-uplink interference is a big challenge since the downlink power dominates the uplink one in general. Therefore, using optimization frameworks, future works need to focus on:

- designing new self-interference cancellation techniques,
- managing the downlink-to-uplink interference,
- allocating resources to optimize the system performance in terms of the information and power transfer.

C. What are the main concerns of wirelessly powering Internet of Things networks?

Due to large-scale deployments of IoT networks, replacing or recharging the device's battery is one of the main challenges. Specifically, a large number of IoT sensors are implemented in indoor locations where natural resources might be not available to harvest directly. In this context, the green RF-WPT is a promising candidate for prolonging the lifetime of the IoT low-power devices. Thus, this implies a scenario as illustrated in Fig. 5 where a sink node is responsible for harvesting energy from natural resources and then wirelessly transferring power to devices in a IoT wireless sensor network. In addition, the devices can communicate with each other. Given the model, some important concerns need to be addressed as follows.

- scheduling the power transfer to energy-hungry users according to the harvested energy at the sink node,
- exploiting interference from ambient environments to improve the EH performance,
- maximizing the information performance while satisfying EH requirements.

V. Concluding Remarks

In this work, we have presented a review of promising trends towards future green networks. Based on the platform of EH techniques, several potential concepts such as HetNet, mm-wave and IoT networks, have been presented. In particular, we discuss a promising architecture, so-called green RF-WPT. In fact, the latter plays a crucial role as a bridge between natural energy resources and smart energy-hungry devices. Accordingly, we have shown a vision of future green networks in which smart devices can be recharged by green resources even when they cannot harvest energy directly. Furthermore, to facilitate the regreening process while adopting intensive system performance required in future networks, the combinations of techniques, such as SWIPT, mm-wave, full-duplex, can bring outstanding outcomes. Given this concern, we have identified some challenges in mixing the potential concepts, and discussed how they can work together. Indeed, it is expected that the green RF-WPT-based approaches can be one of the potential solutions for regreening the future ICT world.

Keywords: energy harvesting and wireless power transfer, rectennas, printed dipole array, satellite application

Abstract

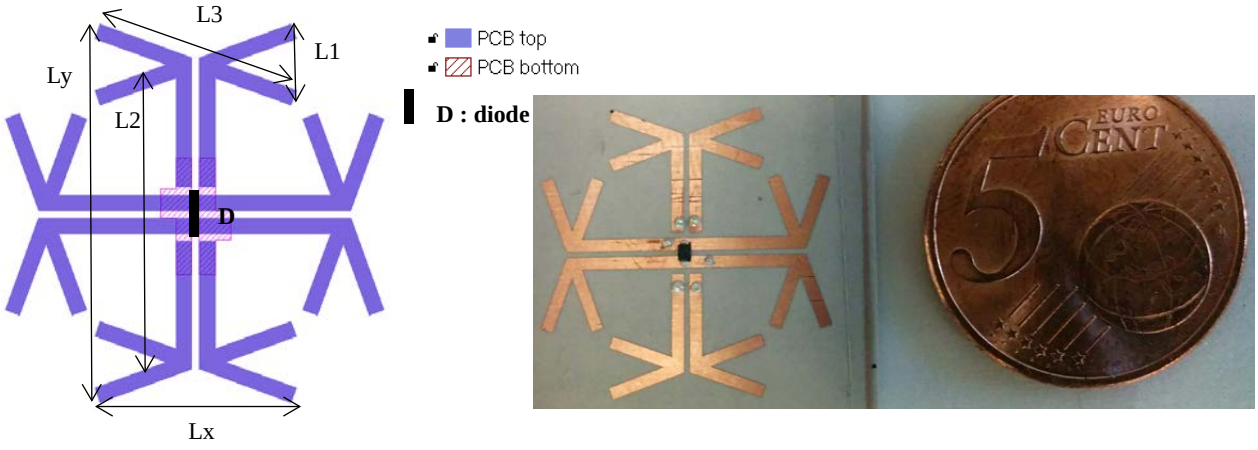
This paper addresses recent results obtained by using cross dipole rectennas designed for Ku band. The targeted application is the harvesting of the spill-over losses of microwave antennas in order to power autonomous wireless sensors used for satellite health monitoring.

Introduction

Recently, the harvesting of the spill-over losses of the microwave antennas was identified as a realistic solution to power autonomous wireless sensors for health monitoring of the antenna panels of the broadcasting satellites [1]. The electromagnetic power radiated by microwave antennas is almost constant and consequently the DC power regulatory circuits should be minimal for the harvesting systems/rectennas. Nevertheless the rectenna should be compact, energetically efficient and robust. Moreover it should be as simple as possible and compatible with space design requirements in terms of thermal, mechanical and radiation safety/immunity behavior. This paper presents recent results obtained in Ku band by using an innovative rectenna topology based on a compact printed cross dipole antenna array and low cost Schottky diode.

1. Topology

The proposed topology is composed by: four cross dipoles array (4CDAA) and a silicon Schottky diode – Skyworks SMS7630 [2]. The PCB layout and a photo of the manufactured rectenna is shown in Fig. 1. The antenna array and the diode are mounted on the top of the PCB while the RF shunt capacitor is mounted on the bottom side of PCB. A reflector metallic plate is added on the bottom side in order to improve the antenna gain. This compact topology (its size is fixed by the size of the antenna array) is an extension of a rectenna using two cross dipole antenna array 2CDAA presented in [3] and a non-resonant matching technique is used. This non-resonant matching is obtained by properly controlling (i) the input impedance of the antenna array and (ii) the input impedance of the rectifier itself (composed by the diode and the low pass RC filter implemented by using the shunt capacitor and the load).

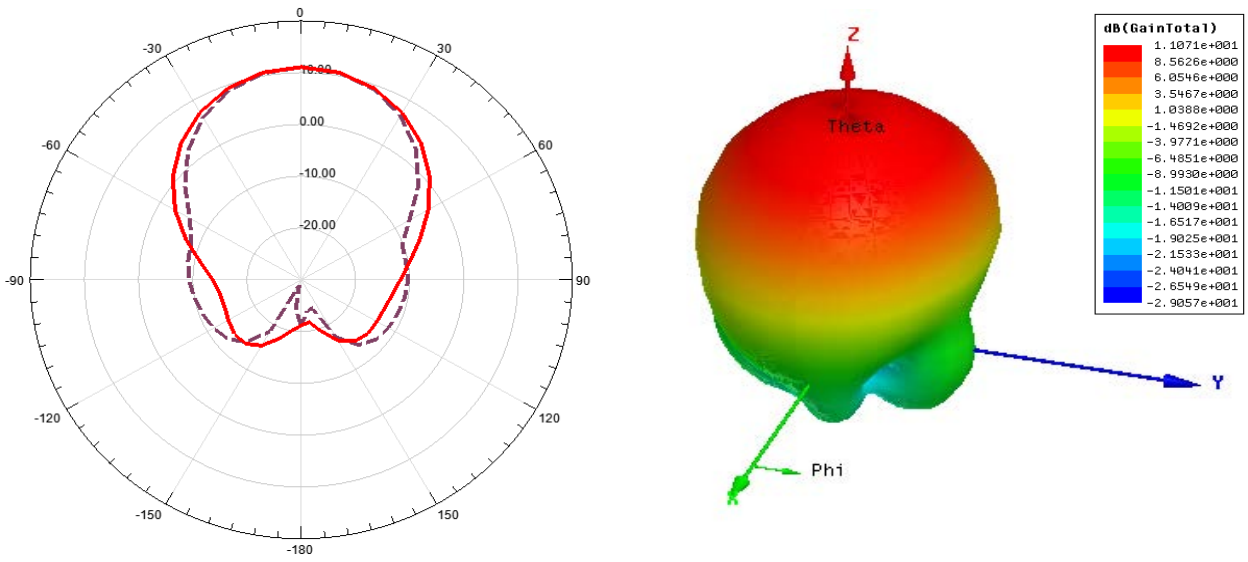


(a) (b)

Fig. 1. (a) Top view (not to scale) of the layout of the 4CDAA rectenna its main geometrical dimensions and (b) a photo of the manufactured rectenna

2. Design and Results

First, the cross dipole antenna was designed and optimized under HFSS software. Six via holes were used (as shown in Fig. 1) in order to connect the top and the bottom part of the PCB. The bottom side of the PCB (used to interconnect the cross dipole antennas and for the mounting of the RF shunt capacitor) was taken into account in the HFSS simulation model. The designed antenna was not measured separately. As shown in Fig. 1, the appropriate feed technique for such an array is based on the use of coplanar striplines. Consequently a complex transition between the coplanar stripline and a coaxial connector has to be designed and implemented before measuring such an antenna in a standard anechoic chamber. The simulated gain (maximum gain: 11dBi) obtained for the 4CDAA at the targeted operating frequency (12 GHz) as well as the 3D radiation pattern are shown in Fig. 2.



a) **b)**

Fig. 2. Simulated gain (HFSS) in the xOz plane (phi=0°, red continous line) and in the xOy plane (phi=90°, black dashed-line of the 4CDAA) at the frequency of 12 GHz.

Second, a generic electrical diode model existing in the ADS software was customized with the following parameters: ohmic resistance R_s = 20Ω, junction capacitance C_{j0} = 0.14 pF, saturation current I_s = 5 µA, forward voltage V_f= 0.34V, reverse breakdown voltage B_v = 2V and the current at reverse breakdown voltage I_{bv}= 0.1mA. This model allows performing an initial design of the PCB bottom side.

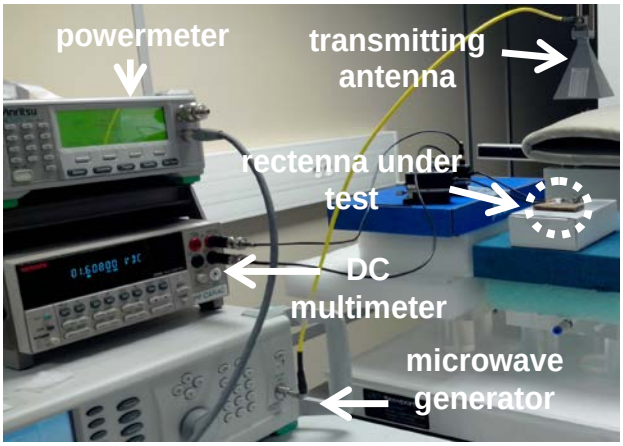
The experimental setup shown in the Fig. 3 was used to characterize the rectenna. A microwave signal generated from an Anritsu MG3694B generator was injected at the input of a horn antenna which illuminated the rectenna under test with a linear polarized E-field. An automatic acquisition routine was implemented in Labview software from National Instruments to speed-up the acquisition process. The harvested DC voltage was measured by using a DC multimeter. The DC power can be computed from the measured DC voltage as long as the load is known. The measured losses due to the coaxial cable and connectors between antenna and the signal generator were in the range of 3 dB in the operating frequency band. The main dimensions of the fabricated rectenna are: L1= 4 mm, L2= 15.3 mm, L3= 10.6 mm, Lx= 10 mm, Ly= 19.5 mm.
The efficiency η (in %) of the rectenna can be computed by using the following definition [4]:

$$\eta = \frac{P_{DC}}{S \cdot A_{eff}} \cdot 100 = \frac{4 \cdot \pi \cdot P_{DC}}{S \cdot G_R \cdot \lambda^2} \cdot 100 \qquad (1)$$

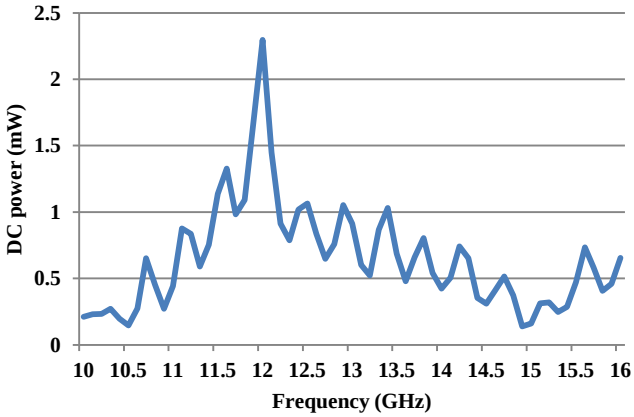
where P_{DC} is the harvested DC power, S is the incident electromagnetic power density, A_{eff} is the antenna effective area, G_R is the gain of the (rectenna's) antenna and λ is the wavelength of the illuminating electromagnetic wave. The power density (µW/cm^2) can be computed as a function of E-field effective value E (V/m) on the antenna surface or as a function of the RF power P_t injected to the input of the transmitting horn antenna of gain G_t and positioned at the distance *d* from the rectenna, as follows:

$$S = \frac{E^2}{120 \cdot \pi} \cdot 100 = \frac{30 \cdot P_t \cdot G_t}{d^2 \cdot 120 \cdot \pi} \cdot 100 \qquad (2)$$

The experimenal results obtained as function of frequency are reported in Fig. 2 for an optimal load RL=300Ω (this is the optimal load for 2CDAA rectenna). The following configuration was used : d=21 cm, G_t=19 dBi, power delivered by the microwave generator: 22 dBm and the injected power at the input of the transmitting horn antenna: 19 dBm. The simulated (by using HFSS software) gain of the receiving antenna (4CDAA) was G_R=11 dBi. The maximum DC power (2.3 mW) was obtained at 12 GHz for RL=300Ω. By using equation (1) and (2) we obtain : E~65.5 V/m, S~1138 μW/cm^2 and the efficiency of the rectenna is 32% at 12GHz.



(a)



(b)

Fig. 3. (a) Experimental setup used to characterize the rectenna and, (b) Measured DC power on a load of 300 Ω as function of frequency.

3. Conclusion

A rectenna based on the use of four cross dipoles antenna array was designed, manufactured and measured. The experimental results demonstrate that a DC power of 2.3 mW can be obtained if the rectenna is illuminated by an electromagnetic field of E=65.5 V/m. This DC power is sufficient to power a wireless sensor (including the sensing device, the power management unit and the wireless tranceiver) for satellite health monitoring application.

ABSTRACT: A rectenna, which consist of a yagi Microstrip antenna along with rectifier circuit is proposed for wireless power transmission in the far field region. The wireless power link is examined between an insitable antenna and an external antenna. A method of adding directors in yagi antenna is used to increase the wireless power link, thus to enhance the efficiency of the designed antenna. After calculating an receiver power level of an insitable antenna, the rectifier circuit efficiency is optimized. Yagi uda antenna is operated at a frequency of 2.4GHz to 2.485GHz.

KEYWORDS: Far field wireless power transfer, insitable rectenna, ISM band, power conversion, Yagi uda antenna.

I. INTRODUCTION

Wireless technology have gained a lot of attention recently. Wireless power transfer can be attained by two methods namely near field and far field region. When compared to near field wireless power transmission, far field wireless power transfer has achieved greater advantages such as longer distances and accurate alignment avoidance. An insitable antenna has many challenges when designing for various requirements. The requirements such as radiation efficiency, acceptable bandwidth and compact size.

Many research have been conducted on designing implantable antennas[2]-[13]. In [3] and[4] designing of insitable antenna in different environment is provided. To improve and extend the lifetime of insitable devices, a dual band antenna was studied in [6]. In [11] and [12] for biomedical application, antenna such as slot and microstrip antenna was studied respectively.In other words for far field wireless power transmission an insitable antenna is a important component. An insitable rectenna is used to receive and store energy from RF power and it consists of an rectifier circuit and an implantable for wireless power transmission , an efficient rectenna is needed. To optimize the antenna design optimal diode RF,dc impedances and function of input power were obtained in[15]. Circuarily polarized rectennas were studied in[16]and[18]. A low input RF power 2.45GHz rectenna were designed in [19]. Rectifier circuit conversion effciency of 15.7% at -20 dBm is obtained in[21]. In [22], separate transmit and receive on-chip antenna was designed for pressure monitoring application. A triple band implantable antenna was designed for wake up controller at 2.45GHz in[23],[24]. The proposed antenna provide an efficiency of 78% at a frequency range of 2.45GHz. In [25] wireless power transmission through dispersive tissue was studied. In the proposed work harmonic termination technique in a single voltage doubler rectifier is used to boost the DC output voltage and conversion efficiencies.

To achieve an longer distance, an insitable rectenna is designed in this paper, shown in Fig. 1. The designed insitable yagi antenna is utilized at the operating frequency of 2.45GHz for the wireless power link. After increasing the resonant frequency of the antenna in the implantable device, the wireless power is transferred. The power level received by the yagi antenna is calculated based on the certain rules. A rectifier circuit is designed finally and efficiency of rectenna is estimated.

II. INSITABLE ANTENNA DESIGN

A. Antenna Composition

An Insitable antenna shown in Fig. 2 is designed on theThree-layer FR-4 susbstrate with dielectric constant( ) of 4.4. The ground plane of yagi antenna are 100mm x 35mm. The dipole element height is 60.96mm and width is 3.05mm. Directors of yagi antenna are 3.4mm x 34.49mm.The spacing between dipole and directors are less than 0.3 .The reflector is designed greater then dipole and dipole is designed greater than directors. 2.4GHz were used in the simulation model. For design and analysis, Ansoft High Frequency Structure Simulator is used. Simulated reflection coefficient for the proposed antenna is shown in the Fig. 3. From Fig. 3. It is observed that the antenna covers from 2.3556GHz to 2.566GHz for $|S_{11}|$ less than -10dB. The gain obtained in the simulation is 8.14dBi at 2.45GHz is shown in Fig. 4. By tuning the resonant length and ground plane, the yagi antenna can operate at 2.45GHz with accurate matching. The geometry parameters of yagi antenna is shown in Fig. 2. The value of VSWR is estimated between 1 to 2 and results is shown in Fig. 3. The polar pattern of directivity is shown in Fig. 5. The comparison of frequency with reflection coefficient is shown in Fig. 6. The real and imaginary part of yagi uda antenna is shown in Fig. 7. Maximum efficiency of antenna is shown in Fig. 8. The loss tangent of an yagi antenna is 0.02.

B. Fabrication of Yagi Uda antenna

The designed antenna was fabricated on a copper material and substrate using standard photolithography technique. First the design was transferred on to a transparent mask. The copper material was cleaned, dried and applied using spinner. The thickness of FR4 substrate is 1.6mm. Above the substrate, an reflector with spacing of dipole and director is placed. Between the holder and reflector, an Microstrip line feed is soldered using copper material.One of the advantage of fabricating an yagi uda antenna is, the wider bandwidth is achieved. Fabricated yagi uda antenna is shown in Fig. 9.

III. ANTENNA FEEDING METHOD

The Microstrip antenna can be feed through various method. These methods is classified in to two types. 1. Contacting method, RF power is fed directly to the radiating antenna using a connecting element such as a Microstrip line feed. 2. Non-Contacting method, the EMF coupling is done directly to transfer the power between Microstrip line and the radiating element.

A. Microstrip Feeding method

The feeding method used in designing yagi uda antenna is Microstrip line feeding method. In this method, the conducting strip is connected from the reflector to the driven element is shown in Fig. 2. The strip which conducting the signal is vey thin, compare to the reflectors, driven elements and dipoles.

B. Measurement

By using homogeneous mixture liquid, the antenna was measured. 58.2% de-ionized water, 5.1% DGBE(Diethylene glycol butyl ether) are the recipes's used. The measured VSWR is shown in Fig. 3. Indicates that the measured impedance bandwidth of the proposed antenna is from 2.3556 to 2.557GHz for $|S_{11}|$ less than -10dB.

IV. RECTIFIER CIRCUIT

In this paper, the rectifier is proposed with schottky diode HSMS2860, SMA pF capacitor which is need to convert RF-to-DC for wireless power transfer.In order to improve the rectifier efficiency, the matching and filter is added between the antenna and rectifier and between the rectifier and the load.
HSMS2860 schottky diode was chosen because of its high speed and low voltage drop. In order to avoid impedance mismatching, the characteristic impedance is set to 50Ω with proposed insitable antenna. The proposed 2.45GHz linearly polarized Yagi Uda antennahas been designed and pertinent to the Microstrip rectifier to obtain the rectenna.

A. Fabrication of Rectifier

Matching stub, band pass filter, high frequency Schottky diode, DC filter, SMA capacitor is usedfor fabricating a rectifier. First we fabricate an ground plane and coated with copper material. Secondly, we placed an FR4 substrate on top of the ground plane. Thirdly, above the FR4 substrate, 5Ω resistor and capacitor is soldered, in between that schottky diode is soldered. Finally they are connected with transmission lines coated with copper material. The fabricated rectifier and antenna is connected with the help of RF cable known as rectenna. The fabrication of rectifier is shown in Fig. 10

A. Measurement of Wireless Power Transfer

A Yagi Uda Antenna is placed in the transmitter side withgain of 8.14dBi at resonant frequency of 2.45GHz connected to the Agilent RF signal generator. In the receiver side a yagi uda antenna along with rectifier(rectenna) is placed. The input power fed to the yagi uda antenna is 10dBm. The distanceobtained between thistwo antenna is improved upto 2m. The power is transferred wirelessly between transmitter and receiver. The received power is measured using power meter. Measure the Dc output voltage of the rectenna and then estimated the total power transmission efficiency. The parameters such as VSWR, reflection coefficient, impedance is measured using Vector network analyzer(VNA). The measurement block diagram is shown in Fig. 11.The value obtained by 50Ω impedance matching of fabricated antenna is shown in Fig. 12.

V. CONCLUSION

This paper presents a insitable rectenna for far field wireless power transfer at 2.45GHz. We first designed an yagi uda antenna and simulated using high frequency structure simulator with improved efficiency and gain. Secondly we designed rectifier for high RF to DC conversion HSMS2860 schottky diode.The value achieved between simulation and measurement is more or less similar. Further, frequency range can extend upto 20GHz, distance can be improved more and size of the rectenna can be miniaturize and it can be used for real time application.The simulated parameters is tabulated in Table given below

S.No.	Parameters	Microstrip Yagi Uda antenna
1.	Gain	8.14dB
2.	Directivity	9.19dB
3.	Efficiency	78%

yosip@ariel.ac.il

ABSTRACT

The concept of millimeter wave radiative power transmission in the W-band is presented. The power beaming system consists of a powerful source generating radiation at 94GHz, which is fed to a transmitting dish antenna. The transmitting antenna directs the electromagnetic radiation and focuses it onto a receiving rectifying array. The rectifying antenna (rectenna) converts the received radiation into DC electrical power, which is supplied to a consumer.

Various high power radiation sources have been used in the characterization of the rectenna. Solid states devices produce relatively low power (less than 400mW), while Free-Electron laser and Gyrotrons can produce several tens of kilo-Watts and above. This enables measurements of the rectifying antenna efficiency in different operational regimes.

We will discuss the expected performances of each element, including selection of optimal radiation frequencies as well as possible variable focusing transmitting antenna configuration. The characteristics of a complete power beaming at millimeter waves will be reviewed and design aspects of rectifying antenna array will be demonstrated.

I. INTRODUCTION

Wireless power transfer (WPT) techniques are being used to transfer electrical energy without physical wire connection between the power supply and the consumer. Radiative power beaming systems utilize high power electromagnetic radiation source. The electromagnetic energy is fed to a transmitting antenna which focuses the radiation onto a rectifying antenna at the receiving site [1]. A schematic illustration of a WPT system is shown in Figure 1. When millimeter waves (MMW) are used, electromagnetic wave may be generated by powerful radiation sources like gyrotrons [2] and free-electron masers [3]. The transmitting antenna is usually a dish in a cassegrain configuration, of which the focal length can be changed [4]. The rectenna is an array of patches connected to rectifying diodes that convert the MMW to a DC voltage [5].

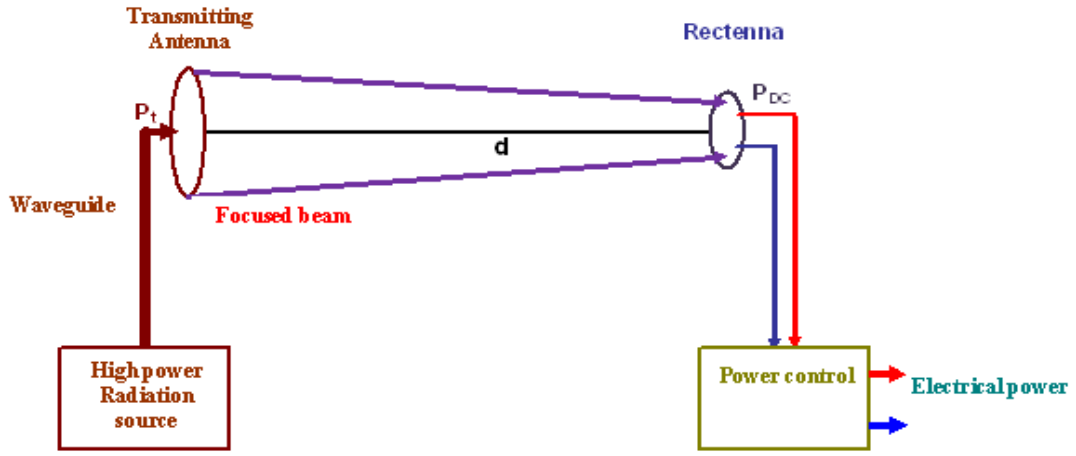

Figure 1: Schematic illustration of a radiative energy transmission system.

II. SOLID STATE TRANSMITTER

Several experiments have been carried out using different power sources at a frequency of 94 GHz. Continuous wave sources producing power of 0.4W and 2W where used. In these experiments, it was found that when the source strength is increased, the efficiency of the rectification increases. It should be noted that the power should not exceed a certain level which damages the rectifiers.

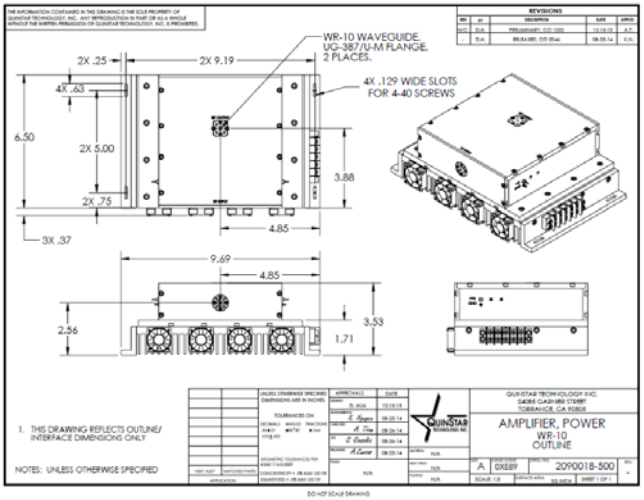
Increasing radiative power will improve the operational parameters of the system:

a. The DC voltage obtained after rectification will rise.

b. If storage capacitors are used, their charging time will be shortened

c. conversion efficiency of the rectenna will improve, while increasing the voltage obtained at the output.

In order to increase the power, a solid state amplifier was purchased from Quinstar. The amplifier model is QPN-94043314, operating at W-band and producing a continuous power of 2W. The Quinstar's amplifier is given in Figure 2.



Specification		
Frequency	92 to 96	GHz
Output Power (Psat)	33dBm min 32.5dBm typ	from 92 to 95 GHz @ 96 GHz
Gain	30 dB	min
VSWR	2 : 1	
Flatness	+/-2	dB
In/Out Waveguide Interface	WR-10	W/G
DC Supply	5V @ 10A typ	
Outline	2100005-500	Includes Heatsink w/ Fans

Figure 2: Quinstar solid stated power amplifier.

The experimental setup including the amplifier is shown in Figure 3. Several power beaming experiments have been conducted with the amplifier, showing improvement in the conversion efficiency.

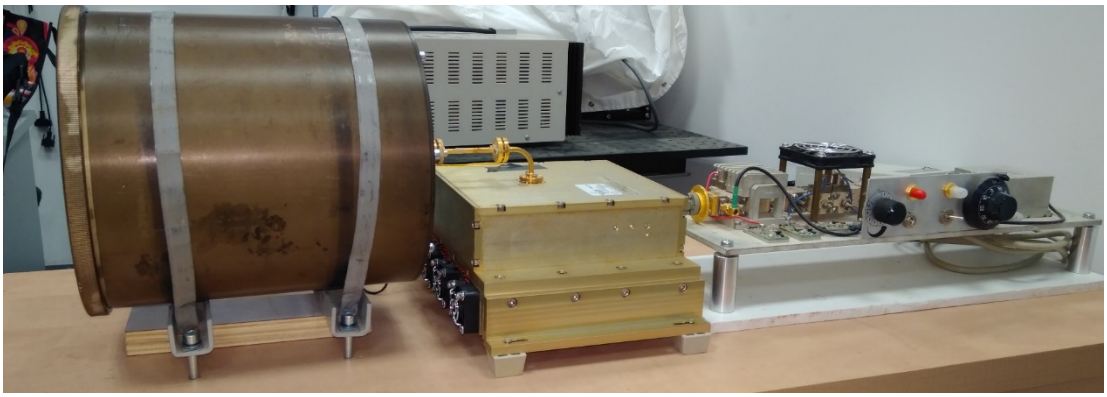


Figure 3: Power beaming solid-state transmitter.

III. THE RECTIFYING ANTENNA

The rectifying antenna consists of a 2x2 patches array connected to a single Schottky diode, as shown in Figure 4. Such diodes are used as detectors based on demonstrating high voltage responsivity, up to 16005 mV/mW at 87.8 GHz [6]. As reported in [5] these diodes can also be integrated with an mm-wave rectenna and operated in large-signal rectifying mode.

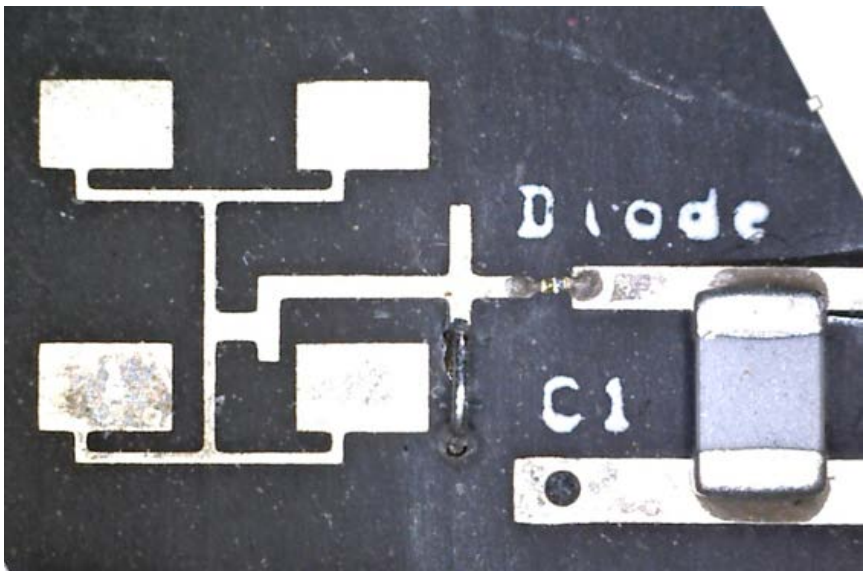

Figure 4: The fundamental 2x2 rectenna array.

In order to increase the received power, a design of 64 elements rectenna was made. A sub-array consisting of 4x8=32 patches was assembled using the 2x2 fundamental arrays, as depicted in Figure 5. Simulation of the rectifier and optimization of its performance has been done using ADS solver. The equivalent circuit used in simulation and typical results of ADS simulation are shown in Figure 6.

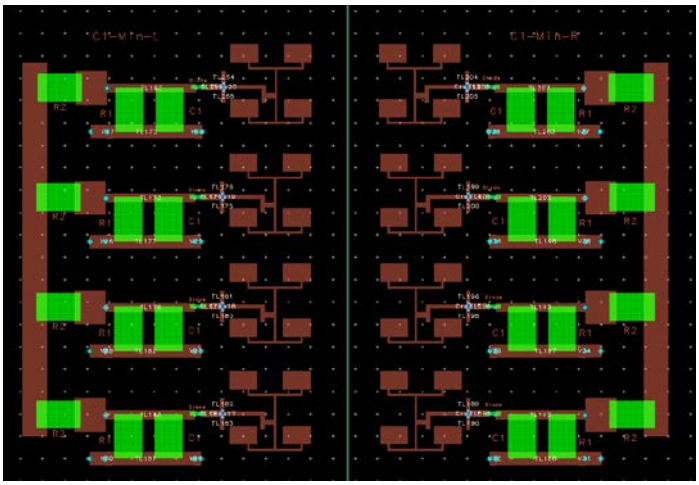

Figure 5: The sub-array rectenna consisting of 4x8 =32 patches.

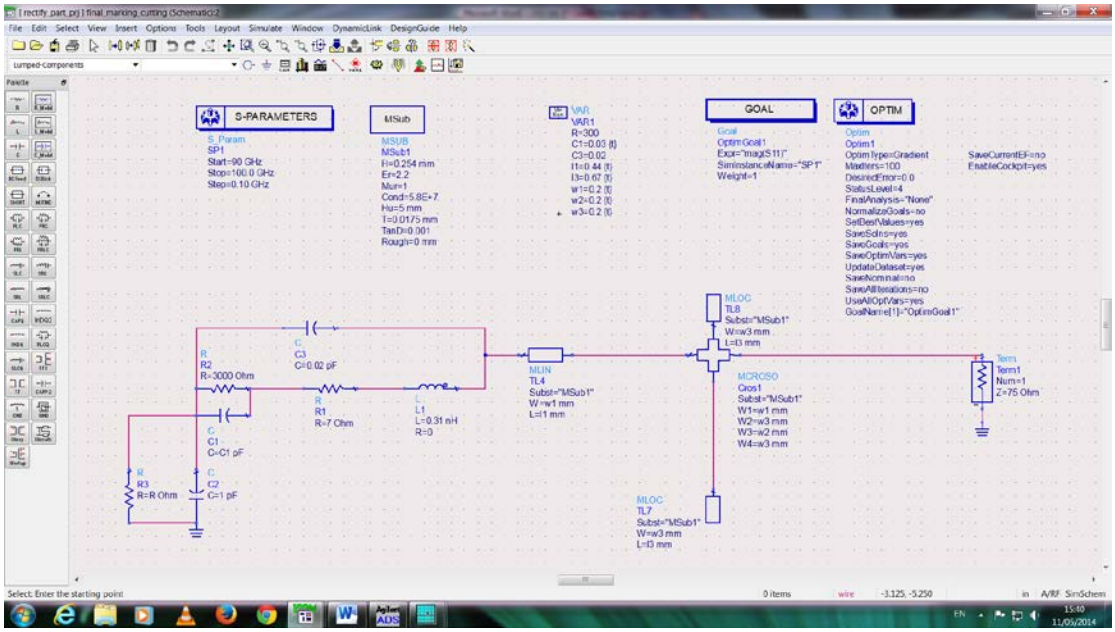
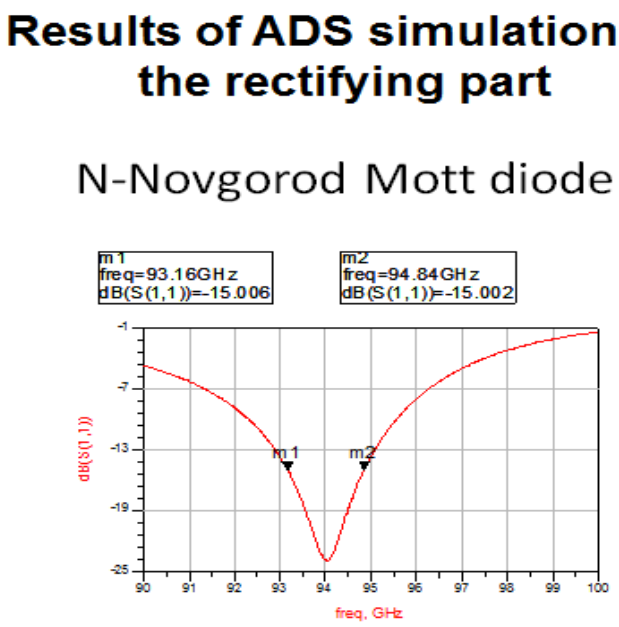


(a)



(b)

Figure 6: The ADS simulation; a) The equivalent circuit, b) Reflectivity S11.

In the fundamental 2x2 array, the 4 patches are connected together to a single rectifying diode. The rectified waveform is filtered by a capacitor and fed to a resistor serving as a load. After optimization of the matching circuit to each of the diodes, the selected circuits were collected together to create a 64 patches rectenna as shown in Figure 7.

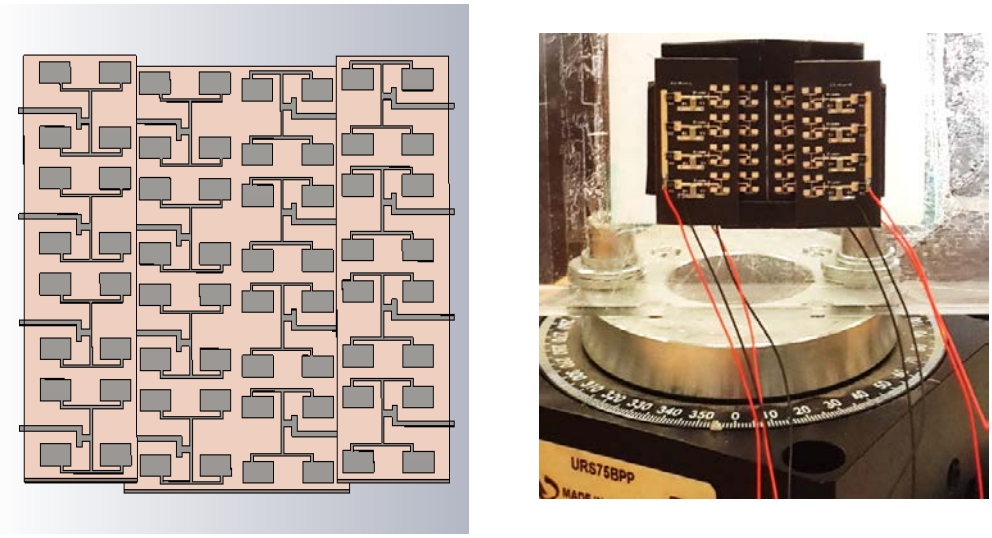


Figure 7: The layout of 64 elements rectenna.

IV. EXPERIMENTAL SETUP

Figure 8 presents the setup of the radiative power beaming experiment. A continuous wave, solid-state W-band source capable of producing 0.4W output power is connected to a 200mm lens transmitting antenna. The 2x2 fundamental array rectenna is placed behind the focusing lens of diameter 6 cm in a position of the beam spot, having a minimum diameter of approximately 1cm. distance between transmitting antenna and the receiving one is 1m. The graph of Figure 9 shows the measured DC power as a function of the load resistances. The maximum output power is 2.7mW for a load of 200 Ohms. The latter corresponds to the 15% of RF-to-DC conversion efficiency. This estimation was done using the technique reported in [5, 8].

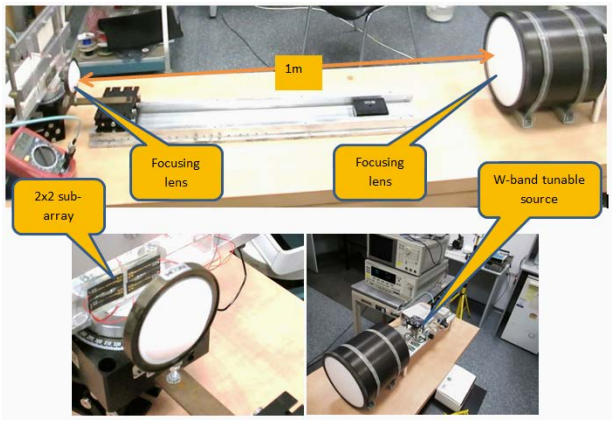

Figure 8: Experimental setup used for rectenna characterization in the W-band, using a 0.4W solid state tunable source

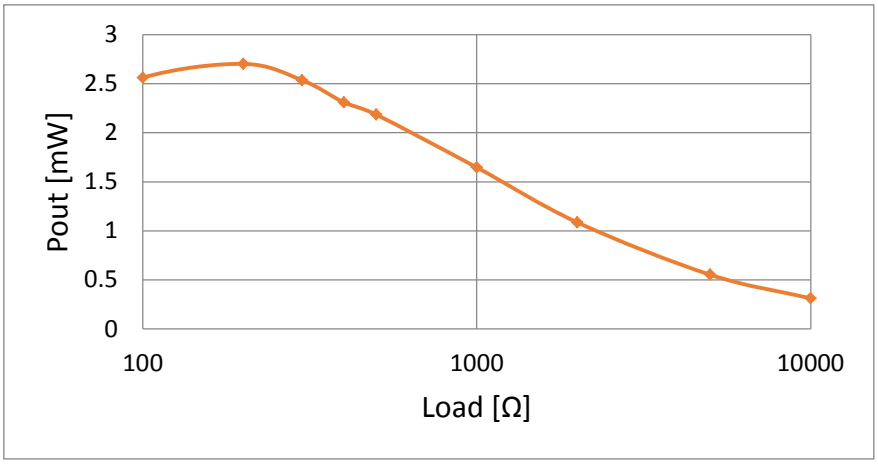

Figure 9: The measured DC power as a function of the load resistance.

V. SUMMARY

Millimeter wave radiative power beaming is demonstrated using solid-state power source and a rectifying antenna (rectenna). The rectenna is based on a fundamental 2x2 patches connected to a low-barrier Shottky diode. These modules are connected together to create a large rectifying array. Power beaming experiments at W-band, using continuous wave solid-state source demonstrate RF-to-DC conversion efficiency of 15-20%.

Abstract

This paper develops a novel power harvesting system to harvest ambient RF energy to power a wireless sensor. Harvesting ambient RF energy is a very difficult task as the power levels are extremely weak. Simulation results show zero threshold MOSFETs are essential in the RF to DC conversion process. $0.5V_{DC}$ at the output of the RF to DC conversion stage is the minimum voltage which must be achieved for the micro-power sensor circuitry to operate. The weakest power level the proposed system can successfully harvest is -37dBm. The measured available power from the FM band has been measured to fluctuate between -33 to -43dBm using a ribbon FM dipole antenna. Ambient RF energy would best be used in conjunction with other forms of harvested ambient energy to increase diversity and dependability. The potential economic and environmental benefits make such endeavors truly worthwhile.

1. Introduction

The contamination of landfills by batteries is a worldwide problem. Nearly three billion dry-cell batteries are consumed each year in the United States alone [1]. At the end of their operating life most batteries end in landfills. This contributes to a significant amount of hazardous compounds and heavy metals in the environment. To reduce reliance on batteries, energy harvesting techniques will be of vital importance in the near future. Energy harvesting is defined as the conversion of ambient energy into usable electrical energy [2-16].

The Citizen Eco-Drive is a famous example of energy harvesting. The watch collects ambient light and stores it as electrical energy in cells. These cells never need replacement and last longer than the life of the user [10], thus eliminating batteries ending up in landfills. There are many sources of ambient energy that can be harvested to perform work, such as solar power, wind power, energy from physical vibrations [12-15], thermal [11, 16], ocean tides and the RF spectrum. The primary focus of this investigation is to harvest energy directly from the RF spectrum. The RF spectrum covers the range from 3Hz to 300GHz [17]. The frequency band of interest is from the FM transmission band, it is located between 87.5 and 108 MHz of the RF spectrum [18]. There are two main reasons for selecting FM, firstly because of the extensive coverage and the polarization of the electro-magnetic fields are circular, which will enable the energy harvesting antenna to be positioned in virtually any orientation and still be able to receive a signal. The energy collected will be used to power a wireless temperature and humidity sensor node. The wireless and battery-less capability of these devices will greatly increase their utility.

The ultimate aim is to be capable of harvesting energy from across the entire RF spectrum, to maximize the amount of power collected. Additional investigation has been conducted, to further understanding on the challenges of harvesting RF energy at higher frequency levels. The frequency investigated is the GSM 900 cellular network. Historically, the attempts at harvesting energy from the cellular frequency band have only been of limited success as one is either restricted to transmitting their own power [19-20] or limited by the distance from the actual transmission tower [21].

This paper is structured as follows. Section 2 introduces the circuitry of the proposed RF power harvesting system. Section 3 provides an overview of the energy management system. Section 4 presents the energy harvesting performance of the prototype and also provides discussions on the results and the implications. Section 5 discusses future work is required. This paper is concluded in Section 6.

2. Energy Harvesting Circuitry

The proposed energy harvesting topology is shown in Figure 1.

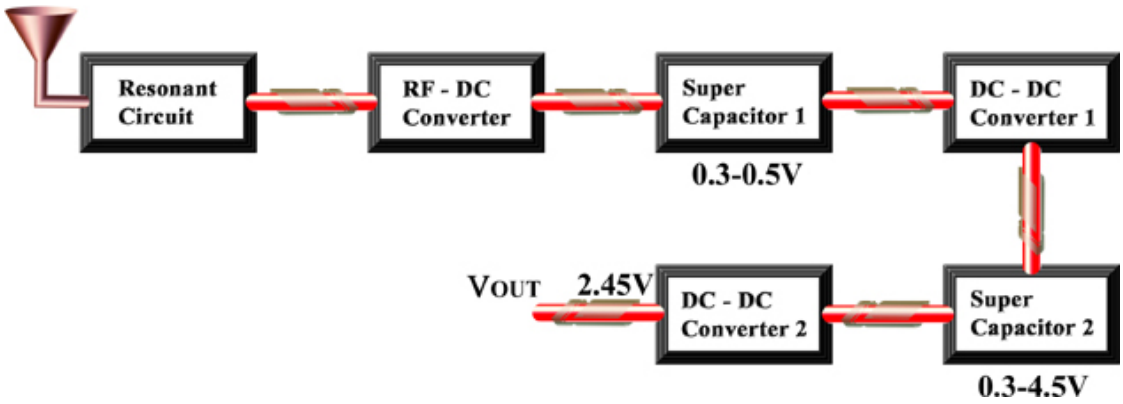

Figure 1*:* RF energy harvesting sequence

An impedance matching network has not been implemented between the energy harvesting antenna and the resonant circuit. This is because the energy harvesting circuit is a non-linear load, the input impedance changes with changes in voltage. Since the antenna and the input is not matched, reflection will always occur. The tuned series resonant circuit boosts the voltage amplitude of the incoming RF signal. The RF-DC converter rectifies the zero mean RF signal into DC and stores the charge on Super Capacitor 1. Super Capacitor 1 is used as a temporary storage capacitor, once the voltage reaches 0.5V, DC – DC Converter 1 transfers the energy to Super Capacitor 2 where the energy is stored at a higher voltage. This enables much more energy to be stored. DC-DC converter 2 is used to supply a constant 2.45V to the digital electronic components of the sensor node. By using a second DC-DC converter the voltage across Super Capacitor 2 can drop down to 0.3V before the sensor node will stop functioning.

2.1. Resonant Circuit

To increase the output voltage amplitude, the inductance is made as large as possible when compared with the capacitance value as shown in Figure 2. Surface mount components are used to reduce parasitic capacitance. The actual components are selected by their frequency response performance. The capacitors used are Class I ceramic capacitors. Their capacitance can be assumed to be frequency independent up to 1GHz [22]. The inductors used are high frequency multilayer chip inductors. The inductors are made from advanced ceramics with low resistance silver as the conductor [23]. The physical layout on the PCB is also important. To prevent the PCB from appearing as a transmission line, the components are placed as close together as possible. To reduce mutual inductance between inductors, the inductors are placed at 90 degrees to each other. For harvesting at FM transmission frequencies the resonant frequency is set at 100MHz.

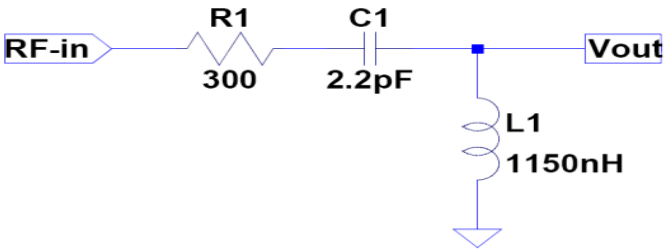

Figure 2*:* Series tuned resonant circuit

2.2. RF-DC Converter

The RF-DC converter is realized by cascading voltage doublers into a large voltage multiplier. In total 25 stages have been implemented. The Zero threshold MOSFETs are operating in the cut-off region, therefore the weak inversion current is utilized to rectify the RF signal as shown in Figure 3. Zero threshold MOSFETs reduce the voltage drop across each stage, therefore it increases the number of stages which can be cascaded. This is effectively Self-Synchronous Rectification (SSR).

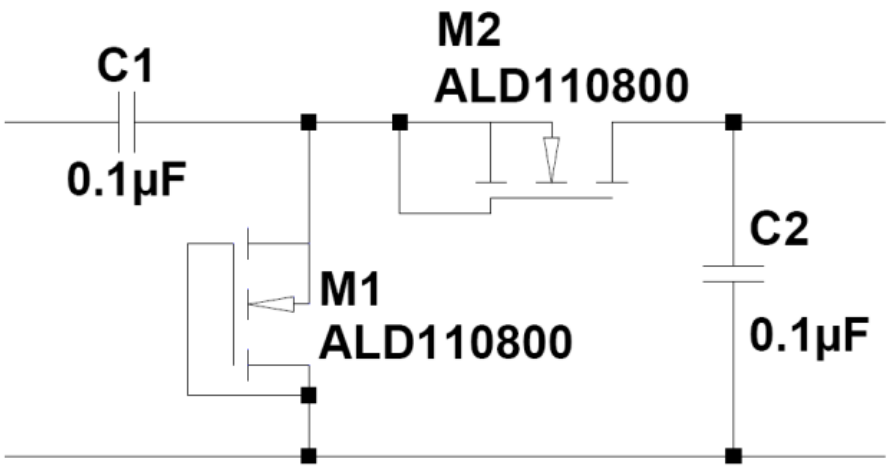

Figure 3*:* One voltage doubling stage

The capacitors used in the RF-DC converter are NP0 Class I ceramic capacitors. These are selected because of their excellent frequency response and the low leakage characteristics of the dielectric material. These are both very important qualities as the voltage multiplier is designed to work at frequencies in the MHz range. Also in order to improve efficiency any leakage current must be minimized.

2.3. Super Capacitor

Super capacitors are selected over conventional energy storage devices such as lithium-ion or lithium-ion polymer cells, because super capacitors have a close to infinite charging and discharging life cycles. There are two types of super capacitors used in the energy harvesting stage. The first super capacitor is used as a temporary energy storage device. Therefore an ordinary 1.5 Farad super capacitor is used to lower the cost of implementation. The second super capacitor is used to store the collected energy at a higher voltage to maximize the amount of energy which can be stored as shown by Equation 1.

$$E = \frac{1}{2} CV^2 \qquad (1)$$

The second super capacitor is a 1 Farad Bestcap, it has an ultra-low ESR, together with an extremely low leakage current [9]. A low leakage current is critical because harvesting ambient RF energy is very difficult therefore any charge collected is very valuable.

2.4. DC-DC Converter

The micro-power energy harvesting circuitry design contains two DC-DC converters. Existing available integrated chip converters were chosen over designing a converter from scratch because of several key reasons. The first reason is because of the very high efficiencies which can be achieved by using existing integrated converters. Efficiencies up to 90% can be easily attained. The second reason is a DC-DC converter which is able to accept a very large input voltage range is required. The input voltage range can vary between 0.3 to 4.5V. It is very difficult to manually implement a boost converter capable of operating with an input voltage of 0.3V. The final reason is integrated converters can automatically switch between buck and boost conversion thus simplifying development. The DC-DC converter selected for this application is the TPS61200 from Texas Instruments. It has a minimum startup voltage of 0.5V and can operate down to 0.3V. Both DC-DC converters are the same to simplify the design and manufacturing process.

3. Energy Management System

In Figure 4, the arrows show the direction of data flow. Some data lines are bi-directional. In Appendix B the schematic for the entire energy management system and the digital circuitry can be located.

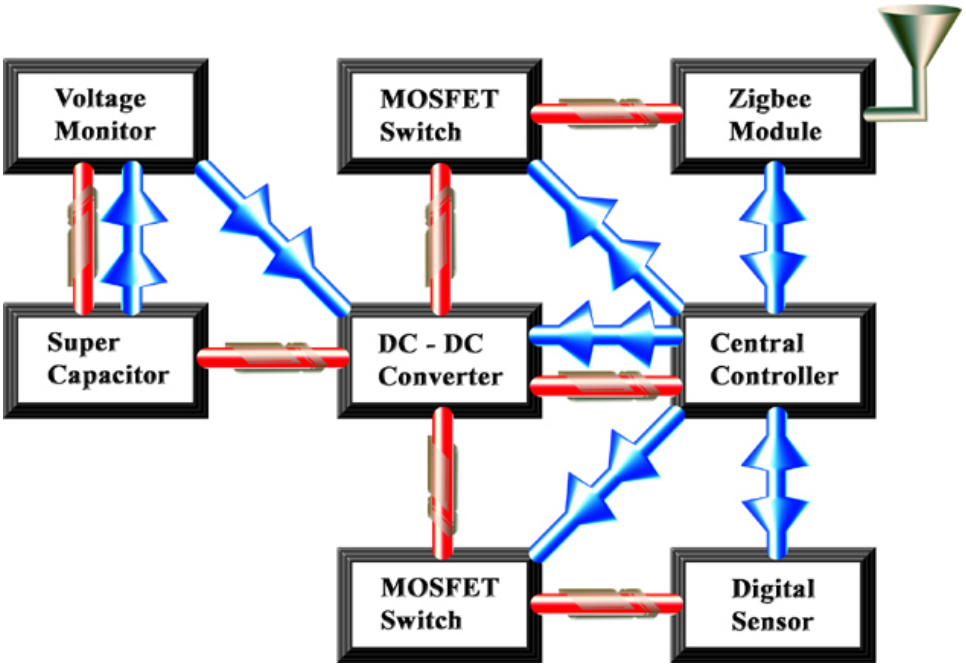

Figure 4: Sensor power and data flow

3.1. Voltage Monitor

The heart of the energy management system is the voltage monitor. It is implemented using an ATmega165P microcontroller. The voltage monitor operates at a clock frequency of 32.768 kHz and is powered directly from the super capacitor as shown in Figure 7. The voltage at which the voltage monitor starts to operate is 1.8V. The voltage monitor consumes 0.6 uA of current while in power-save mode. While in power-save mode, the real time clock is still operating. Once every week the voltage monitor will wake up from the power-save mode and check the voltage across the super capacitor. The regularity at which the voltage monitor checks the voltage stored on the super capacitor can be programmed to suit the particular application. Once sufficient voltage has been harvested, the voltage monitor enables the DC-DC converter which enables the central controller to operate. The voltage is checked through the ADC of the microcontroller. The code for operating the ADC is located in Appendix C. The ADC requires a voltage reference. The internal voltage

reference has been utilized to save on external components and can be turned on and off to conserve power.

3.2. Central Controller energy management

The central controller is also implemented using an ATmega165P microcontroller. It was selected because of its extremely low power consumption of a mere 10 uA in the active mode. Once the central controller powers up, the first priority is to gain control of the DC-DC converter. This is because the voltage monitor will return back to power-save mode to conserve energy. Without control of the DC-DC converter the central controller will have no power source. To gain control of the DC-DC converter the central controller must set the I/O pin which is connected to the enable pin of the DC-DC converter to high. The central controller is capable of monitoring the voltage across the super capacitor. This enables the controller to know how much time is left for the tasks to be completed. Once the data has been transmitted back to the data recorder, the central controller will disable the DC-DC converter.

3.3. Power MOSFET switch

Although both the zigbee module and the digital sensor have sleep modes, they still consume current. To eliminate this unnecessary leakage current, MOSFET switches have been added to allow the central controller full control of when each device will receive power. This enables precise timing to be achieved thus minimizing the amount of power used. The MOSFET used are the IRLML2502PbF from International Rectifier. These are selected because it has a maximum threshold voltage of 1.2V, this is essential as the operating voltage within the sensor node is 2.45V.

Another advantage with the IRLML2502PbF MOSFET it has a very low ON resistance of 0.045 ohms. Both the zigbee module and the digital sensor node have a MOSFET switch connected.

4. Results and Discussions

The power levels were measured using a spectrum analyzer. Two antennas have been tested at FM transmission levels. The first antenna is a length of insulated copper wire which has been cut to half a wavelength, to resemble a monopole antenna. A SMA connector is used to connect this antenna to the spectrum analyzer. The amount of power measured at the output of the antenna is -50dBm. The second antenna is a standard ribbon FM dipole antenna. The power measured at the output varied between -33dBm and -43dBm. This antenna is shown in Figure 5.

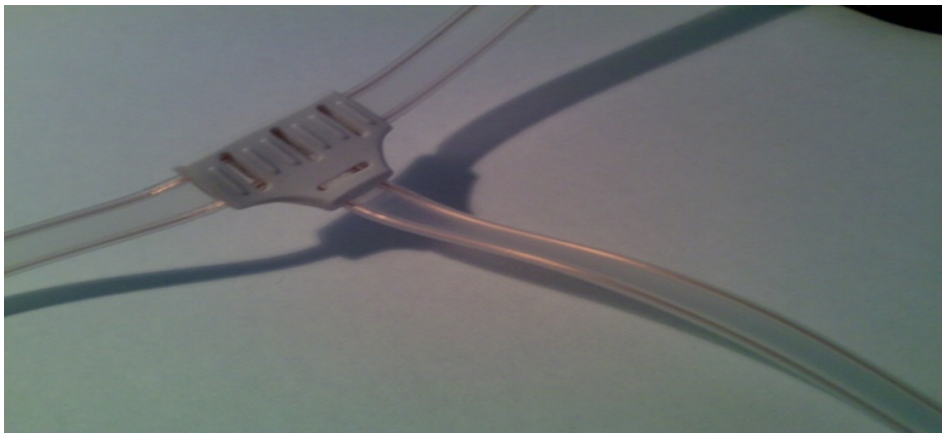

Figure 5*:* Ribbon FM dipole antenna

The procedure used to test the RF energy harvesting performance of a given circuit is as follows. The circuit input is connected to the output of a precision signal generator. The signal generators are capable of varying the amount of power in dBm and also the signal frequency. $0.5V_{DC}$ at the output of the RF to DC conversion stage is the minimum voltage which must be achieved for the micro-power sensor circuitry to operate. $0.5V_{DC}$ is therefore the standard by which we compare the two different rectifying schemes.

A total of 20 cascaded voltage doubling stages have been built to test the performance of Schottky diodes in rectifying small signals. The smallest power that could be rectified to 0.5V was -18dBm. It is also worthy to note after 7 to 8 doubling stages have been cascaded, the voltage gain of adding additional stages diminishes. To further improve the energy harvesting circuit, a series resonant circuit was added to boost the amplitude of the incoming RF signal. The hardware implementation was successful. A 9 dB voltage gain has been achieved. However this is at the cost of compromising the RF bandwidth from which we are harvesting. The top and bottom layers of the prototype are shown in Figures 6 and 7, respectively.

The energy required for each device is based on how long each device is operating and the amount of current each device draws. Power calculations for a typical wireless sensor application are tabulated in Table 1. It is shown that the energy required to complete one data transmission cycle is 0.32 Joules. The result has been confirmed by measuring the voltage difference before and after data transmission.

Device	**V (V)**	**I (mA)**	**T (s)**	**E (J)**
ATmega165P	1.8	0.01	10	0.00018
ATmega165P	1.8	0.01	8	0.00014
Sensor	3.3	0.55	5	0.00908
Zigbee	3.3	35	2.7	0.31
Total				**0.32**

Table 1*:* Power Calculations for a wireless sensor

Assuming there is a constant -37dBm power flow entering the energy harvesting antenna. It will take 11.7 days for the RF harvester to collect 0.32 Joules of energy. This does not take into account the reflection which may occur between the antenna and the input of the RF harvester,

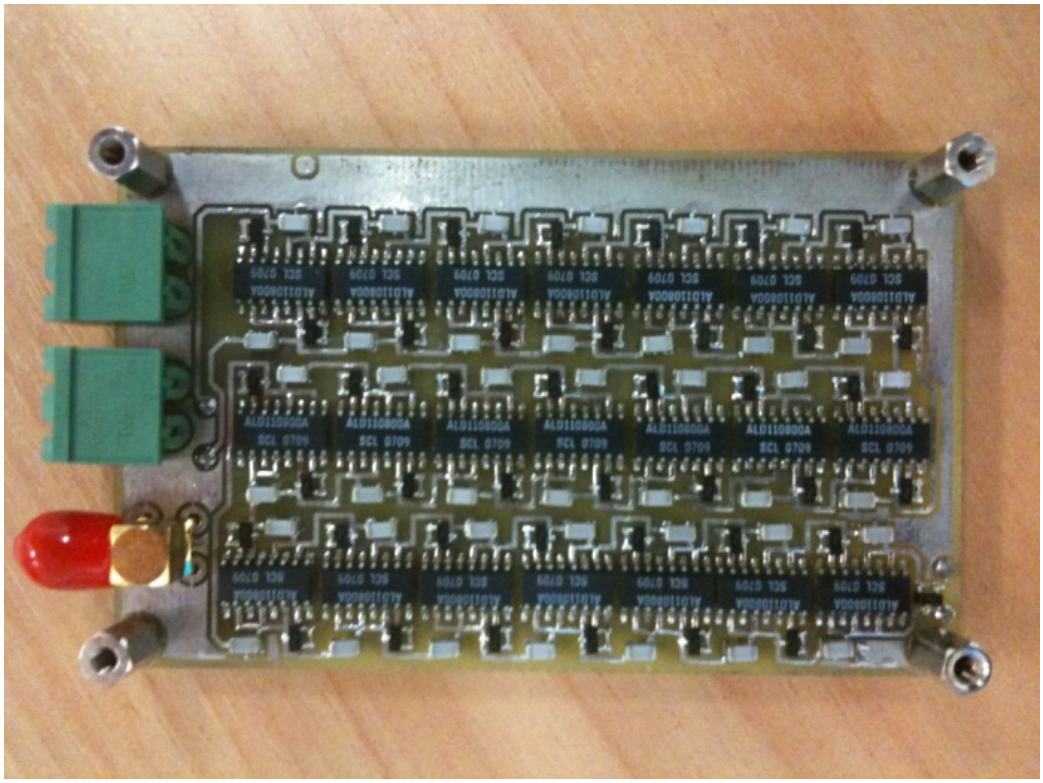

Figure 6: Power harvesting system (top layer)

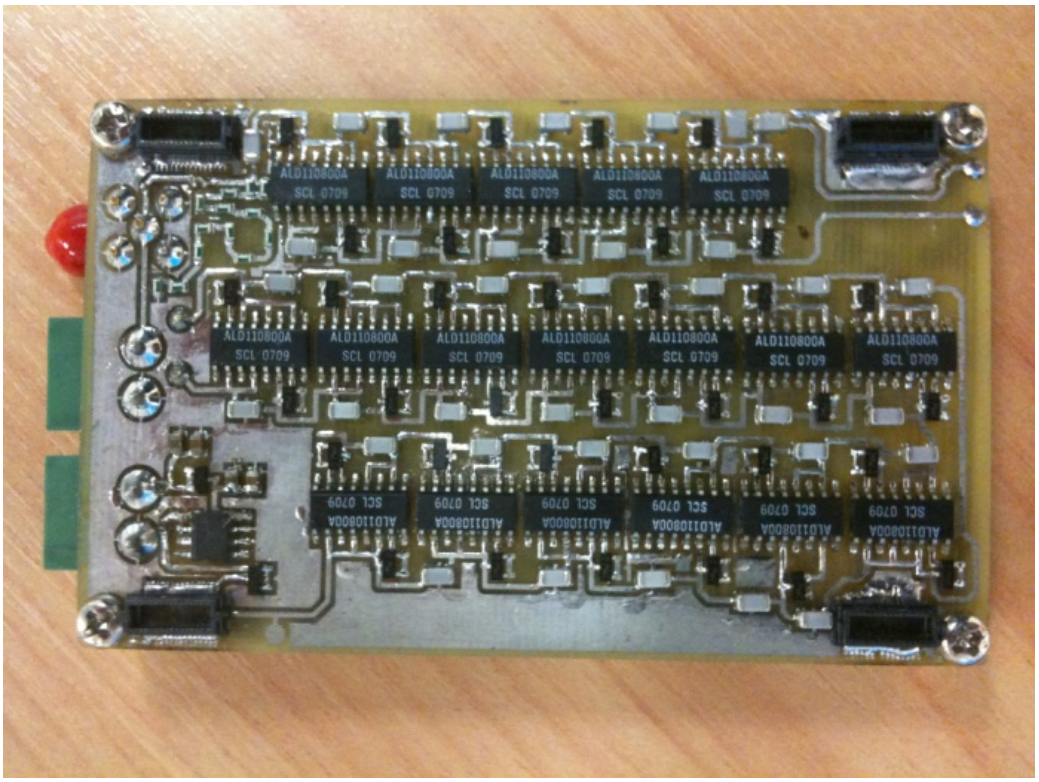

Figure 7: Power harvesting system (bottom layer)

The realistic time the RF energy harvesting circuit will take to collect enough energy for one data transmission will be closer to 20 to 30 days. This is taking into account the reflection coefficient and the fluctuations in power levels. There are still many applications where such a device will be very useful. One such application is in silver-culture. Here circumferential sensors are used to measure the growth of trees. Since the trees grow very slowly the time between measurements is usually a month or more. By powering these sensors from an ambient source, it eliminates the need to ever change the batteries. For applications requiring faster charge rates, it is possible to combine energy harvested from various different ambient sources to increase the available power and diversity.

5. Future Developments

To be truly successful at harvesting ambient RF energy, the entire energy harvesting circuitry must be integrated on a single IC. This is to reduce leakage losses, increases the overall efficiency of the system and help energy harvesting from the RF spectrum to be economically viable. For this project the objective was to harvest only from the FM transmission band, however the power collected is very limited and the time taken to harvest the energy is very long. Therefore the next step is to increase the bandwidth from which the RF energy harvester can collect energy. This is no trivial task, because in radio systems it is easy design a circuit to work at a certain frequency but for the circuit to work at multiple frequencies may require different harvesting techniques. It will be necessary to design a broadband antenna. Another area which needs improvement is the power sensitivity. It is highly probable that by making the entire circuitry physically smaller the system will be capable of harvesting even lower power levels. A possible future development is to integrate RF energy harvesting with other forms of ambient energy such heat and physical vibrations.

6. Conclusions

Harvesting ambient RF energy is very difficult as the power levels are very weak. Schottky diode based voltage multipliers are not suitable for rectifying such weak signals. A tuned series resonant circuit enables the energy harvesting circuitry to harvest at lower power levels but the bandwidth is compromised. The real hardware implementation supports the simulation results showing that SSR using n-MOSFETs is essential in the RF to DC conversion process. The lowest power level which can be boosted and rectified is -37dBm at 100MHz. At 900MHz the lowest power level the energy harvesting circuit can harvest increased to -25dBm therefore the harvesting performance at higher

frequencies is not as good. Since the measured available power from a FM ribbon dipole antenna fluctuated between -33 and -43dBm, harvesting energy from the FM spectrum it feasible.

ABSTRACT

This paper presents the RF energy harvesting module (RECTENNA). The working range of this module includes multiple bands i.e. GSM, ISM, WLAN, and UWB band. To enhance the capturing RF power capability an array arrangement of coplanar monopole antenna has been proposed. Wilkinson power combiner has also been implemented to combine the powers of this antenna array. The RF-DC converter circuit having seven stages has also been integrated with this structure. This module produces the DC voltage of 1.8 V with respect to + 40 dB RF input. It is the unique module because it has no need of port connectors. The impedance matching of antenna and converter has been fulfilled by incorporating the passive component at the combiner's branch. The value of this passive component is kept equal to the existing value of impedance at input port of converter circuit.

Key words: *Rectenna, coplanar monopole antenna, Wilkinson power combiner, antenna array, impedance matching, RF-DC converter circuit.*

I. INTRODUCTION

The primary focus of the Rectenna circuit is to design a suitable RF receiving antenna. For this purpose, an antenna should be designed to resonate on single, dual and multiband frequencies according to the need of the applications. The main aim of proposed work is to design a RF energy harvesting module for a wide range of frequencies which covers most of functional bands, e.g. GSM, Radio, ISM and UWB. It is well known that the RF spectrum widely employed for 900 MHz – 2 MHz (television and radio applications, GSM), 2.1GHz - 2.6 GHz (ISM band for various applications), and 3.1GHz -10.6 GHz (ultra wideband for satellite applications) [1]. Narrow band systems such as WLAN (3.1GHz - 4.4GHz), HIPERLAN (5.1GHz - 5.3GHz), C-BAND (4.4GHz - 5GHz) are also the useful bands. Keeping this in mind a compact coplanar monopole antenna has been designed and its 2 X 2 arrangement was reported [2]. For preparing the array arrangements of the antenna the literature [3-5] were profoundly studied.

This antenna works for the wide range of frequencies of the above specified bands. As reported in the structure [2] the Wilkinson power combiners were preferred because it accomplishes two essential tasks of the structure. Firstly it combines the powers of two or four antennas serially and increases the input power of RF-DC converter circuit of energy harvesting module. Secondly it considered as the element of afford, for the impedance matching of antenna port and converter circuit. The maximum power transfer concept has been chosen for this impedance matching.

The multi band operation of the RF energy harvesting module developed on a single substrate is the innovation of this paper.

II. ANTENNA DESIGN

In RF energy harvesting module antenna is the major functionary part. It receives the power from the electromagnetic spectrum. The received RF power is converted into the DC output voltage from the module. So the antenna should be capable enough to receive the maximum energy/power from the spectrum. As the working range of our design is preferred from 900 MHz -10 GHz, the modification in the monopole antenna structure for multi frequencies resonance has investigated. For increasing the area of receiving as well as gain of the structure the 2 x 2 array of the coplanar monopole antenna has been designed and presented [2]. In this paper [2] only the simulated results were presented. The simulated antenna structure was as shown in figure 1[2]. The power of the individual structure has been combined by the Wilkinson power combiner. The reason for selecting this combiner is that we may externally adjoin the surface mount components at the combining branch of it for impedance matching purpose.

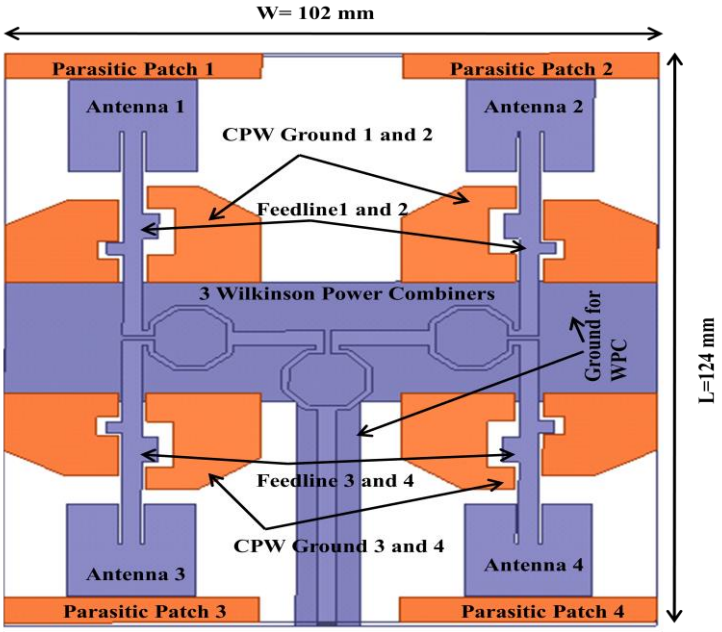

Figure 1. Simulated structure of 2 x 2 array arrangement of coplanar monopole antenna [2].

The simulated structure from licensed software HFSS version16 has been exposed resonant on the multi frequencies of different allocated bands as 900 MHz and 1.75 GHz (GSM band) 2.7 GHz (ISM), 3.5 GHz, 4 GHz and 5.2 GHz (WLAN), 6.5 GHz, 7.4 GHz, 8.5 GHz and 10 GHz (UWB).

Further in this paper all measured results have been reported for the validation of proposed antenna structure. For the measurement purpose proposed structure has been fabricated as shown in figure 2. The measured result of return loss from VNA (Keysight Technologies) for fabricated structure is shown in figure 3. The resonant frequencies of the fabricated structure has

exposed on 900 MHz (GSM), 1.29 GHz (ISM), 4.1 GHz and 5.6 GHz (WLAN), 6.8 GHz and 9 GHz (UWB), that is the almost same as simulated result of the structure reported earlier [2].

.

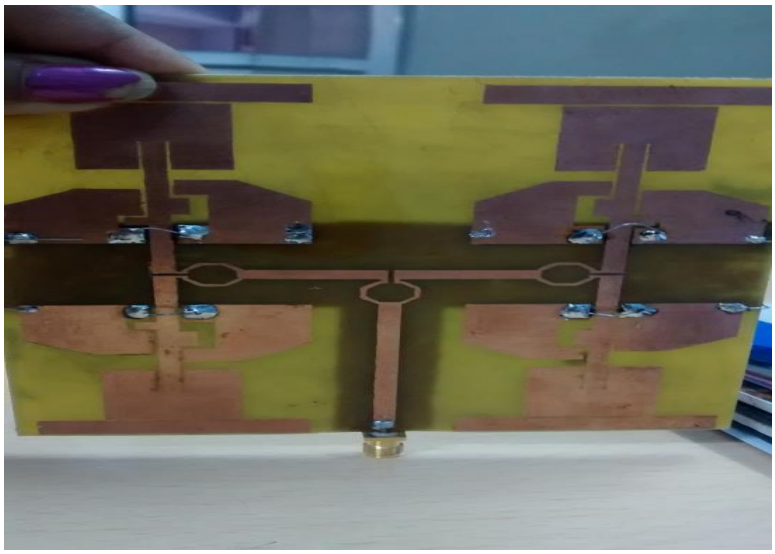

Figure 2. Fabricated structure of the 2 x 2 array of coplanar monopole antenna.

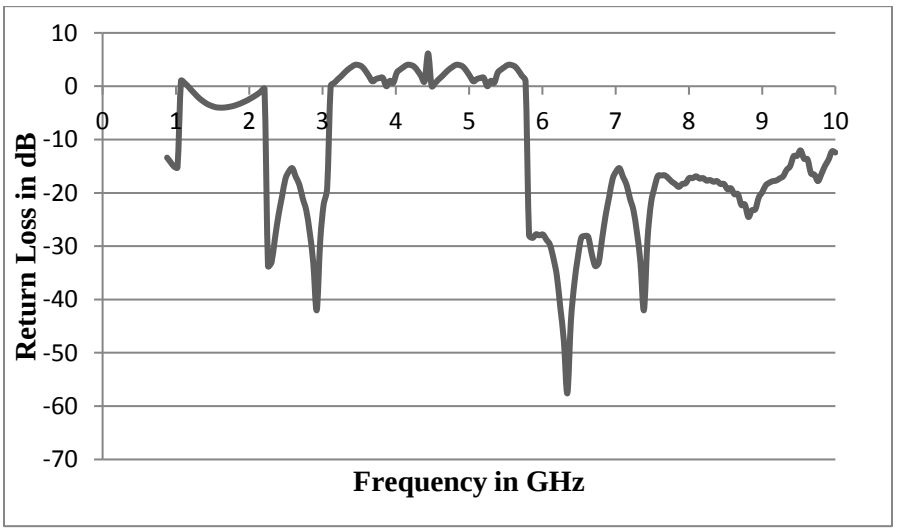

Figure 3. Measured return loss (S_{11}) of the 2 x 2 array of coplanar monopole antenna.

The measured H- field patterns for these frequencies are shown in figure 4(a) and E-field patterns are shown in figure 4 (b). These patterns show that the antenna supposed to be worked as omnidirectional.

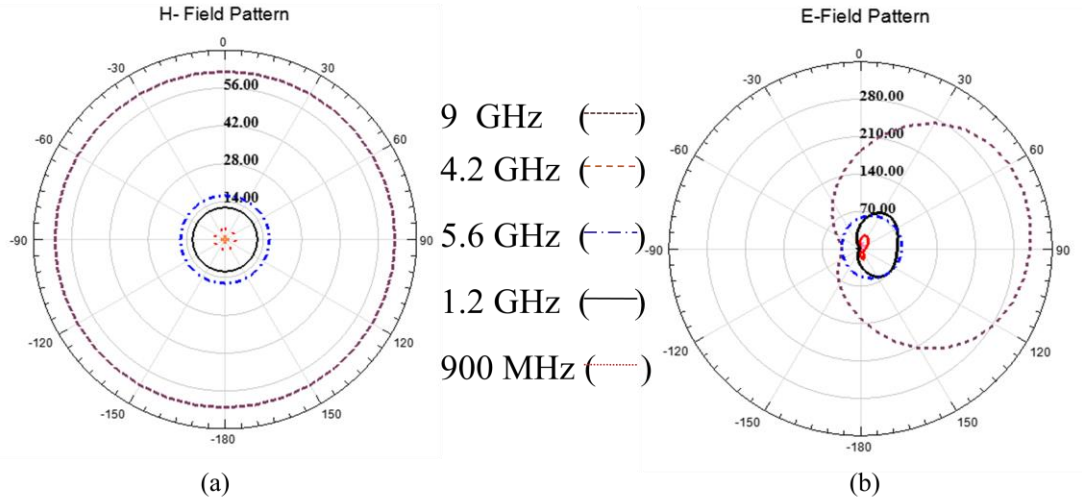

Figure 4. (a) H- field pattern (b) E- field Pattern

III. RF-DC CONVERTER

The RF-DC converter circuit is also the important part of energy harvesting module. The output of harvester circuit is the DC voltage. The input of this module is the magnitude of AC voltage at the antenna port. This AC voltage is proportional to the captured power on the antenna from the RF spectrum. In this paper for energy conversion purpose a voltage doubler circuit has been used. The number of stages of the converter circuit may be increased for escalating the DC output voltage value. The relation of number of stages (n) and output voltage ($V_{o/p\ volt}$) of converter circuit is considered as

$$V_{o/p\ volt} = \frac{nV_{o/p\ volt}}{nR_0 + R_L} R_L$$

In this paper conversion design contains seven numbers of stages of Villard voltage doubler circuit. The main function of this conversion circuit is to convert the RF harvested energy from the ambient into the direct current (DC) voltage. This seven stage Schottky diode voltage doubler circuit is first designed, modelled and simulated on ANSYS RF circuit designer and then fabricated and tested. After that, this circuit has integrated with the same substrate of antenna. The converter circuit in this design uses zero bias Schottky diode (SMS7621-001-SOT23) from Skyworks. The simulated design of seven stage RF-DC converter circuit has been presented for this purpose [6]. The simulated DC output voltage at the first stage and seventh stage of RF-DC converter circuit from the RF circuit simulator was as 48.2 mV and 289.6 mV respectively. The fabricated circuit of seven stage RF-DC converter and its analysis has already been presented [6]. So in this paper we implemented that designed RF-DC circuit (having seven stages) [6] with the same single substrate of designed antenna array.

IV. RF ENERGY HARVESTING MODULE

This part of paper presented a RF energy harvesting module on a single substrate working on multi bands of the frequency range 900 MHz to 10 GHz. The DC output from the multiband harvesting circuit has been presented it produces 3.4 V DC output [8]. The motive of this part is to design whole module on a single substrate for a wide range of operation and should be able to produce the DC output voltage of the value more than 1.5 V from the ambient RF spectrum. This DC voltage may be boosted by adding the booster circuit. In addition to the structure on a single substrate of RF module, it is also proposed that any value of impedance measured at the converter circuit input impedance may be matched to antenna port by using SMD (Surface mount device) resistor components. This is possible only due to the use of Wilkinson power combiner implemented at the antenna structure. No need of matching of connectors impedances. So it may be called connector-less module. This is the uniqueness of the structure.

The novel idea of impedance matching is that; for any wilkinson power combiner a given number of output ports N, an input impedance R_S and output load impedance R_L, and the characteristic impedance of each quarter-wave section, $Z_{\lambda/4}$, is given by

$$Z_{\lambda/4} = \sqrt{N\, R_L R_S}$$

Additionally

$$R = R_L$$

the resistor (R) that connect between the common junction and the output ports are simply equal to the load impedances (R_L) at each output. Now considering the input impedance of RF-DC converter circuit as the value of load resistance (R_L) of the output of the Wilkinson power combiner. This impedance has been measured by vector network analyzer. The SMD resistor of this measured value (R) has been mounted in between the combining leg of Wilkinson power combiner. In this way we can easily match the impedance of antenna and converter circuit. This satisfies the condition of maximum power transfer.

The fabricated RF energy module on a single substrate with impedance matching arrangement is shown in figure 5. The seven stage RF-DC converter has been implemented by the combination of seven Schottky diodes and seven capacitors. The load resistance and source resistance has also been added into the circuit. The overall size of the module is 124 x 102 mm^2.

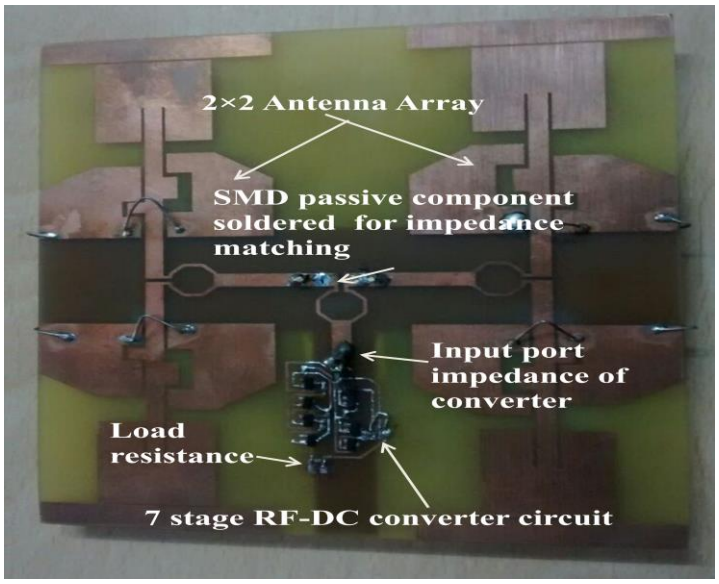

Figure 5. Fabricated RF energy harvesting module integrated on a single substrate.

The measurement with module in RF lab has been shown in figure 6. The measurement has taken at ICRS (International center for Radio Science) lab, Jodhpur. Rajasthan, INDIA. The RF source is of 40 GHz. First of all with respect to the source on the resonant frequencies of the module; power received at the antenna port has been measured on the power-meter.

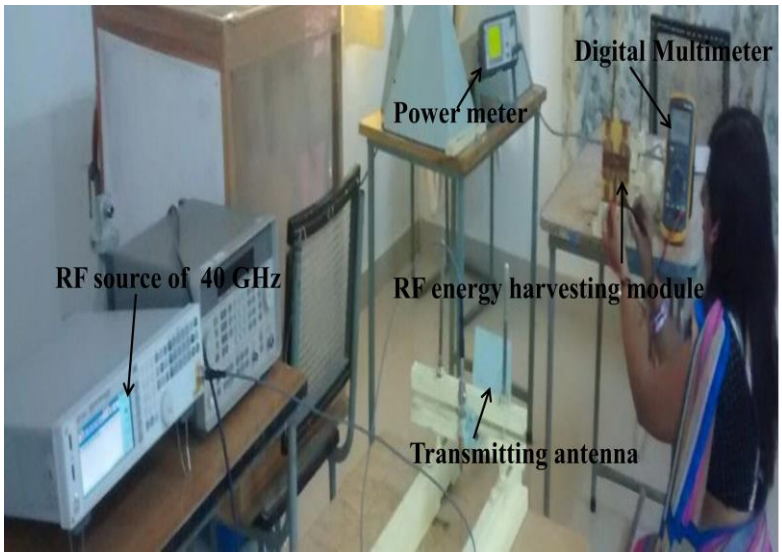

Figure 6. Measurement of output DC voltage from the module with respect to RF input voltage from RF source.

The DC output voltage at the module output with respect to RF input power varying from - 40 dB m to + 40 dB m has been plotted for five resonant frequencies (900 MHz, 1.2 GHz, 4.1 GHz,

5.6 GHz and 9 GHz). The plot of the data is as shown in figure 7. The maximum DC output is 1.823 V.

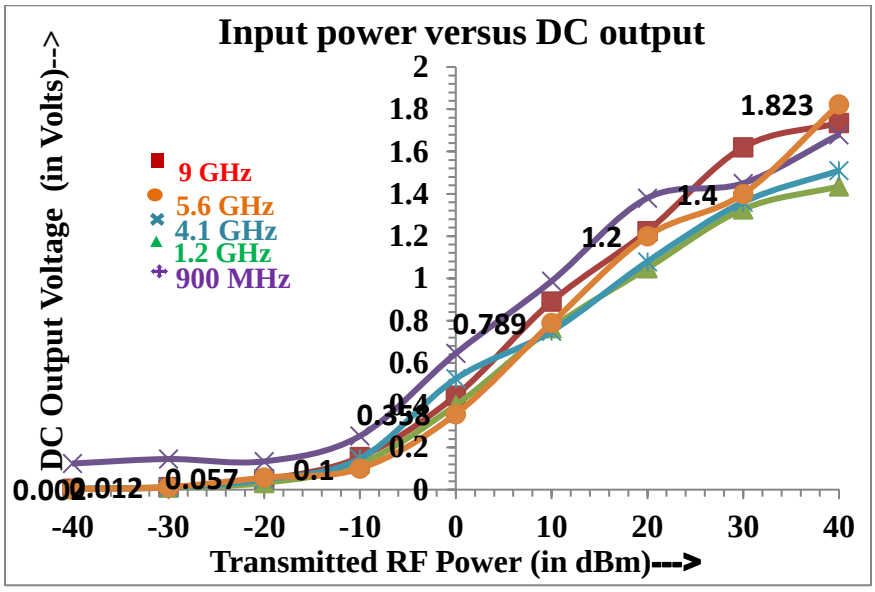

Figure 7. The transmitted RF input power versus DC output at the module graph.

The conversion efficiency (in %)of the module is calculated by the formula

$$\eta = \frac{V_{DC\ output}}{V_{input}} \times 100$$

The $V_{DC\ output}$ is the output measured by the digital multimeter and V_{input} is the magnitude of the input voltage at RF power source. The efficiency for the 9 GHz frequency is shown in the figure 8. As shown in figure the efficiency increases as the RF power increases.

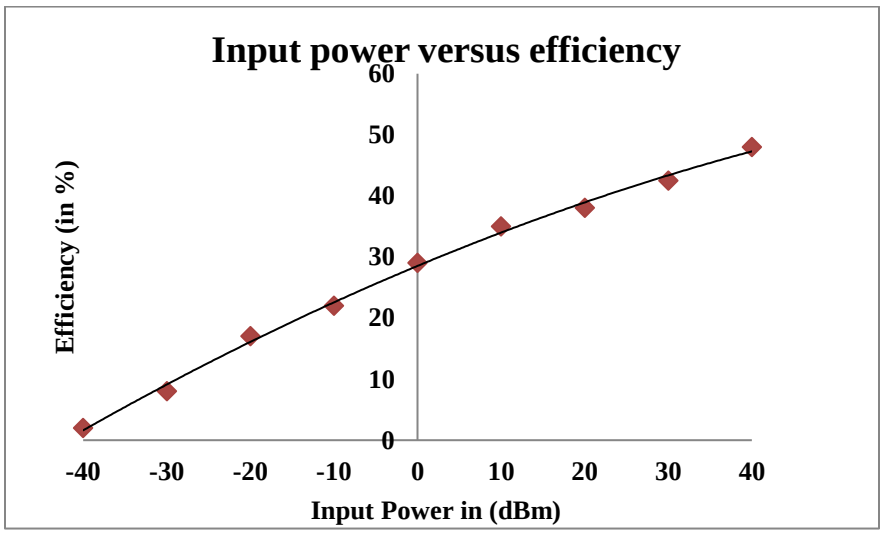

Figure 8. Input RF power versus efficiency graph.

The efficiency increases by the change in load resistance. For the input RF power +10 dBm the change in efficiency with respect to the change in load resistance is shown in figure 9. The maximum DC output voltage (1.823 V) for +40 dBm has been noted on the load resistance 22 k-ohms.

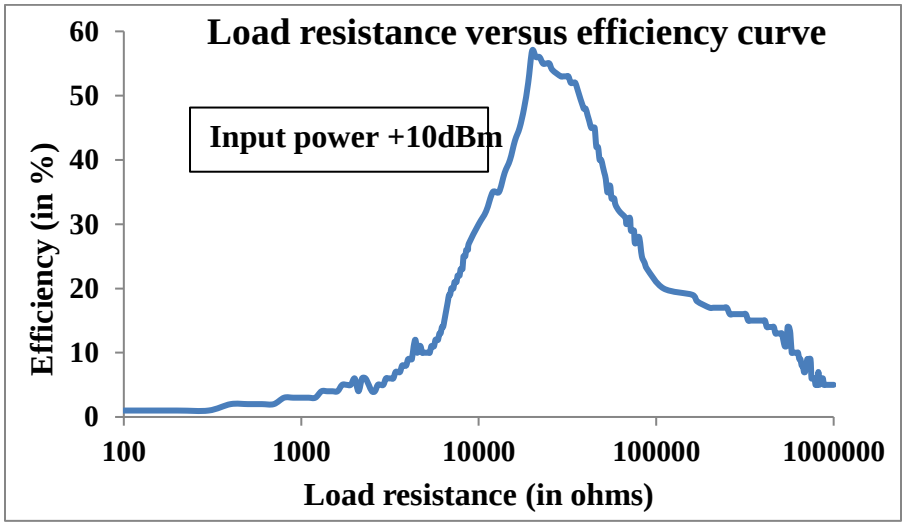

Figure 9. The load resistance versus efficiency curve.

V. CONCLUSION

A novel RF energy harvesting module has been presented in this paper. The antenna for this module has the structure of 2× 2 array of the coplanar monopole antenna. The novelty which is proposed lies in the fact that a seven stage RF-DC converter circuit has been integrated on the same substrate of antenna. This makes the module connector-less. Another uniqueness of this module is that the impedance between the antenna and the converter circuit is matched by using the maximum power transfer concept. The Wilkinson power combiners have been specifically selected for this purpose as they combine the powers of antenna arrays. For impedance matching between the antenna output port and RF-DC converter port, the existing input impedance at the input port of the converter circuit is measured. And the component of that measured value has been mounted at the Wilkinson combining branch. This arrangement reported the matching between the antenna and circuit ports. The DC output of the module has been measured. The maximum DC output is 1.823 V with respect to +40 dB m input RF power, with the load resistance 22 k ohm for the frequency 9 GHz. This voltage may be boosted by integrating a booster circuit. The voltage may be increased by using the super capacitor at the output of module.

VI. ACKNOWLEGEMENT

The authors are thankful to our Institutes Swami Keshvanand Institute of Technology, Management and Gramothan, Jaipur and Malaviya National Institute of Technology Jaipur, Rajasthan, India for providing the licensed software and fabrication facilities. The authors are

also thankful to Dr. O. P. N Calla, Director- ICRS (International Center for Radio Science) lab, Jodhpur, Rajasthan, India for providing the measurement facilities.
The author(s) declare(s) that there is no conflict of interest regarding the publication of this paper.

Summary

Practical Rectennas: Far-Field RF Power Harvesting and Transport

Energy harvesting from renewable sources such as the sun and wind, as well as from other sources like heat and vibration have been the focus of research recently. However, an increasing number of applications, especially inside buildings where light/solar energy is not always sufficient, cannot profit from these sources. Wireless Power Transmission (WPT) overcomes the lack of different power sources, such as light, heat and vibration and is an attractive powering method for battery-less sensor nodes, and active Radio-Frequency Identification (RFID) tags.
In this thesis, different rectenna topologies are investigated and state-of-the-art rectenna systems are discussed. The basic far-field energy harvester (rectenna) consists of an antenna, which captures a part of a transmitted RF signal, that is connected to a rectifier which converts the AC captured signal into a DC power signal. For a maximum power transfer, a matching network between the antenna and the rectifier is needed. In order to decrease the size of the system and improve the power conversion efficiency, the matching network can be removed by directly matching the antenna to the rectifier. A power management circuit is needed after the rectifier to store the harvested DC power and regulate the output voltage. This thesis is divided into four main parts:

- The rectifier is investigated in the first part. Since the rectifier is a nonlinear device and its impedance changes as a function of frequency and power, an accurate analysis model of the rectifier's impedance as a function of both is presented. The model is verified using Harmonic Balance simulations and measurements. In addition, the optimization of the rectifier's parameters for maximizing the output voltage is presented.

- The second part of the thesis presents a far-field power transport system employ-

ing rectennas using matching networks. A novel, modified, 50Ω Yagi-Uda antenna is presented. The main advantage of the presented antenna is that it can operate as a broad-band, dual band or a multi-band antenna. Three prototypes are fabricated, and the simulation results are validated by measurements. A rectenna system operating at 868 MHz is experimentally validated. Results are reported, demonstrating, at an input power level of -10 dBm, an RF to DC power conversion efficiency (PCE) of 49.7%. The 50Ω rectenna system exhibits an increased PCE of at least 5 % at -10 dBm and at least 10 % at -20 dBm, compared to reported state-of-the-art results.

- The focus of the third part of the thesis is on reducing the antenna size and at the same time keeping a high radiation efficiency. A novel (modified) rectangular loop antenna is presented. The benefits of the suggested novel antenna topology are the compact size and the ability to tune its input impedance while keeping a constant radiation efficiency. Using the suggested antenna, at an input power level of -10 dBm, the power conversion efficiency reaches 54%. The novel compact rectenna system is smaller in size and exhibits an increased PCE of at least 10 % at -10 dBm compared to reported state-of-the-art results.

- The fourth part of the thesis introduces a method to harvest RF power using Frequency Selective Surfaces (FSS). The novel FSS design is capable to harvest power from arbitrarily polarized incident waves. The design does not involve a matching network which results in a simple, polarization-independent power harvester. A simple equivalent circuit model to predict the transmission and reflection characteristics of the gridded-square-loop FSS is employed. Two prototypes have been fabricated and an RF to DC conversion efficiency of 25 % for the first prototype and 15.9 % for the second one are measured at $3.2\mu\,\mathrm{W/cm^2}$ available power density level.

Recommendations, future work, and means to enhance the power conversion efficiency as well as the system performance are addressed in the conclusion chapter.

Chapter one

Introduction

1.1 Introduction

In this chapter we will give the rationale for the analysis and development of *rect*ifying ant*ennas* or *rectennas*. Rectennas are used for converting RF energy, radiated by a distant (intentional or unintentional) source, into usable DC energy. Rectennas are used for transferring far-field, radiative RF energy into DC energy and in that respect differ from inductive or non-radiative, resonant, RF energy transferring systems. The differences between the two ways of RF-to-DC power conversion will be given and potential applications for far-field RF energy transfer will be discussed. These applications will be linked to wireless sensors. The outline of the thesis will be discussed, highlighting the new and original contributions. The chapter will be concluded by an overview of frequency bands used throughout the thesis and a single-number Figure of Merit used to compare complex numbers resulting from various simulations and measurements.

1.1.1 Trends and Needs

The use of wireless devices is rapidly expanding. The number of mobile phone subscriptions worldwide, for example, has expanded more than twelve times between 1997 and 2007, see Fig. 1.1 [1].

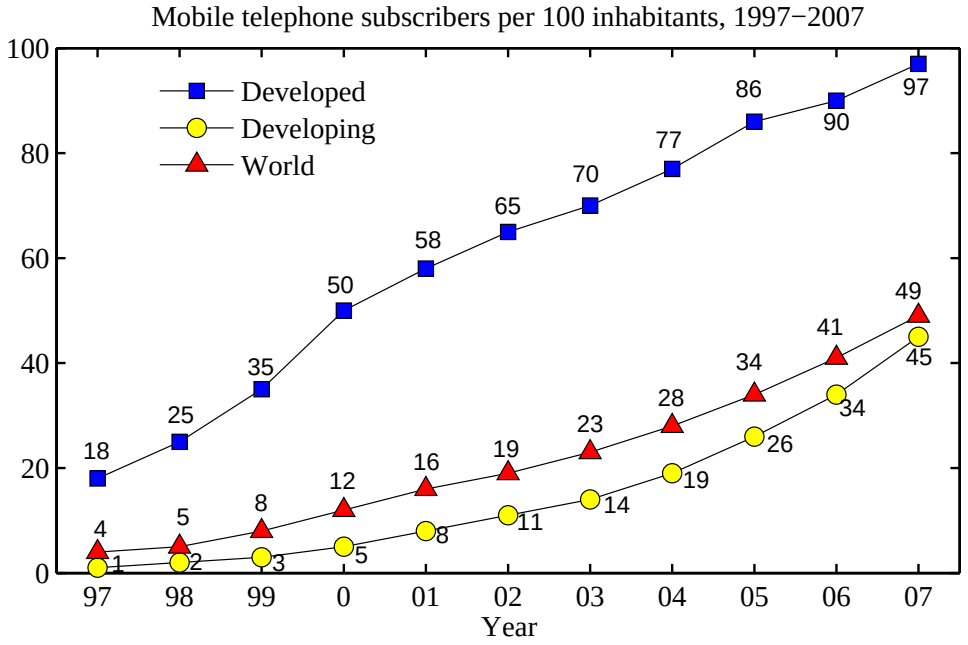

Figure 1.1. Mobile phone subscribers per 100 inhabitants, 1997-2007 [1]. Courtesy ITU .

Both Cisco [2] and Ericsson [3] expect 50 billion wireless devices to be connected to the internet in 2020, serving a population of 7.6 billion [2]. For wireless devices in general, the world Wireless Research Forum (WWRF) estimates 7 trillion wireless devices serving 7 billion people [4]. The total market for wireless sensor devices totaled $532 million in 2010, $790 million in 2011 and is expected to increase to $4.7 billion in 2016 [5].

Next to this expected growth in the use of wireless devices, also a need is developing for an increased wireless sensor autonomy and small form factor, see Fig. 1.2 [6]. The need for long lifetime and small form factors of future wireless sensor nodes do not match up well with currently available battery technology [7]. Alternative ways of powering may be found in energy harvesting where energy is taken from ambient sources like vibration, thermal differences, light and radiofrequency (RF) signals.

One of the main potential applications we see for employing far-field RF energy harvesting and transfer is in the so-called Smart Building Initiative (SBI) concept [8]. Before discussing SBI in detail, we will first discuss the differences between inductive resonant-

coupling and radiative far-field power transfer and the differences between transfer and harvesting.

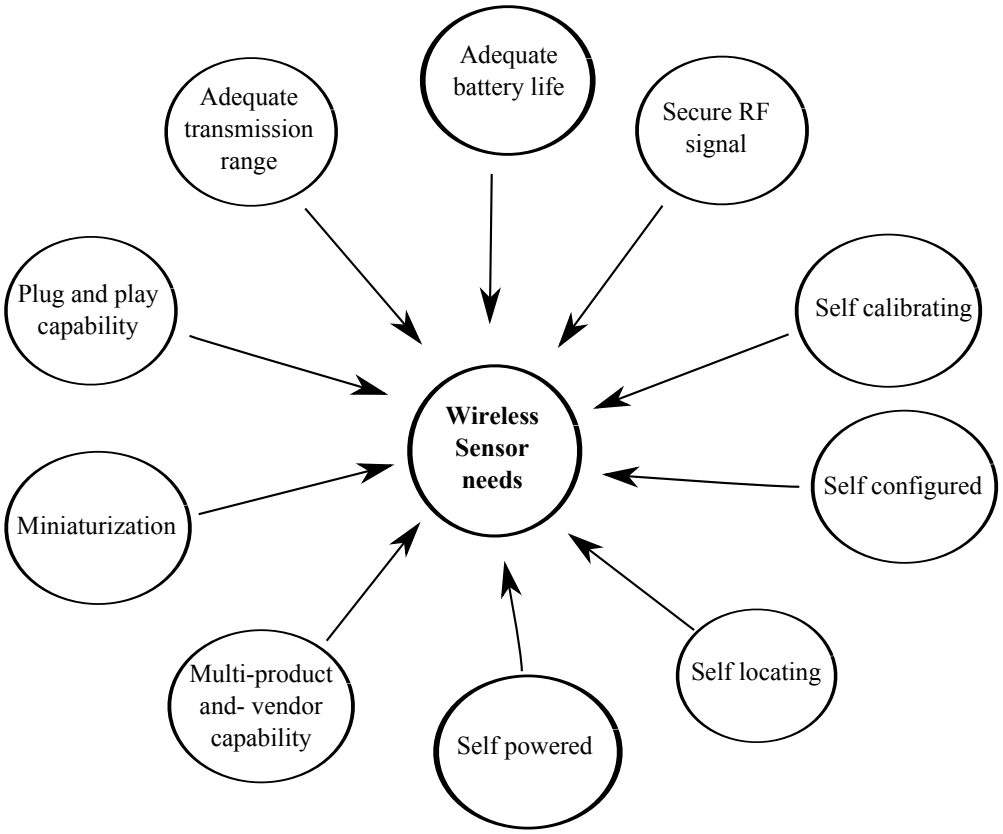

Figure 1.2. Needs for wireless sensors.

1.2 Non-Radiative and Radiative RF Power Transfer

When employing RF signals for the transfer of energy, we make a distinction between non-radiative and radiative RF energy transfer. The former is based on (inductive) coupling, the latter uses the transmission and reception of radio waves. When the transmitting source is unintentional, we call the transfer of energy *harvesting*. For a radiative system this might take the form of converting e.g. the energy in radio broadcasting signals into DC energy.

1.2.1 Non-Radiative Transfer

Non-radiative RF energy transfer is mostly employed in inductive systems, obeying the Qi standard [9]. Two coils are brought in each others vicinity for transferring RF energy, see Fig. 1.3. The two coils in close proximity form an electrical transformer. By

applying capacitors, a resonant coupling system is created [10], increasing the power transfer efficiency.

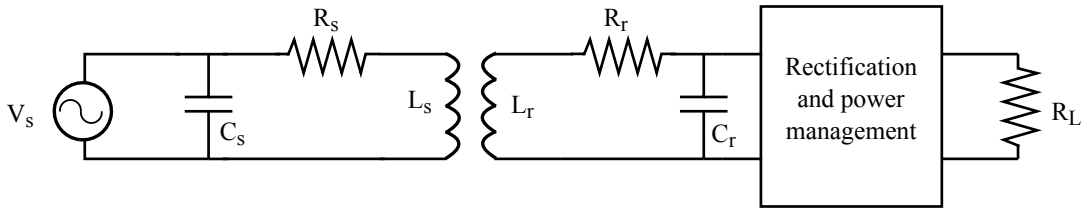

Figure 1.3. Resonant coupling (non-radiative) RF energy transfer system.

In the circuit shown in Fig. 1.3, a RF source is connected to a coil L_s, that is resonated with a capacitor C_s. A receiving coil L_r, resonated with a capacitor C_r is placed in close proximity and the received signal is rectified, eventually accumulated and used to power a source that is represented by load resistance R_L. The resistances R_s and R_r represent the losses in the transmitting and receiving coils, respectively. The benefit of this resonant coupling energy transfer, apart from being subject to a standard, lies in the high power transfer efficiency [11]. The drawbacks are in the limited transferring distance, the transfer efficiency falls off very steeply for distances larger than approximately one coil diameter, which also makes harvesting (taking energy from the ambient) impossible. For RF energy transfer over a distance, we need to employ radiative transfer.

1.2.2 Radiative Transfer

In a radiative transfer system, a RF source (unintentional or intentional) is connected to an antenna that emits radio waves. At a distance from this radio source, a receiving antenna intercepts a part of the radiated waves and the RF signal captured by the antenna is rectified, eventually accumulated and transferred to a load (wireless sensor), see Fig. 1.4. The dashed box in this figure is in fact a *rect*ifying ant*enna*, commonly known as a rectenna.

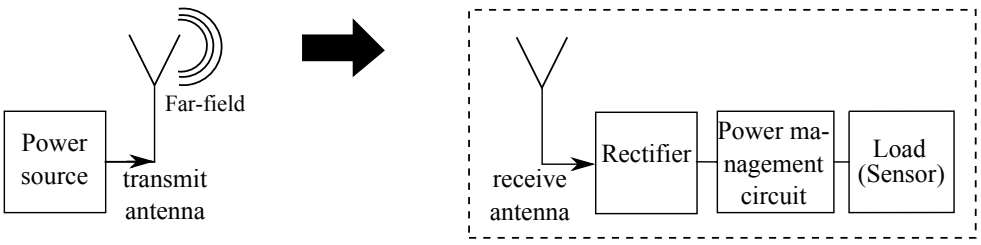

Figure 1.4. Radiative RF energy transfer system. The dashed box is commonly denoted rectenna.

Wireless radio-frequency (RF) energy transmission dates back to the experiments of Heinrich Hertz, in the 1880s, proving Maxwells theory of electromagnetics [12]. Initiated by an interest in short-range ($\leq$ 2 m [13]) radio-frequency identification (RFID) applications, far-field RF energy transfer has become a research topic at many European, American and Asian universities and research institutes [14–22]

1.3 Smart Building Initiative (SBI)

In a smart building, wireless sensors will measure, amongst others, the presence of persons, the local temperature and the lighting strength. Based on these readings that are transmitted to a central station, lighting and heating conditions will be adjusted (switched off or reduced if no persons are present). Thus energy consumption will be reduced. Artificial lighting, for instance, contributes approximately 30% of electricity consumption in a commercial building, and buildings collectively account for 40% of total world energy use [23]. SBI may also add to an increased well-being of elderly people when employed in an assisted living scenario, allowing the aged to live at home for a longer period [24], [25]. SBI relies on the use of a large number of wireless sensors, see also Fig. 1.5 [26].

Figure 1.5. Wireless sensors in a smart building.

Both aspects of SBI, a reduction in energy consumption and assisted living, are expected to generate a large economic impulse. The European home automation market revenues

were US$232.6 million in 2007 with an expected increase to US$446.6 million in 2013 [27]. In April 2011, the European smart homes and assisted living market was estimated to grow by 16.2% from US$1,544 million in 2010 to US$3,267 million in 2015 [28]. Recent estimates of revenues from home automation systems in Europe and North America project a growth at a compound annual rate of 42% from US$ 1.2 billion in 2012 to nearly US$ 9.4 billion in 2017 [29].

This needed widespread use of wireless sensors in offices and houses has, however, been severely slowed down due to the cost of cabling. Cabling an average office unit or a four bed house is estimated at €7,000–11,000 ($9,000–15,000) [30]. This is especially true for offices, that are, on average, reconfigured every five years [31]. Although using batteries may severely reduce these cabling costs, the maintenance issues associated with using primary batteries – i.e. locating batteries to be replaced and disposing of the old ones will not be tolerated by the market [32].

Then what remains for powering the many wireless sensors is energy harvesting. Well known sources for energy harvesting are [7]: vibration, ambient light, temperature gradients, and (ambient) radio waves. With the exception of intentional radio waves, the availability of energy harvesting sources of sufficient power cannot be guaranteed under all circumstances [12]. Therefore we will concentrate on the use of dedicated RF sources, distributed in a building for powering the wireless sensors. The investment in these sources and the costs of powering them will be more than compensated by the reduction in power consumption of the whole building by switching off lights and turning down heating.

1.4 Challenges

For powering the wireless sensors needed in SBI we will employ the license-free frequency bands for Industry, Science and Medicine (ISM). Although these frequency bands can be used without the need for a license, they are restricted in the maximum allowed Effective Isotropic Radiated Power (EIRP), that is the transmit power multiplied by the transmit antenna gain. For ISM frequencies between 865 MHz and 2.48 GHz the maximum allowed EIRP does not exceed 4W [12]. Due to the spherical spreading of the transmitted electromagnetic waves, the power received at the rectenna side will decrease inversely with the squared distance between transmitter and receiver so that, in general, we will have to deal with low received RF power levels. That means that all the subsystems of a rectenna, especially the antenna and the rectifier need to be designed and impedance matched very carefully. As already demonstrated in [33], the RF-to-DC power conversion efficiency of the rectenna may be maximized by directly, complex-conjugate impedance matching the antenna to the rectifier. Thus, we need to be able to determine the (complex) RF input impedance of a rectifier circuit and need

to be able to model and design antennas generating a desired complex input impedance. Furthermore, we need to be able to find the optimum input power level and frequency to operate the rectifier circuit. All these topics will be discussed in this thesis.

1.5 Organization of the Thesis and Original and Novel Contributions

The organization of the thesis is graphically depicted in Fig. 1.6.

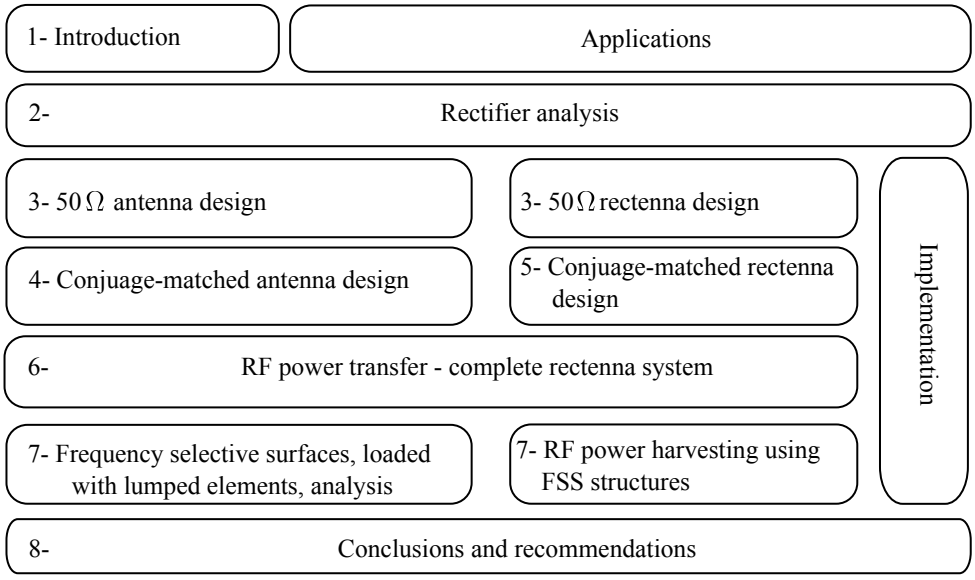

Figure 1.6. Outline of this thesis.

In Chapter 1 the problem of powering an increasing number of wireless devices is discussed as well as the possibilities of harvesting power from the ambient. The use of RF power transfer and harvesting is discussed in more detail and far-field, radiative RF power transfer is chosen as the preferred way to transfer power wirelessly over a substantial distance. The main application of this technology is seen in Smart Building Initiatives and assisted living. Due to restricted power densities it is concluded that the design of the subsystems of a rectifying antenna (rectenna) as well as the impedance matching between these subsystems must be carried out very carefully. Therefore it is important to develop accurate and easy to implement and use models of especially rectifying circuits and antennas. On top of that, a design strategy with respect to the choice of the operating frequency, RF input power and impedance matching needs to be developed. In Chapter 2, the analytical modeling of a high-frequency, rectifying Schottky diode is discussed. Based on the model, the influence of the bulk resistance and the

saturation current on the DC output voltage is analyzed. The main contributions and innovations of Chapter 2 are:

- The derivation of a Schottky diode selection criterion and the selection of commercially available Schottky diodes according to this criterion.

Chapters 3 to 5 deal with antenna design, where the designs are immediately applied in a co-design with a rectifier to create rectenna structures, see Fig. 1.6. Chapter 3 deals with an antenna structure that can be designed for dual, triple or broadband frequency use. Based on a reported broadband strip-dipole antenna, a Yagi-Uda like configuration is created around this active strip-dipole antenna to improve the antenna characteristics with respect to bandwidth and gain. The antenna is designed for a 50 Ω input impedance. The new configuration is used to design a rectenna, using a lumped-element network to match the antenna impedance to the complex input impedance of a voltage doubling rectifier.

The main contributions and innovations of Chapter 3 are:

- A wideband strip-dipole antenna is combined with parasitic elements in a Yagi-Uda like antenna configuration to create a dual, triple or broadband antenna having a moderate gain (3 to 6 dBi).
- The new antenna concept has been used to design a rectenna that demonstrates an increased Power Conversion Efficiency (PCE) of at least 5 % at -10 dBm and at least 10 % at -20 dBm with respect to the state of the art as published in the open literature.

Chapter 4 deals with antenna structures intended for a direct conjugate matching to the rectifier, thus omitting an impedance matching network that will lead to a higher power conversion efficiency (less loss) and a more compact design (fewer lumped elements). Started is in chapter 4 with the strip-dipole antenna analysis. The derived model is used in modeling a strip folded-dipole antenna. Evolving from this latter antenna, a modified loop antenna is introduced and full-wave analyzed. The main contributions and innovations of Chapter 4 are:

- The validity range (length and width) of the impedance equation for a strip dipole antenna has been extended by deriving new fitting equations.
- The accuracy of an existing strip-folded dipole antenna has been improved by using the improved strip-dipole antenna model.
- A new, electrically small antenna type has been invented that allows for tuning the complex input impedance and the radiation efficiency independently.

In Chapter 5 a design strategy for maximizing the sensitivity of a rectenna is outlined. As a consequence, an antenna should be designed for having a very low real part of the input impedance and a high absolute value of the imaginary part. The new antenna discussed in chapter 4 is used for this purpose and is co-designed with a lumped-element Schottky diode rectifier and with an integrated custom-made rectifier. Both realized rectennas demonstrate characteristics better than the state of the art. The main contributions and innovations of Chapter 5 are:

- The realization of a rectenna with dimensions smaller than the state of the art and demonstrating a RF-to-DC power conversion efficiency larger than state-of-the art.
- A rectenna based on a co-design of the same antenna and a custom made rectifier demonstrating the smallest dimensions paired to the highest sensitivity ever reported in the open literature.

In Chapter 6, a complete rectenna system is presented where a commercially available power management circuit, a 1000 μF storage capacitor and a dynamic load are used. The average DC output power and the system's RF to DC conversion efficiency are measured, and compared to those measured for a commercially available rectenna system operated under the same conditions. It is shown that the commercially available rectenna system fails to operate at low power levels (≤ -6dBm) while the presented system can operate at an RF input power level as low as -13 dBm. At an input power level of 0 dBm, the power conversion efficiency of the commercially available system does not exceed 19 %, while the power conversion efficiency of the presented system reaches 40 %, resulting in more than 20 % improved power conversion efficiency. The main contributions and innovations of Chapter 6 are:

- Full rectenna system prototyped and characterized.
- Improved performance compared to commercially available system.

In Chapter 7, the analysis of a gridded square loop Frequency Selective Surface (FSS) is extended with the inclusion of lumped elements to model the presence of Schottky diodes for harvesting RF power. The updated model that is validated through cross-simulations and waveguide simulator measurements predicts the resonance frequencies with the diodes included and thus makes it possible to design RF harvesting FSS structures. The main contributions and innovations of Chapter 7 are:

- The recognition of the harvesting structure being essentially a FSS.
- The inclusion of square loops in a grid to maximize the current density in that grid.

- The modeling of the RF power harvesting FSS and the use of this model to optimize a large area RF power harvesting structure.

Finally, Chapter 8 presents a summary of the main results, conclusions and recommendations for future research.

1.6 Figure of Merit

In the comparison of different simulation and measurement results for a complex impedance throughout this thesis, we want to end up with a single-number Figure of Merit. For that purpose the power wave reflection coefficient is an excellent tool, relating to a practical use [33].

1.6.1 Power Wave Reflection Coefficient

When a source with internal impedance Z_R is connected to a load impedance Z_L, see Fig. 1.7, the standard (voltage) reflection coefficient Γ is given by

$$\Gamma = \frac{Z_L - Z_R}{Z_L + Z_R}. \tag{1.1}$$

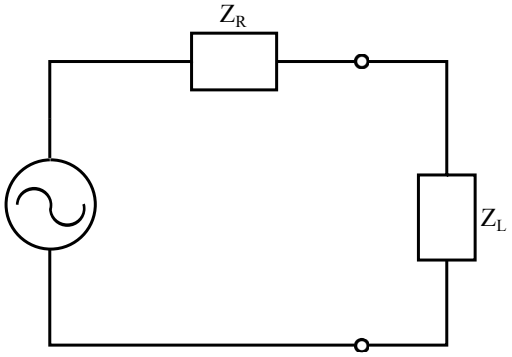

Figure 1.7. A source with internal impedance Z_R is connected to a load impedance Z_L.

This reflection coefficient is a direct measure for the reflected power only when Z_R is real-valued [34]. When Z_R is complex and conjugate impedance matching is applied to maximize the power transfer from generator to load, the standard reflection coefficient in Eq. 1.1 will be nonzero. Therefore, the standard definition of reflection coefficient, based on physical waves propagating along a transmission line, does not in general

represent the reflection of power. Power waves, mathematical constructs from the circuit world, have been introduced to correctly describe the reflection of power in systems with complex reference impedances. The reflection coefficient based on power waves Γ_p is given by

$$\Gamma_p = \frac{Z_L - Z_R^*}{Z_L + Z_R}, \tag{1.2}$$

where Z_R^* denotes the complex conjugate of Z_R. The reflection coefficient according to Eq. 1.2 works for both real-valued and complex impedances.

1.6.2 Application of the Power Wave Reflection Coefficient as a Figure of Merit

We will now apply this power wave reflection coefficient as a Figure of Merit (FoM) to describe the differences between two simulated complex impedance values or between a simulated complex impedance value and a measured value. The FoM will yield a single number describing the discrepancies between two complex impedance values. Lets assume that we have two complex impedance values, Z_{m1} and Z_{m2} and we want to compare the two. First we have to make a choice about the reference. Lets assume that we take Z_{m1} as a reference and compare the Z_{m2} value to Z_{m1}. We now assume that we have a black box with input impedance Z_{m1}^*, see Fig. 1.8.

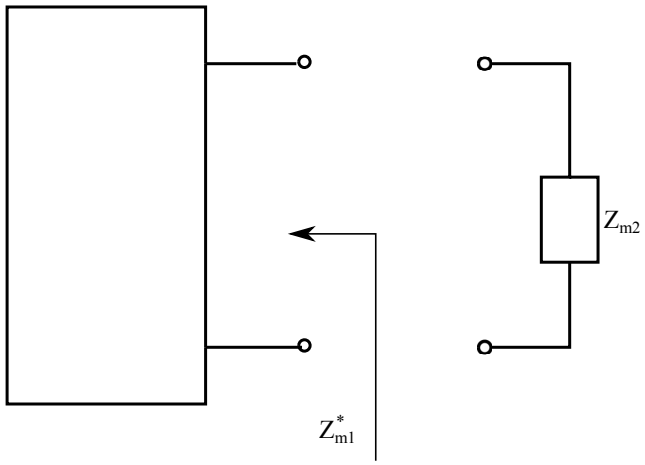

Figure 1.8. 'Connecting' the impedance to be evaluated to a black box having an input impedance that is the complex conjugate value of the reference impedance.

If we 'connect' an impedance Z_{m1} to this black box, we will have a perfect impedance match and the power wave reflection coefficient for this imaginary system, our Figure

of Merit, will be zero. We are not connecting Z_{m1} to the imaginary black box however but Z_{m2}. The amplitude of the power-wave reflection coefficient, our FoM, will give us a single number describing how 'far off' this complex impedance is from the desired value Z_{m1}. Moreover, the FoM relates to real physics, describing how the mismatch will relate to the reflection of power. A reflection of 10 % of the input power (FoM$\leq$ -10 dB) is considered as acceptable and realizable in practice.

Chapter two

Rectifier Analysis for RF Energy Harvesting and Power Transport

In this chapter a complete design method to accurately calculate the impedance and the DC output voltage of the rectifier part in a wireless power transmission system is presented. The presented method uses circuit analysis to calculate the input impedance of a Schottky diode as a function of frequency for different RF input power levels. For the DC output voltage, the Ritz-Galerkin method is used to predict the output DC voltage across different load resistances. Moreover, the influence of the diode parameters on the output voltage is discussed. All the simulated results are validated by measurements and by Harmonic Balance (HB) simulations.
The rectenna design criteria with respect to the operating frequency and the input power level are also motivated in this chapter.

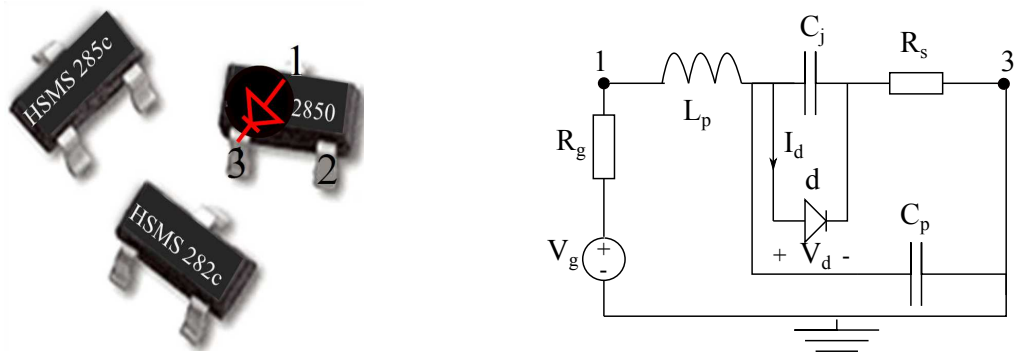
2.1 Introduction

Energy harvesting from renewable sources such as solar light and wind, as well as from other sources like heat and vibration, have been the focus of research recently [7]. However, an increasing number of applications, especially inside buildings where light/solar energy is not always sufficient, cannot profit from these sources. Power transport [35] might be a perfect substitute for batteries to drive wireless sensor nodes.
Recent achievements have shown that far-field energy harvesting [3] and power transport, i.e. means to send power over distances, may overcome the lack of different power sources such as light, heat and vibration.
The basic far-field energy harvester consists of an antenna, which captures part of the transmitted RF signal, connected to a rectifier (AC/DC converter) which converts the AC captured signal into a DC power signal. A power management circuit is needed to guide and store the DC power. For maximum power transfer, a matching network is needed between the rectifier and the antenna [36, 37]. The design, fabrication and measurement of an RF harvester employing a matching network will be presented in Chapter 3.
In order to decrease the size of the system, the matching network is removed in [38] and [39] and the antenna is directly matched to the rectifier ($Z_{antenna} = Z^*_{rectifier}$). The design, fabrication and measurement of a rectenna directly matched to the rectifier circuit will be presented in Chapter 5. In both situations, i.e. with or without a matching network, an accurate analysis of the rectifier's RF input impedance is crucial. This chapter investigates the input impedance of the rectifier as a function of frequency for different power levels. In addition, the influence of the diode's parameters on the output voltage and consequently on the rectifier efficiency are discussed.

2.2 Schottky Diode Equivalent Circuit Model

The diode analysis method to be presented has been introduced in [40] and verified in [33, 41, 42]. The method uses circuit analysis to calculate the input impedance of a packaged Schottky diode as a function of frequency for different power levels.

Figure 2.1(a) shows some commercially available Schottky diodes in SOT-23 package. The equivalent electrical circuit is shown in Fig. 2.1(b). C_j is the junction capacitance, C_p and L_p are the parasitic packaging capacitance and inductance respectively. d is the ideal diode. V_g is an RF voltage generator and R_g is the internal resistance of the generator. Since the Schottky diode is a non-linear device, and its input impedance changes as a function of input power and frequency, the main objective is to present a standard analysis that is fast, accurate and reliable to calculate the impedance of the Schottky diodes.



(a) (b)

Figure 2.1. Commercially available, packaged Schottky diodes (SOT-23) (a) and their equivalent circuit model (b).

To be able to determine the impedance of the rectifier between pins 1 and 3 (see Fig. 2.1), the voltage across and the current through the diode d should be determined. The electrical behavior of the rectifier is investigated assuming a voltage source with a single frequency f_0 as input, $V_g = |V_g| \cos(2\pi f_0 t)$. The electrical behavior of this circuit can be described with the following expressions, obtained by applying Kirchhoff's relations:

$$V_g = I_g R_g + L_p \frac{\partial I_g}{\partial t} + V_{C_P}, \tag{2.1}$$

$$V_{C_P} = V_d + V_{R_s}, \tag{2.2}$$

$$V_{R_S} = R_s(I_{C_j} + I_d), \tag{2.3}$$

$$I_{C_j} = Cj \frac{\partial V_d}{\partial t}, \tag{2.4}$$

$$I_d = I_s(e^{\alpha V_d} - 1), \tag{2.5}$$

so that

$$\frac{\partial V_d}{\partial t} = \frac{1}{R_s C_j} \left\{ \psi \left(\frac{\partial I_g}{\partial t} \right) - R_s I_s \left(e^{\alpha V_d} - 1 \right) \right\}, \tag{2.6}$$

where $\psi \left(\frac{\partial I_g}{\partial t} \right) = V_g - R_g I_g - V_d - L_p \frac{\partial I_g}{\partial t}$. $\alpha = \frac{q}{nKT}$, where $\frac{q}{KT}$ is the thermal voltage and n is the ideality factor. With the aid of the fourth-order Runge-Kutta method (RK4), Eq. (2.6) can been solved as in [33], and the voltage V_d across the diode d is calculated. By using Eq. (2.5), the current I_d flowing through the diode is determined. After the evaluation of V_d and I_d the input impedance of the diode d is found using Ohm's law:

$$Z_d = \frac{V_d}{I_d}. \tag{2.7}$$

After evaluating the input impedance of the diode Z_d, using the (Spice) parameters extracted from the manufacturer data sheet, the input impedance of the Schottky diode Z_{in} including its series resistance and packaging parasitics is calculated. Table 2.1 summarizes the Spice parameters for two commercially available Schottky diodes, Avago HSMS-2820 and HSMS-2850 [43]. C_{23} accounts for a second diode between pins 2 and 3 and is determined empirically from measurements.

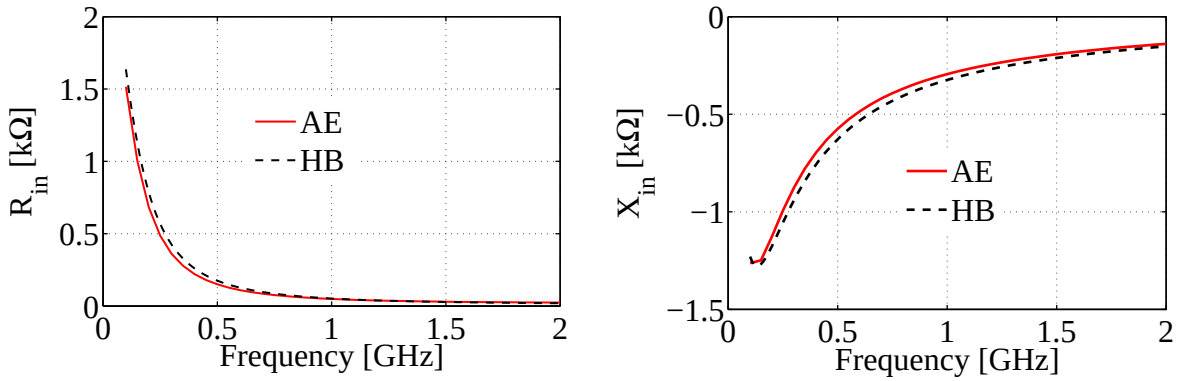
To verify the accuracy of the equivalent circuit model, the two different Schottky diodes HSMS-2820 and HSMS-2852 will be investigated. The input impedance versus frequency for different power levels is calculated with the aid of the equivalent circuit model and is compared with harmonic balance simulation results [44] and with measurement results.

Table 2.1. Spice parameters used to calculate the impedance of the rectifier shown in Fig. 2.1(b) using the analytical procedure.

Parameter	**HSMS-2820**	**HSMS-2850**	Units
I_s	2.2E-8	3.0 E-6	A
n	1.08	1.06	-
R_s	6.0	25	Ω
C_j	0.7	0.18	pF
L_p	2.0	2.0	nH
C_p	0.08	0.08	pF
C_{23}	0.06	0.06	pF

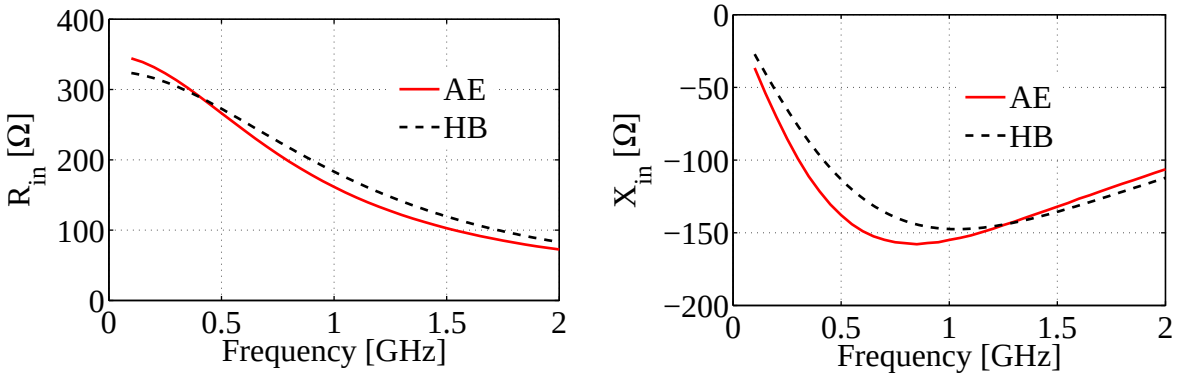
Figures 2.2 and 2.3 show the impedance of the rectifier as calculated by using ADS harmonic balance simulations and the presented analytical expressions. Figures 2.2(a) and 2.2(b) show the real and imaginary parts of the input impedance versus frequency at an input power level of -20 dBm. It is shown in the figures that the equivalent circuit model can predict the impedance of the rectifier with a relative difference of less than 10 % for the real and imaginary parts of the input impedance. In the next paragraph, we will investigate whether this accuracy is sufficient.

In Figs. 2.3(a) and 2.3(b) the input power level is increased to -10 dBm. The input impedance is again calculated using ADS harmonic balance simulations and the equivalent circuit model. It is shown in the figure that the results of the analytical equations are matching the results obtained using harmonic balance simulations. The relative difference for the input impedance calculated by Harmonic Balance (HB) simulation and by the Analytical Expressions (AE) will be presented in detail next.



(a) (b)

Figure 2.2. Real (a) and imaginary (b) parts of the input impedance of the Schottky diode HSMS-2852 versus frequency for a maximum available power level of -20 dBm calculated using the analytical equations (AE) and harmonic balance (HB) simulations. $R_g = 50\Omega$.



(a) (b)

Figure 2.3. Real (a) and imaginary (b) parts of the input impedance of the Schottky diode HSMS-2852 as a function of frequency for a maximum available power level of -10 dBm calculated using the analytical equations (AE) and harmonic balance (HB) simulations. $R_g = 50\Omega$.

To quantify the accuracy of the simulated results shown in Fig. 2.2 and in Fig. 2.3, the Figure of Merit introduced in the previous chapter (see Sec. 1.6), is used. Here, $Z_{m_1} = Z_{AE}$ and $Z_{m_2} = Z_{HB}$, with $Z_{AE} = R_{AE} + jX_{AE}$ and $Z_{HB} = R_{HB} + jX_{HB}$. R_{AE} and X_{AE} are the real and imaginary parts calculated using the presented equivalent circuit model. R_{HB} and X_{HB} are the real and imaginary parts of the input impedance calculated using Harmonic Balance simulations. Figure 2.4 shows that the deviations between the results of the analytical circuit model (AE) and the results of Harmonic Balance (HB) simulations do not exceed -10 dB, which satisfies the FoM criterion, which leads to the conclusion that AE results are a good alternalive for HB simulations.

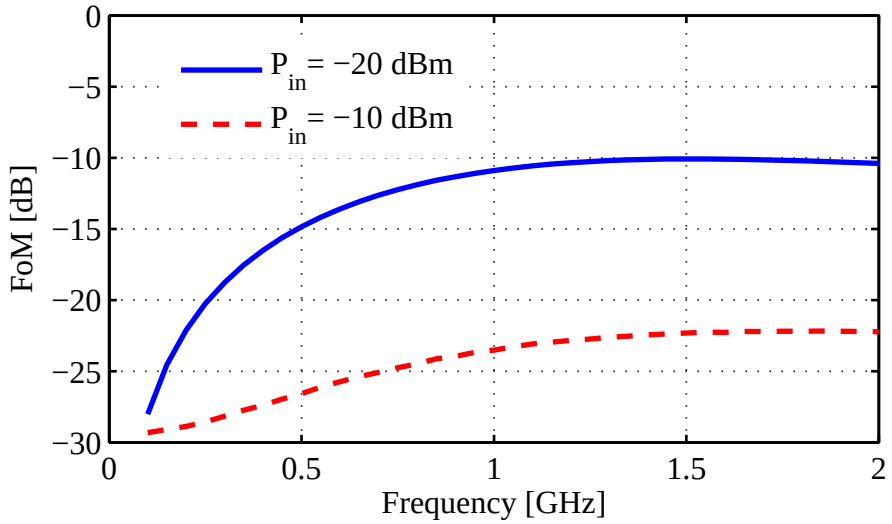


Figure 2.4. Figure of Merit to calculate the deviation between the results of the presented equivalent circuit model (AE) and harmonic balance simulation results (HB) as presented in Figs. 2.2 and 2.3. Note the different vertical axis scales in Figs. 2.2 and 2.3.

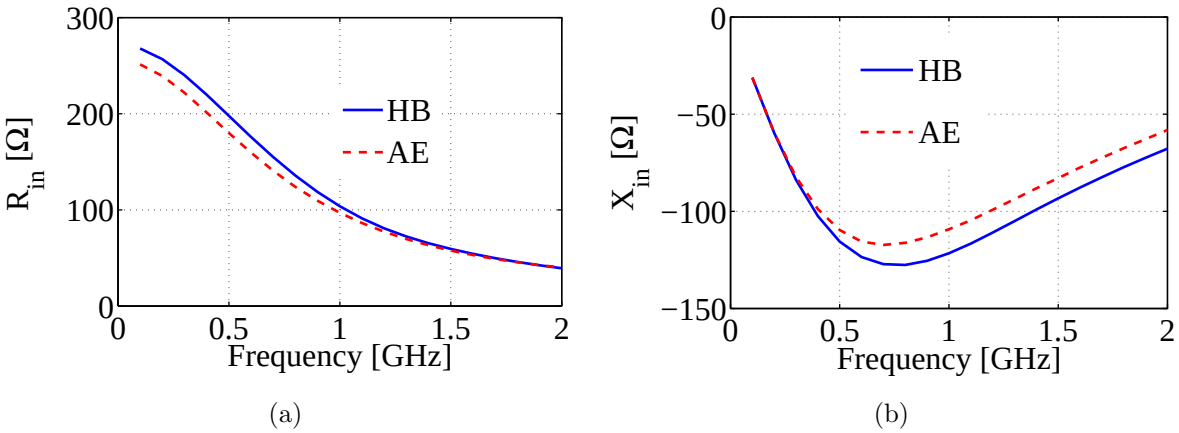
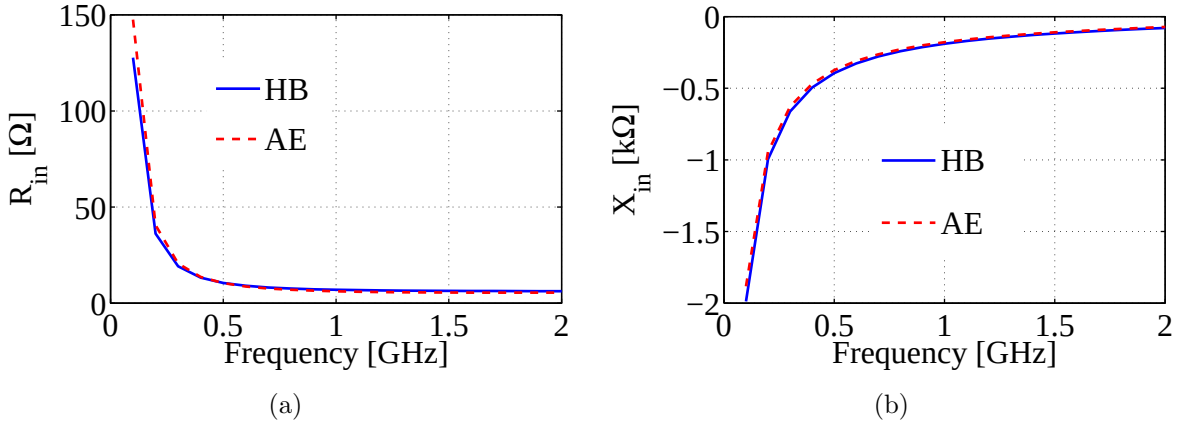
The real and imaginary parts of the input impedance of the commercially available Schottky diode Avago HSMS-2820 are also calculated from the analytical expressions presented in this section and are compared to the ones obtained by Harmonic Balance simulations [44]. The results at an input power level of 0 dBm and -10 dBm are plotted in Fig. 2.5 and Fig. 2.6, respectively.



(a) (b)

Figure 2.5. Real (a) and imaginary (b) parts of the input impedance of the commercially available Schottky diode Avago HSMS-2820 versus frequency for a maximum available power level of 0 dBm calculated using the analytical expressions and harmonic balance simulations. The source has a 50Ω internal resistance.



(a) (b)

Figure 2.6. Real (a) and imaginary (b) parts of the input impedance of the commercially available Schottky diode Avago HSMS-2820 versus frequency for a maximum available power level of -10 dBm calculated using the analytical expressions and harmonic balance simulations. The source has a 50Ω internal resistance.

The deviations between AE and HB have been calculated as a function of frequency using the Figure of Merit introduced in Sec. 1.6. The deviations do not exceed -10 dB, which validates the accuracy of the presented equivalent circuit model, taking the Harmonic Balance results as a reference. What remains is to confirm the correctness of taking the Harmonic Balance simulation results as a reference. Therefore, we will compare both simulations (AE and HB) with measurements.

2.3 Measurement Setup and Measured Results

In this section, the equivalent circuit model will be verified by measurements. In order to fully verify the accuracy of the presented analytical equations, the commercial Schottky diode HSMS-2822 is used for measurements. To measure the impedance of the rectifier the setup shown in Fig. 2.7 is used. The Device Under Test (DUT) is mounted directly on a SMA connector and then connected to the Vector Network Analyzer (VNA) using a phase-stable coaxial cable. A DC blocker is used to prevent DC currents flowing through the VNA. After calibrating, the phase reference point is at the SMA connector (point 1 in Fig. 2.7), so that the phase-stable coaxial cable of length l has no influence on the measurements. The PNA-X Network Analyzer [45] is used to measure the reflection coefficient S_{11} at the DUT (Voltage reflected due to the mismatch between Z_0 and Z_{DUT}).

$$S_{11} = \frac{Z_{DUT} - Z_0}{Z_{DUT} + Z_0}. \tag{2.8}$$

The input impedance of the rectifier $Z_{rectifier}$ is calculated from the reflection coefficient

$$Z_{rectifier} = Z_0 \frac{1 + S_{11}}{1 - S_{11}}, \tag{2.9}$$

where $Z_0 = 50\Omega$. It should be mentioned that this measurement setup can only be used to measure the impedance of two or more diodes in parallel. If the impedance of a single diode has to be measured, the measurement setup in Fig. 2.7 should be modified and an inductor should be connected in parallel to the rectifier so that the diode can self-bias itself allowing the diode's DC current to return to ground. Pins 1,2 and 3 in Fig. 2.7 correspond to the ones indicated in Fig. 2.1(a).

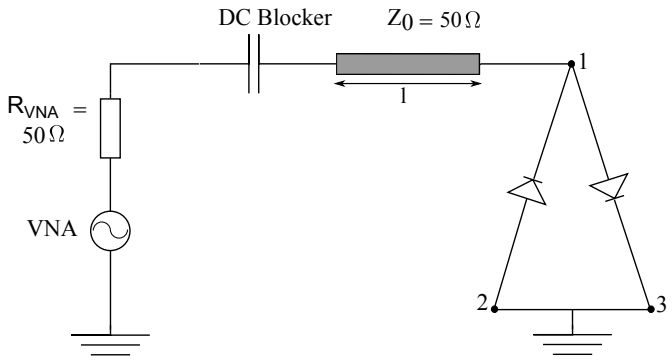


Figure 2.7. Setup to measure the impedance of the diode using a Vector Network Analyzer (VNA).

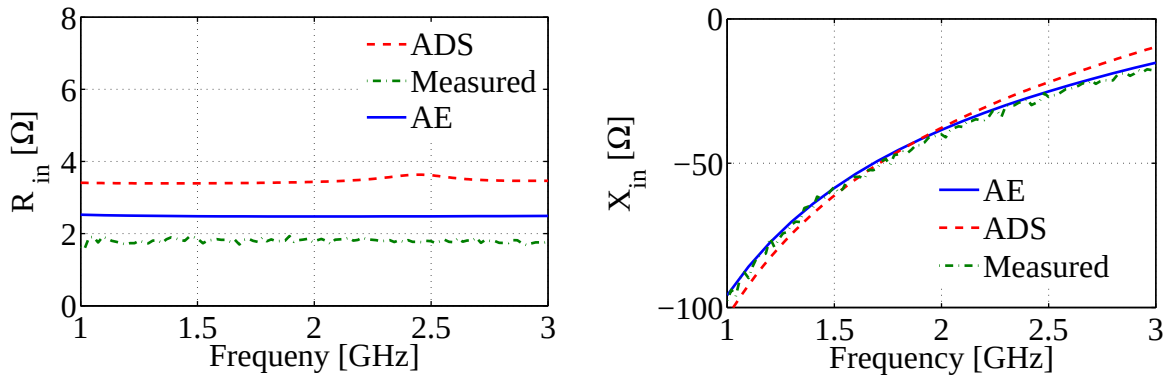
Figures 2.8(a) and 2.8(b) show the real and imaginary parts of the input impedance as a function of frequency at an available power level of −15 dBm.



(a) (b)

Figure 2.8. Real (a) and imaginary (b) parts of the input impedance versus frequency for the diode HSMS-2822 at an available power level of −15 dBm.

Figures 2.9(a) and 2.9(b) show the input impedance as a function of available power level P_{in} at an operating frequency of 2.45 GHz.

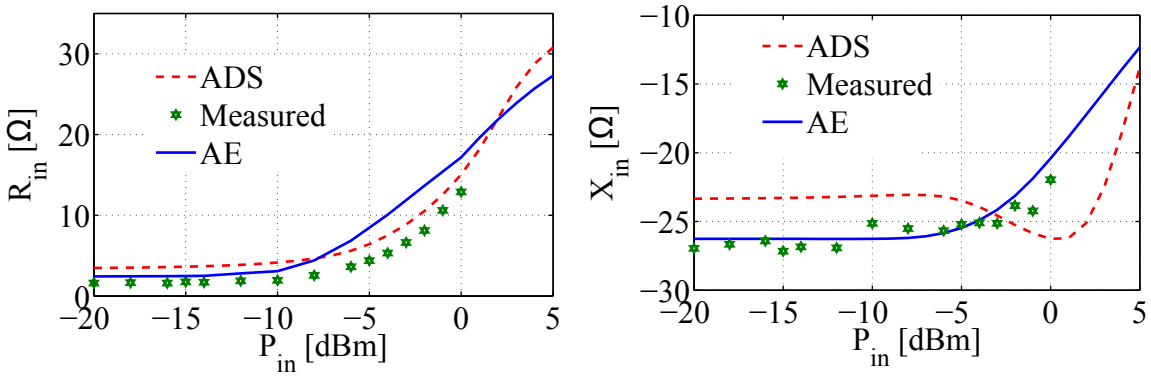


Figure 2.9. Real (a) and imaginary (b) parts of the input impedance versus P_{in} for diode HSMS-2822 at an operating frequency of 2.45 GHz.

It is demonstrated in Figs. 2.8 and 2.9 that the presented analytical expressions as well as Harmonic Balance simulations can predict the impedance behaviour of the diode as a function of frequency (see Fig. 2.8) and as a function of the available power level (see Fig. 2.9). To quantify the agreement between the results of the AE and measurements, the Figure of Merit as a function of input power level is plotted in Fig. 2.10. It is depicted in the figure that the deviations do not exceed the -10 dB threshold, thus validating the accuracy of the analytical expressions with respect to measurements.

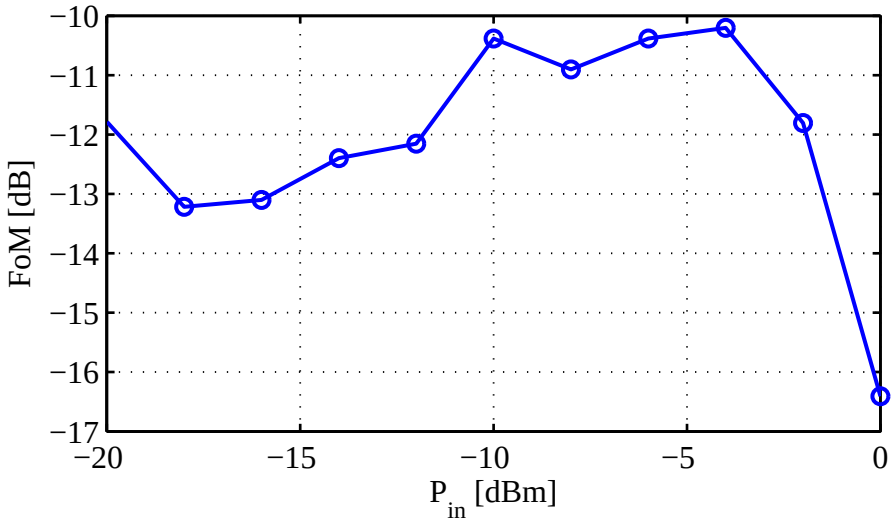

Figure 2.10. Figure of Merit versus maximum available power level for the equivalent circuit model and the measurements shown in Fig. 2.9.

2.4 Output Voltage of the Rectifier Circuit

In this section we will investigate the DC output voltage as a function of maximum available input power for a single diode. The Ritz-Galerkin averaging method [46] is used to predict the DC output voltage across different resistance values. An implicit equation is obtained for the output voltage as a function of the maximum available input power P_{in}, the generator resistance R_g, the saturation current I_s, the contact resistance R_s and the load resistance R_L,

$$\mathrm{I}_0\left(\alpha\sqrt{8R_gP_{in}}\right) = \left(1+\frac{V_{out}}{R_LI_s}\right)\exp\left(1+\frac{R_g+R_s}{R_L}\right)\alpha V_{out} \tag{2.10}$$

where $\mathrm{I}_0\left(\alpha\sqrt{8R_gP_{in}}\right)$ is the zero-order modified Bessel function of the first kind. $\alpha = \frac{q}{nkT}$, where q is the electron charge, k is Boltzmann's constant, T is the temperature in Kelvins, and n is the diode ideality factor. By solving Eq. (2.10) the output voltage for different load resistances is calculated. Note that the generator is not matched to the rectifier and that P_{in} is the power that would be available if the diode would have the same impedance as that of the generator. Therefore, P_{in} is the maximum available power. The output voltage of the commercially available diode HSMS-2850 ($I_s = 3\,\mu$A and $R_s = 25\Omega$, $n = 1.03$) is calculated and compared to harmonic balance simulation results. Figure 2.11 shows the DC output voltage calculated by the Ritz-Galerkin (RG) method and by Harmonic Balance (HB) simulations for different load resistances.

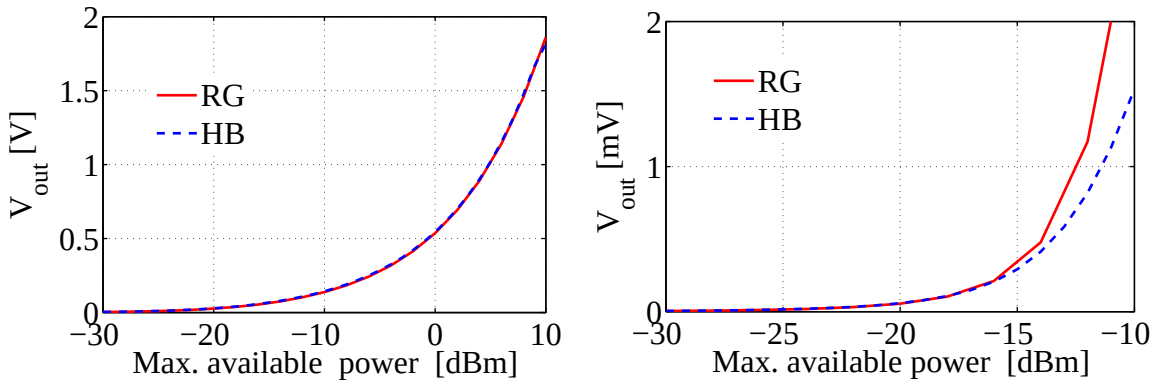

Figure 2.11. Output voltage as a function of maximum available input power calculated by Ritz-Galerkin averaging (RG) method and by Harmonic Balance (HB) for a load resistance of (a) $R_L = 100\mathrm{k}\Omega$, and (b) $R_L = 10\Omega$. The generator impedance $R_g = 50\Omega$.

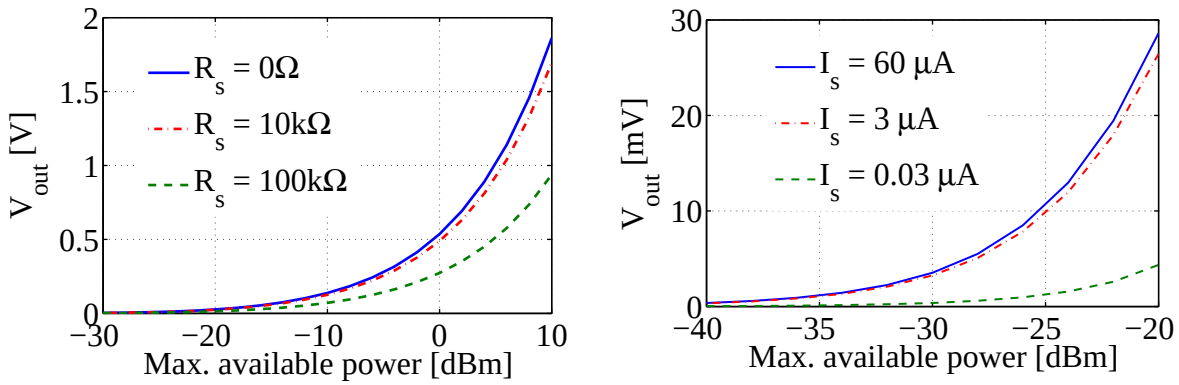
It is shown in the figure that the simulation results calculated by Ritz-Galerkin aver-

aging method can accurately predict the output voltage of the rectifier with a relative difference of less then 5 %, when the load resistance is high (100kΩ). On the other hand when the load resistance decreases the relative difference increases to 43 % for $P_{in} = -12$ dBm. For a 10 Ω load resistance, the Ritz-Galerkin averaging method is accurate up to Pin = -15 dBm (relative difference $\leq 5\%$) as depicted in Fig. 2.11(b).

2.5 Investigation of the Diode Parameters on the Output Voltage

The influence of the diode parameters (the junction capacitance C_j and the contact resistance R_s) on the conversion efficiency was first investigated in [47]. In this section we investigate the effect of the contact resistance R_s and the saturation current I_s on the output voltage. The Ritz-Galerkin averaging method [46] presented in the previous section is used to calculate the DC output voltage as a function of maximum available input power level for different contact resistance values R_s and for different saturation current values I_s. Figure 2.12(a) shows the output voltage of the rectifier as a function of maximum available power for different values of the contact resistance R_s. Figure 2.12(b) shows the output voltage versus maximum available power for different saturation current values I_s. The load resistance R_L is set to 100 kΩ.
The figure shows that the DC output voltage increases with a decreasing value of R_s and increases with an increasing value of I_s. These results provide additional selection criteria for choosing commercially available Schottky diodes.



(a) (b)

Figure 2.12. Influence of the contact resistance (a) and the saturation current (b) on the output voltage as a function of maximum available power. $R_L = 100$ kΩ.

Table 2.2 lists the I_s and the R_s values of different commercially available Schottky

diodes.

Table 2.2. I_s and R_s values for commercially available Schottky diodes.

Schottky diode	I_s (A)	R_s (Ω)
HSCH-5310	3.00E-10	13
HSCH-5314	3.00E-10	9
HSCH-5340	4.00E-8	13
HBAT-540X	1.00E-7	2.4
HSMS-270X	1.40E-7	0.65
HSMS-280X	3.00E-8	30
HSMS-281X	4.80E-9	10
HSMS-282X	2.20E-8	6
HSMS-285X	3.00E-6	25
HSMS-286X	5.00E-8	6

Figure 2.13 shows the calculated DC output voltage as a function of the load resistance (R_L) for two different maximum available power levels, for three chosen Schottky diodes. The figure shows that the Schottky diode HSMS-285X outperforms the two other diodes HSCH-5310 and HSMS-280X with respect to the DC output voltage for the two simulated maximum available power levels. This is due to the higher saturation current.

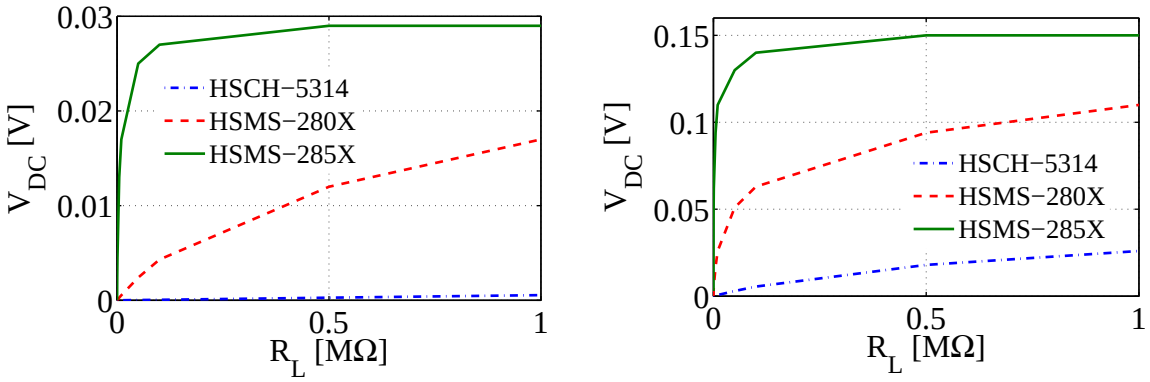


Figure 2.13. DC output voltage as a function of load resistance (R_L) for different maximum available power levels for three Schottky diodes. (a) $P_{in} = -20$ dBm, (b) $P_{in} = -10$ dBm.

The Schottky diode HSMS-285X is characterized by a saturation current that is higher

than that of the other diodes. Since this leads to a higher DC output voltage, this diode is selected for rectenna designs to be discussed in subsequent Chapters.

2.6 Voltage Multiplier

At low input power levels, the DC output voltage of the rectifier is well below 1 V. Modern low-power electronics needs at least a voltage in the order of 1 - 1.2 V to operate [48]. To increase the DC output voltage, a voltage multiplier may be employed. A much used configuration is based on a Dickson charge pump circuit [49] and is shown in Fig. 2.14.

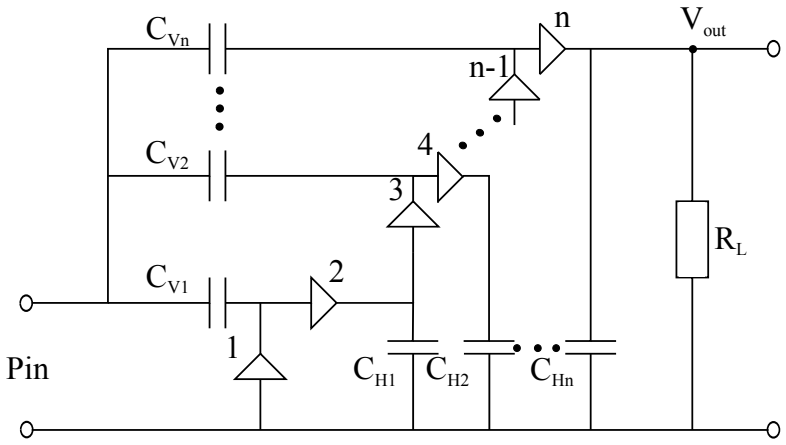

Figure 2.14. Voltage multiplier configuration based on a Dickson charge pump circuit.

As an illustration, ADS harmonic balance has been used to simulate the DC output voltage. For an operating frequency of 1 GHz and based on the Schottky diode HSMS 2822, the DC output voltage across R_L has been simulated as a function of the number of rectifier stages. The results are shown in Fig. 2.15 for two maximum available power levels.

At an input power level of +10 dBm (solid curve), the maximum output voltage is reached after cascading 8 Schottky diodes, while at a power level of −6dBm (dashed curve), the output voltage is saturated after cascading only 4 Schottky diodes. It is clearly shown in Fig. 2.15 that, at a low input power level (e.g. -6 dBm), increasing the number of the rectification stages will eventually result in a lower DC output voltage, and consequently the RF-to-DC power conversion efficiency will decrease.

The saturation point depends on the operating frequency, the input power level, and the load resistance value. In view of this saturation effect, and since this thesis deals with harvesting power at very low input power levels ($P_{in} = -10$ dBm) a voltage doubler configuration (n=2, see Fig. 2.14) will be adapted for the designed rectennas in Chapter

3 and in Chapter 5.

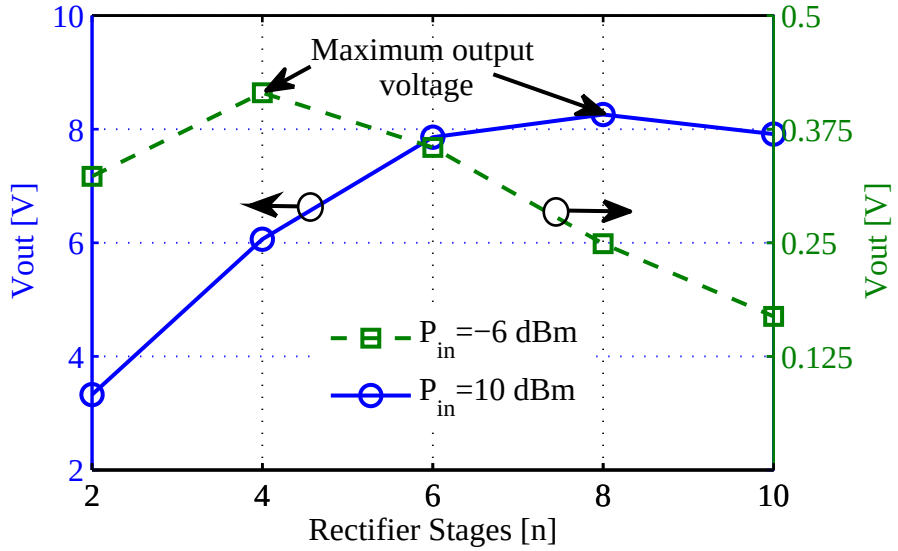

Figure 2.15. DC output voltage as a function of the number of multiplier stages (diodes) for two maximum available power levels simulated by ADS. Frequency = 1 GHz, R_L =1MΩ, $C_{Vi} = C_{Hj}$ = 100 pF. R_g = 50Ω. P_{in} is the maximum available input power.

After choosing the commercially available Schottky diode HSMS-285X for the design of the rectenna and limiting the multiplier to a voltage doubler, the following section will present the selection of the design frequency and the input power level.

2.7 Rectenna Design

Since the rectifier's impedance changes as a function of frequency and as a function of input power level, an operating frequency f_0 and an input power level (P_r) should be selected first, before proceeding to the investigation of different rectenna topologies. Based on the two design criteria, operating frequency and assessed input power level (f_0, P_r), different rectenna topologies will be presented. Figure 2.16 shows a general far-field wireless power transmission system. The rectenna in this system consists of an antenna that is directly complex-conjugate matched to the rectifier.

The power density (S) at the receiving side is dictated by the effective isotropic radiated power, $EIRP = P_t G_t$, where P_t is the transmitted power and G_t is the transmit antenna gain, and by the distance R between the transmitting and the receiving antennas as shown in Fig. 2.16.

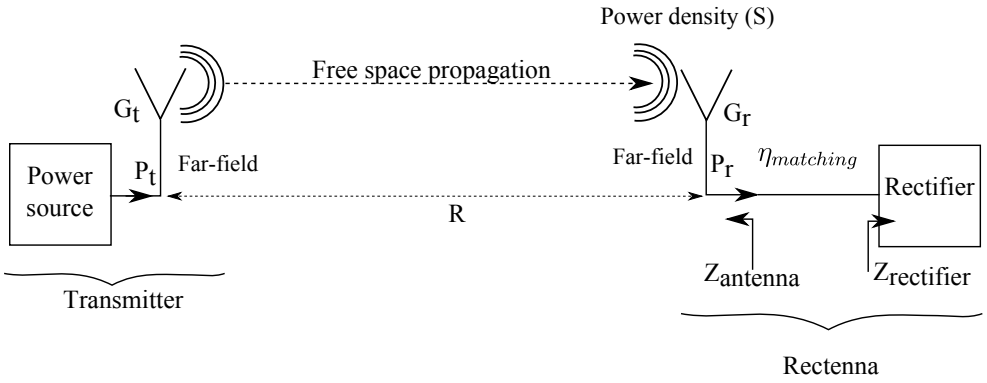

Figure 2.16. Far-field wireless power transmission system, where no matching circuit is used at the receiving side.

The power density is obtained by distributing the total power over a spherical surface with area $4\pi R^2$:

$$S = \frac{EIRP}{4\pi R^2} = \frac{P_t G_t}{4\pi R^2}. \tag{2.11}$$

The antenna at the receiving side captures part of this power density with an effective aperture A_r. The received power P_r (see Fig. 2.16) is given by:

$$P_r = A_r S, \tag{2.12}$$

where A_r is the effective aperture of the receiving antenna in the direction of the transmitting antenna. According to [50], the effective aperture is related to the antenna gain by

$$A_r = G_r \frac{\lambda_0^2}{4\pi}, \tag{2.13}$$

where λ_0 is the wavelength of transmitted signal. Substituting Eq. (2.13) in Eq. (2.12) leads to the Friis transmission equation where the received power at the terminals of the rectifier is expressed as

$$P_r = P_t G_t G_r \left(\frac{\lambda_0}{4\pi R}\right)^2 = P_t G_t G_r \left(\frac{c}{4\pi f_o R}\right)^2, \tag{2.14}$$

where c is the free-space speed of light and f_0 is the operating frequency of the transmitted signal. The term $\left(\frac{c}{4\pi f_o R}\right)^2$ is called the free-space path loss. The term path loss may lead to confusion. It gives the impression that, apart from a spherical spreading, a frequency dependent path loss exists. This is not true, since the gain changes with frequency.

2.7.1 Operating Frequency

For practical reasons we will aim for a rectenna that is ideally credit-card sized, so that it can be applied in wireless sensors for smart building applications.

Since there are no special regulations for rectenna systems yet, it makes sense to operate these systems in the licence-free Industry-Science-Medical (ISM) frequency bands, see Table 2.3. The frequency bands around 0.9 GHz and 2.4 GHz are of special interest due to our credit card size constraint and due to the relative high EIRP allowed. Adapting a frequency band from 865 to 928 MHz will allow RF power transfer operation both in Europe and North America, and RF harvesting from GSM transmissions on both continents.
After having thus selected the design frequency, the expected input power level will be presented next.

Table 2.3. Frequency band allocations and transmit power restrictions for RFID applications as reported in [12].

Frequency Band	Power	Duty Cycle/ Tx type	Channel Spacing / BW	Region
2446 - 2454 MHz	500 mW EIRP 4 W EIRP	Up to 100 $\leq$ 15%	No spacing	Europe*
865.0 - 865.6 MHz	10 mW ERP		200 kHz	Europe
865.6 - 867.6 MHz	2 W ERP		200 kHz	Europe
867.6 - 868.0 MHz	500 mW ERP		200 kHz	Europe
902 - 928 MHz	4 W EIRP	FH ($\geq$ 50 channels) or DSSS		USA Canada
2400-2483.5 MHz	4 W EIRP	FH ($\geq$ 75 channels) or DSSS		USA Canada
2400-2483.5 MHz	10 mW EIRP		1MHz BW	Japan Korea

In Table 2.3, ERP is the Efective Radiated Power, the EIRP is 1.64 times ERP. FH stands for Frequency Hopping. DSSS stand for Direct Sequence Spread Spectrum and BW indicates Band Width. *Power levels above 500 mW are restricted to use inside the boundaries of a building and the duty cycle of all transmissions shall in this case be $\leq$ 15% in any 200 ms period (30 ms on / 170 ms off).

2.7.2 Expected Input Power Level

Possible design operating frequencies have been discussed in the previous section. We will settle for a design frequency of 868 MHz. It is indicated in Table 2.3 that at this design frequency, the maximum allowed Effective Radiated Power (ERP) is 500 mW in Europe.
Based on the applications that have been indicated in the previous chapter, including the Smart Building Initiative (SBI), a direct line-of-sight propagation distance (R) between 2 meters and 10 meters is expected, being related to the size of a general office, hallway or meeting room. Using the maximum allowed ERP at a frequency of 868 MHz, see Table 2.3, the power density as a function of propagation distance is calculated using Eq. (2.11) and is plotted in Fig. 2.17 (solid curve). It is indicated in the figure that the power density does not exceed 12 dBm/m^2. At a distance of 5 meters away from the transmitting source, the power density drops to 4 dBm/m^2.

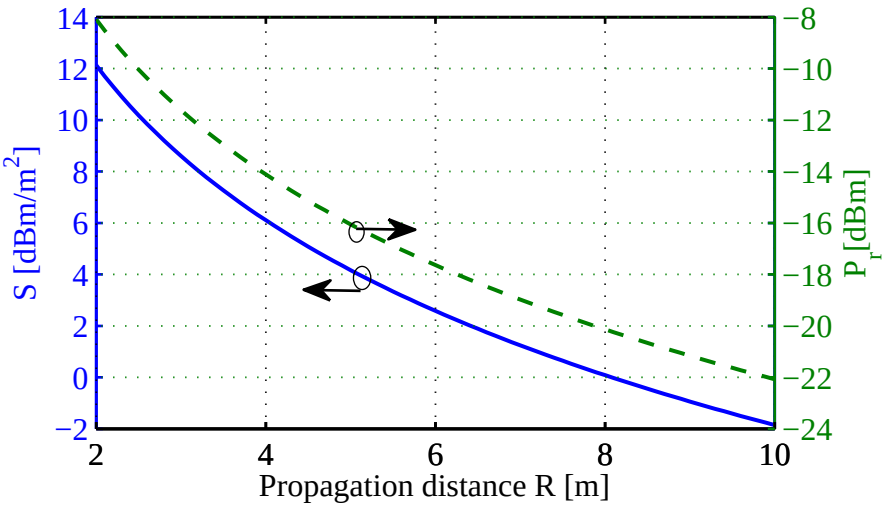

Figure 2.17. Power density and received power calculated using Eq. (2.11) and Eq. (2.14) respectively as a function of propagation distance.

To translate the power density into input power levels P_r (see Fig. 2.16), Eq. (2.14) is used to calculate the input power level, where a receiving antenna gain of 0 dBi[1] is used. The received power within the practical propagation distance ($2 \leq R \leq 10$ m) is plotted in Fig. 2.17 (dashed curve). It is clearly indicated in the figure that the received power is within -8 dBm $\leq P_r \leq -22$ dBm for the practical propagation distances. Based on this argument it makes sense then to choose an assessed input power level of -10 dBm.

[1]The reason behind choosing 0 dBi for the receive antenna gain is the size constraint related to a credit-card size antenna at 868 MHz.

A second reason to choose an input power level around -10 dBm is derived from the results of the input impedance of the Schottky diode as a function of maximum available input power level shown in Fig. 2.9. Since the input impedance of the Schottky diode (both the real and the imaginary part) is almost constant at low input power levels ≤ -5 dBm, choosing a low input power level for the design of the rectenna will ensure that the rectenna will be matched for a broad input power-level band.

To further strengthen this power level choice we will look at the antenna matching. To this end, the term matching efficiency denoted by $\eta_{matching}$ is introduced. The matching efficiency $\eta_{matching}$ describes how well the antenna is matched to the rectifier. Since a matching network is not present (see Fig. 2.16), the antenna is conjugately matched to the rectifier, with an impedance $Z_{antenna} = Z^*_{rectifier}$, where * denotes the complex conjugate. The matching efficiency is calculated as a function of received power level P_r, for an antenna designed to be matched at $P_r = -10$ dBm and for and antenna designed to be matched at $P_r = 0$ dBm.

The matching efficiency is expressed as

$$\eta_{matching} = 1 - S_{11}^2, \tag{2.15}$$

where the power wave reflection coefficient concept [34] [51] is used to calculate the reflection coefficient:

$$S_{11} = \frac{Z_{rectifier} - Z^*_{antenna}}{Z_{rectifier} + Z_{antenna}}. \tag{2.16}$$

Figure 2.18 shows the matching efficiency as a function of input power level for both antennas.

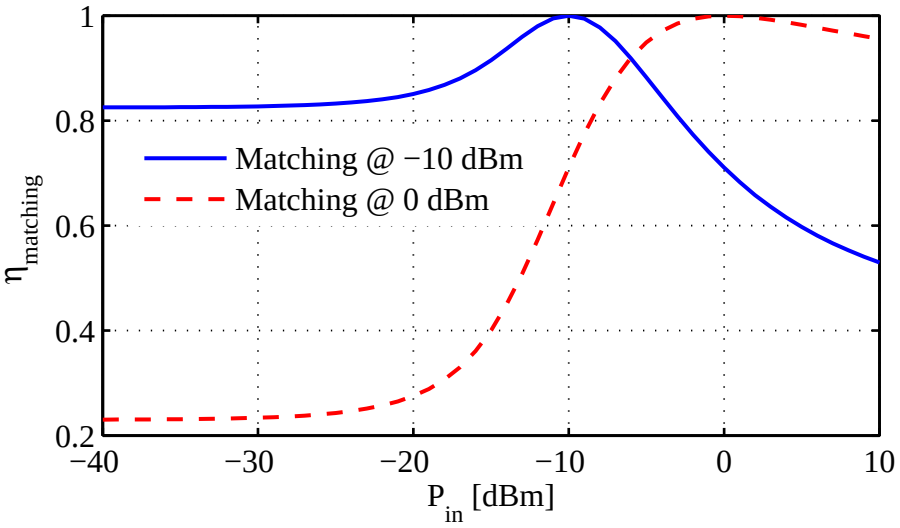

Figure 2.18. Matching efficiency as a function of input power level for an antenna designed to be matched at $P_r = -10$ dBm (solid curve) and for and antenna designed to be matched at $P_r = 0$ dBm (dashed curve).

The figure shows that, when the rectenna is designed for -10 dBm, a matching efficiency higher than 80 % is calculated for a broad input-power-band, $-40\,\text{dBm} \leq P_r \leq -3\,\text{dBm}$. On the other hand, if the rectenna is designed at an input power level of 0 dBm, a matching efficiency higher than 80 % is calculated for an input power band, $-8\,\text{dBm} \leq P_r \leq 10\,\text{dBm}$.
It is thus demonstrated that designing a rectenna for an input power level around -10 dBm will result in a rectenna that is matched to broad input power band from -40 dBm up to -3 dBm, which corresponds to the expected input power levels for our applications (see Fig. 2.17 dashed curve).

2.8 Conclusion

For a maximum power transfer between the receiving antenna and the rectifier in a rectenna system, the antenna's input impedance should be matched to that of the rectifier circuit. A detailed design method to accurately predict the input impedance and the DC output voltage of a Schottky diode based rectifier is presented in this chapter. The presented method uses circuit analysis to calculate the impedance of a Schottky diode as a function of frequency for different maximum available power levels. The simulation results are validated by measurements. In addition, the influence of the diode's parameters on the output voltage are investigated. It is shown that the highest output DC voltage is achieved for the lowest contact resistance and for the highest saturation current. Thus the commercially available Schottky diode HSMS-285X is selected for the design of a voltage doubler.
In addition, the practical rectenna design criteria with respect to the operating frequency and the input power levels are presented. Based on the possible applications, license free frequency bands and allowed transmit powers, chosen is to design rectennas having small or broad frequency bands around 868 MHz for an input power level of -10 dBm ($100\mu\,\text{W}$).

Chapter three

RF Power Transport Employing Rectennas Using Matching Networks

In this chapter a modified Yagi-Uda antenna is introduced. The design is based on a wide-band strip dipole around which a Yagi-Uda structure is formed. The antenna consists of a reflector and a single director placed nearby the driven dipole. The main advantage of the suggested antenna is that, by tuning its geometrical parameters, the antenna can perform as a dual-band, a triple-band or a broad-band antenna. Three prototypes are designed, simulated, fabricated and measured. The simulated results are validated by measurements. The modified Yagi-Uda antenna is then used for RF power transport. A matching network is desigend to match the 50Ω antenna to a voltage-doubler rectifier. The matching circuit and rectifier are characterized as a single unit. The measured Power Conversion Efficiency (PCE) reaches 31.6% and 49.7 % over 10 kΩ load resistance at an input power level of -20 dBm and -10 dBm, respectively. Compared to the state-of-the-art published results, the PCE increases by 5 % at -10 dBm and by 10 % at -20 dBm.
The advantage of this rectenna design is that the antenna may be replaced by any 50Ω antenna having the correct frequency response. The disadvantage is that the matching network introduces additional losses. This disadvantage will be dealt with in a subsequent chapter.

3.1 Introduction

The main challenge in far-field energy harvesting is to overcome the power-density decay due to the long distance between the transmitter and the harvesting location. To partly compensate for this so-called path loss, antenna arrays or high gain antennas can be used at the receiving part. Figure 3.1 shows the 50 Ω rectenna system investigated in this chapter. The arrows indicate the power flow from the transmitting side to the receiving side to reach the load R_L.
First, a novel 50 Ω modified Yagi-Uda antenna for the transmission and reception of RF power is introduced. Three different prototypes are designed, simulated, manufactured and measured. The first antenna is designed to harvest ambient RF power from Digital TV (DTV) broadcasting stations. The second and the third prototype are a dual-band and a triple-band antenna respectively. The dual band prototype is developed for RF power harvesting at 900 MHz (GSM 900) and 2.45 GHz (ISM). The triple-band prototype adds (GSM 1800) to these two frequency bands.

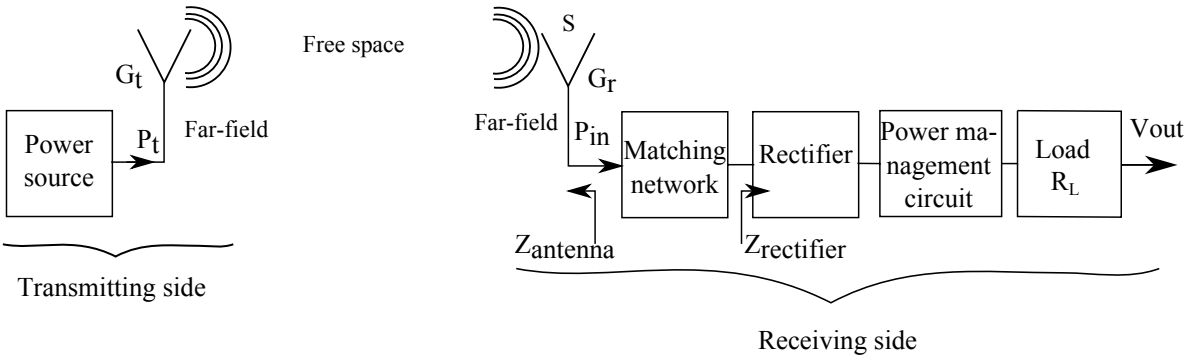

Figure 3.1. RF power transport system employing a (50 Ω) antenna matched to the rectifier using a matching network on the receiving side.

A Schottky diode voltage doubler configuration is used on the receiving side to transform the RF power into DC power. For an improved power transfer, a lumped-element matching network between the 50Ω receiving antenna and the voltage doubler (rectifier) is designed. The main target of the matching network is to transform the impedance of the rectifier ($Z_{rectifier}$) to that of the antenna ($Z_{antenna}$), see Fig. 3.1.

This chapter consists of two parts. In the first part, the design of a novel, modified Yagi-Uda antenna to harvest power from DTV stations is presented. The developed procedure is then employed also to design a dual-band and a triple-band antenna. In the second part, the matching network will be introduced. Using the newly developed antenna, we design one RF power transport prototype system at an operating frequency

of 868 MHz for an input power level of -10 dBm.

For the development of the modified Yagi-Uda antenna, we first need to introduce a wide-band strip dipole antenna that will replace the driven element in a normal Yagi-Uda antenna.

3.2 Center-Fed and Step-Shaped-Fed Strip Dipoles

Various types of printed dipoles have been studied in the literature [52,53]. The printed strip dipole antennas are desirable due to their low profile, low production cost and their ease of fabrication. Many attempts have been performed to enlarge the bandwidth of the strip dipole antenna [54]. A printed wide-band dipole antenna with a step-shaped feed gap for DTV signal reception was suggested in [55] and is shown in Fig. 3.2(b). The wide-band characteristics are obtained by two closely-spaced resonances.

Figure 3.2 shows a conventional centre-fed strip dipole (a) and the step-shaped-fed (the feed of the antenna has a shape of a step strip dipole antenna (b) as introduced in [55] and [56].

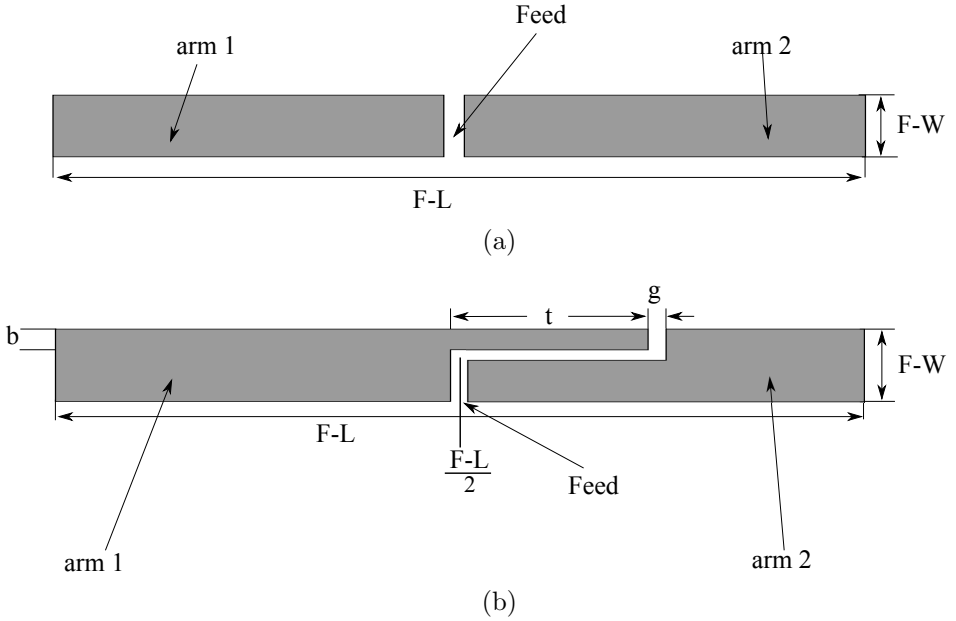

Figure 3.2. Centre-fed strip dipole configuration (a) and the step-shaped-fed strip dipole configuration (b) as introduced in [55].

To verify that the suggested antenna in [55] has two resonance modes, Table 3.1 shows the optimized parameters for having the step-shaped-fed strip dipole resonate at 550

MHz. An ordinary, centre-fed strip, dipole is also designed to resonate at the same frequency. The center-fed and the step-shaped-fed dipole antennas are printed on a 1.6 mm thick FR4 substrate with permittivity $\epsilon_r = 4.4$ and loss tangent $\tan\delta = 0.025$. CST Microwave Studio [57] is used to simulate the reflection coefficients as a function of frequency for both the centre-fed and the step-shaped-fed strip dipole.

Table 3.1. Optimized parameters for the step-shaped-fed dipole to resonate at 550 MHz. The dimensions are explained in Fig. 3.2.

Parameter	mm
F-L	226
F-W	20
b	2.5
g	1
t	42.5

Figure 3.3 shows the simulated reflection coefficient versus frequency for a centre-fed strip dipole antenna having a length F-L and width F-W (see Table 3.1) and for a step-shaped-fed strip dipole antenna of the same length and width. The dimensions of the feed structure of the latter antenna, i.e., b, g and t, are listed in Table 3.1.

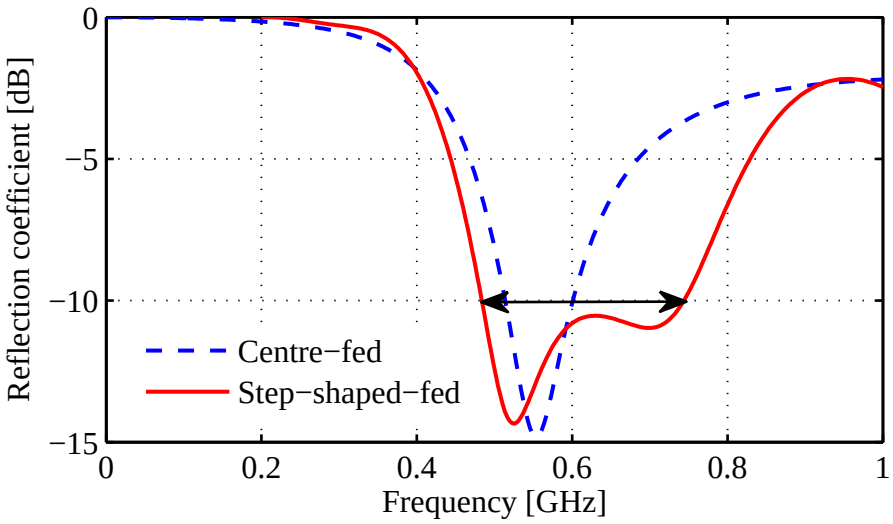

Figure 3.3. Reflection coefficient as a function of frequency for the centre-fed strip dipole antenna and the step-shaped-fed strip dipole antenna, having identical total length and identical width and both placed on the same substrate carrier.

It is indicated in the figure that the bandwidth of the step-shaped-fed strip dipole

antenna is increased by more than 120% compared to the standard centre-fed strip dipole antenna. This increase in bandwidth is realized by the two excited resonant modes, one at 0.5λ controlled by the antenna length F-L, and a second one controlled by choosing a proper value of t (see Fig. 3.2(b)). This additional resonant mode of the antenna is controlled by the total effective length of the antenna comprising its two asymmetric radiators arm 1 and arm 2 [55] (see Fig. 3.2(b)).
The main limitation of this antenna is its restricted gain. Since it is a $\lambda/2$ dipole antenna, its gain is limited to 2.15 dBi. For a higher antenna gain, other types of antennas are needed.

3.3 Printed Yagi-Uda Antenna and Parameter Optimization

The printed Yagi-Uda antenna shown in Fig. 3.4 is a highly directive but narrow-band antenna [58]. The parameters of a quasi Yagi-Uda antenna were optimized for a broad-band operation in [59]. The resulting antenna achieves 48% bandwidth for a Voltage Standing Wave Ratio (VSWR) < 2, but uses a truncated ground plane and a balun structure.

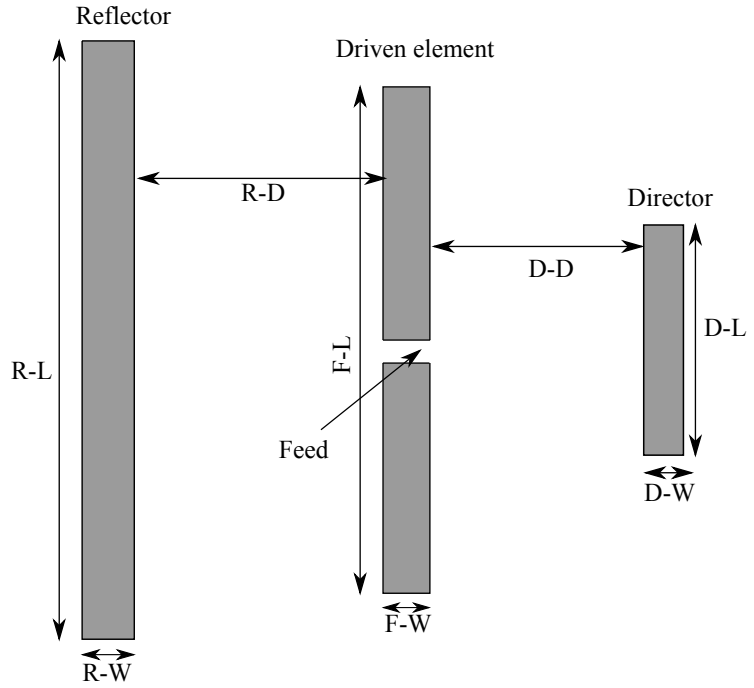

Figure 3.4. Conventional printed strip Yagi-Uda antenna configuration.

A design that serves as a wide-band Yagi-Uda antenna or as a multi-band printed dipole

was realized by using parasitic elements in proximity to a dipole that is parallel to a truncated ground plane [60, 61]. Recently, the effects of all the antenna parameters for such antennas on the frequency response were investigated in [62].

Table 3.2 shows the optimized parameters for the 'standard' Yagi-Uda antenna shown in Fig. 3.4 to resonate in the DTV frequency band between 475 MHz and 794 MHz [63].

Table 3.2. Optimized parameters of the conventional Yagi-Uda antenna to cover the DTV frequency bandwidth. The dimensions are explained in Fig. 3.4.

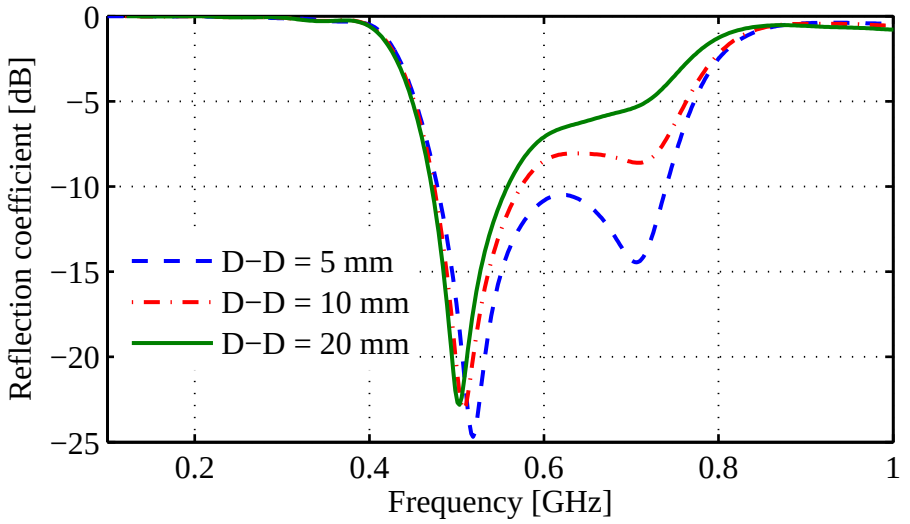
Parameter	mm
F-L	235
F-W	15
R-L	290
R-W	30
D-D, D-L	see Sec. 3.3.1
R-D	see Sec. 3.3.2

The Yagi-Uda antenna parameters including the length of the director (D-L), the distance between the feed and the director (D-D), and the distance between the feed and the reflector (R-D) are optimized to obtain the widest bandwidth possible that can cover the DTV broadcasting frequency bandwidth (475 MHz - 794 MHz). The feed length F-D is set to 235 mm so that the Yagi-Uda antenna resonates in the required frequency band (475 MHz - 794 MHz). The reflector length R-L is set to 290 mm as indicated in Table 3.2.

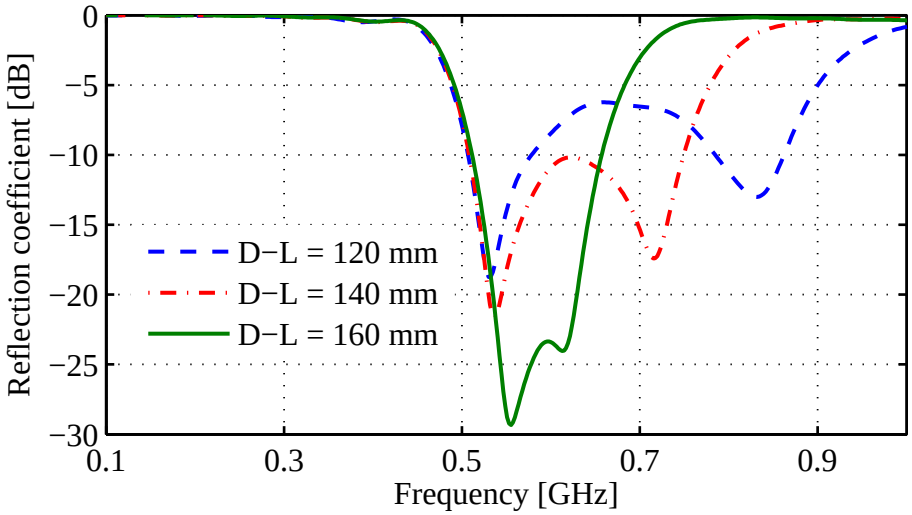
3.3.1 Optimization of the Distance Between Feed and Director (D-D) and the Director Length (D-L)

In this section the distance between feed and director (D-D) and the director length (D-L) are optimized to broaden the frequency response of the conventional printed Yagi-Uda antenna. The distance between the reflector and the feed is fixed to 110 mm and will be optimized in the following section.

Figure 3.5(a) shows the simulated reflection coefficient as a function of frequency for different distances between the feed and the director. It is clear from the figure that, when the director is set close to the feed, a second resonance is generated at a higher frequency which enhances the reflection coefficient bandwidth. This is due to the increased mutual coupling between the feed and the director. Actually the director acts as a resonator of length $\lambda/4$ when it is close to the driven element.



(a)



(b)

Figure 3.5. (a) Reflection coefficient versus frequency for different D-D, D-L = 140 mm, R-D =110 mm. And (b) reflection coefficient versus frequency for different D-L, R-D = 110 mm, D-D = 5 mm.

To confirm this observation, the distance between the director and the driven element is set to D-D= 5 mm, and the director length is swept between 120 mm and 160 mm. As expected, see Fig. 3.5(b), the reflection coefficient is characterised by two resonances. The low-frequency resonance is due to the feeding length (F-L) designed for 530 MHz, the high-frequency resonance is due to the length of director (D-L). The latter resonance shifts toward the lower frequency resonance when the length of the director is increased. This behaviour makes it possible to bring the two resonances together, which results in an improved reflection coefficient over an extended frequency band.

3.3.2 Optimization of the Distance Between Feed and Reflector (R-D)

Based on the parameters in Table. 3.2, the optimization of the distance between the feed and the reflector (R-D) is presented in this section.
Figure 3.6 shows the reflection coefficient as a function of frequency for different distances between the feed and the reflector.

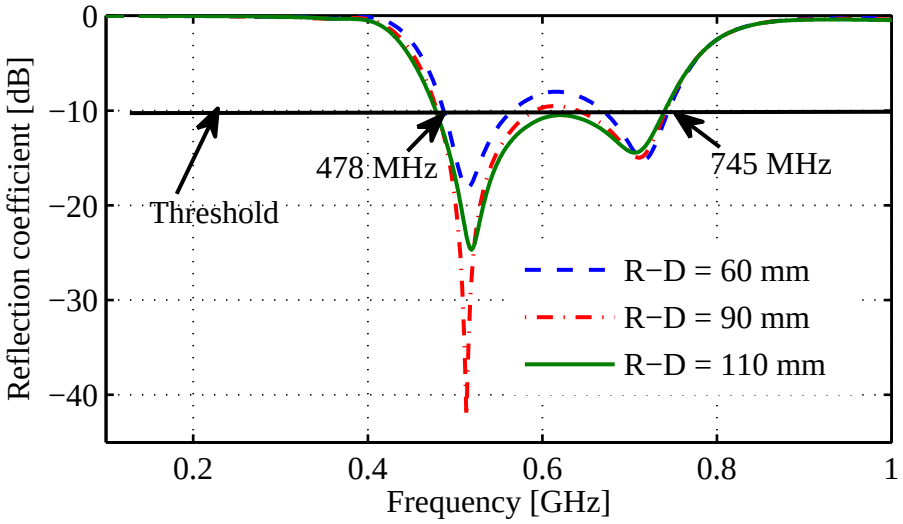


Figure 3.6. Simulated results of the reflection coefficient as a function of frequency for different distances between the reflector and the feed. D-L = 140 mm, D-D = 5 mm.

It is clear from the simulation results that the operating antenna bandwidth is not strongly affected by the distance between the feed and the reflector. However, an increased reflection coefficient exceeding the threshold of -10 dB (dashed curve, R-D = 60 mm), is observed when the reflector is placed nearby the feed. When the distance between the feed and the director is enlarged, the absolute value of the reflection coefficient decreases as illustrated by the solid curve for R-D = 110 mm.

After all the Yagi-Uda antenna parameters have been optimized, it is shown by the solid curve in Fig. 3.6 that the maximum achievable bandwidth is 267 MHz (478 MHz - 745MHz) which does not meet the full bandwidth requirements (475 - 794 MHz).

3.4 Modified Yagi-Uda antenna

To further broaden the frequency band and at the same time preserve the radiation characteristics, a novel broadband modified Yagi-Uda antenna is introduced in this sec-

tion.

As was shown in Sec. 3.2, the step-shaped-fed strip dipole is characterized by two resonant modes, the first one being due to the strip length and the second one due to the total effective length of the antenna comprising its two asymmetric radiator arms 1 and 2 [55] (see Fig. 3.3). We have also seen that by carefully placing the parasitic elements in a 3-elements Yagi-Uda antenna, a dual resonance may be obtained. In this section the driven element in Fig. 3.4 will be replaced by the step-shaped-fed strip dipole antenna shown in Fig. 3.2(b). The resulting configuration is shown in Fig. 3.7.

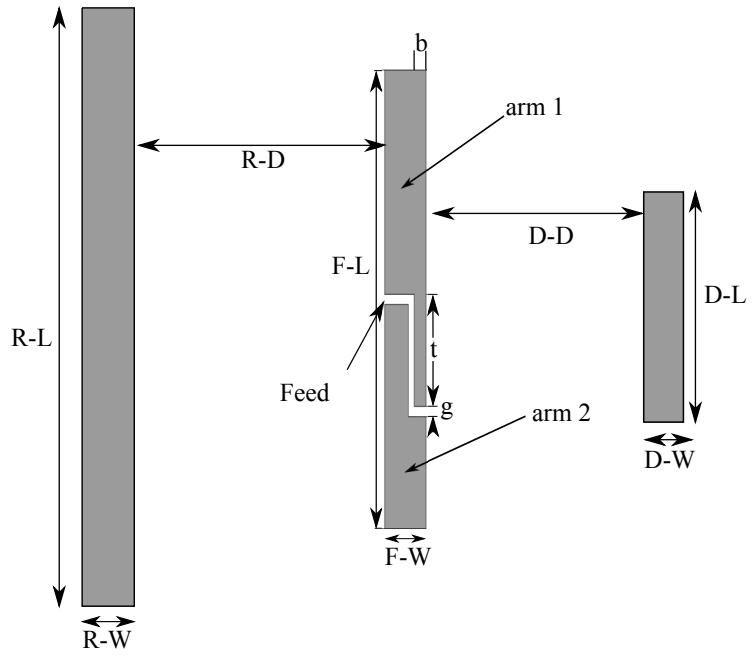

Figure 3.7. Modified Yagi-Uda antenna with a step-shaped-fed driven element.

It is the expected that this modified configuration will be characterised by three resonant modes, one due to the feed length (F-L), a second one due to the director length (D-L) and a third one due to the total effective length of the feed compromising its two asymmetric radiators arms 1 and 2 (0.5F-L + t). The main advantage of this configuration will be that it offers three additional parameters b, t and g (see Fig. 3.2(b) and Fig. 3.7) for resonance frequency tuning. By optimizing these additional parameters the frequency bandwidth will be widened to cover the complete DTV band (475 MHz - 794 MHz).

To validate that the modified Yagi-Uda antenna is characterized by three different resonant modes, that can be tuned independently, CST Microwave Studio is used to simulate the reflection coefficient versus frequency. The previously designed Yagi-Uda antenna is used as a starting point. The dimensions are summarized in Table 3.3. Only

the parameters, D-L, b and t will be sequentially optimized.

Table 3.3. Optimized parameters of the modified Yagi-Uda antenna to cover the DTV frequency band.

Parameter	mm
F-L	235
F-W	15
R-L	290
R-W	30
R-D	110

g	1
D-L	see Sec. 3.4.1
b	see Sec. 3.4.2
t	see Sec. 3.4.3

3.4.1 Modified-Yagi: Three Resonant Modes

In this section the director length is optimized to demonstrate that the modified Yagi-Uda is characterized by three resonant modes. Figure 3.8 shows the reflection coefficient as a function of frequency for different director lengths (D-L). The parameters shown in Table 3.3 are used for simulations.

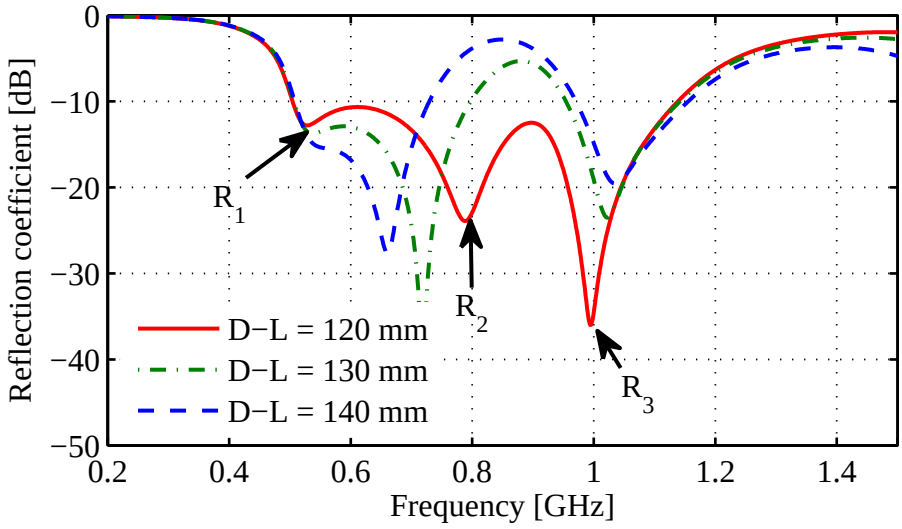

Figure 3.8. Optimization of the novel broad band Yagi-Uda antenna parameter D-L. Simulated results of the reflection coefficient as a function of frequency. b = 1 mm, t = 35 mm, g = 1 mm, R-L = 235 mm.

As expected, the figure indicates that the modified Yagi-Uda antenna is characterised by three resonance frequencies, R_1, R_2 and R_3. The first resonance frequency band around R_1 is due to the driven element length F-L. The second resonance R_2 is due to the length of the director D-L and shifts toward the first resonance when the length of the director increases. The third resonance R_3 is due to the effective length of the feed that is controlled by the arm width b and the step length t.
Possessing three resonant modes that can be tuned independently, the modified Yagi-Uda antenna is potentially a broad-band antenna if these three resonant frequencies are close enough. If the three resonant frequencies are separated, the modified Yagi-Uda antenna operates as a triple-band antenna. If two of the three resonant frequencies are close enough the antenna operates as a dual-band antenna.

3.4.2 Optimization of the Arm Width b

In this section the effect of the parameter b is discussed. The arm width is swept between 3 mm and 7 mm since the strip width F-W (see Fig.3.7) is fixed to 15 mm. Figure 3.9 shows the reflection coefficient as a function of frequency for the different arm widths b.

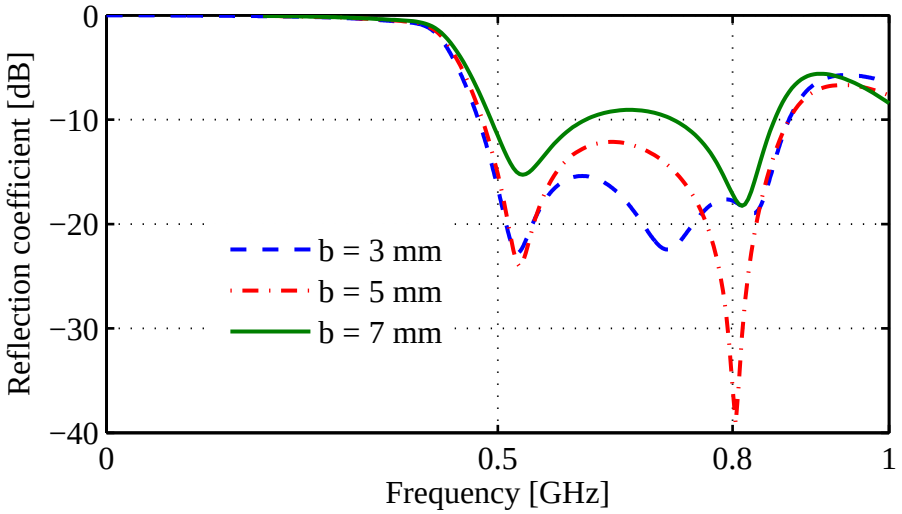

Figure 3.9. Optimization of the novel broad band Yagi-Uda antenna parameter b. Simulated results of the reflection coefficient as a function of frequency for different values of b. $g = 1$ mm, $t = 45$ mm, D-L = 130 mm.

It is observed that b has a strong effect on the reflection coefficients. It is shown in the figure that a smaller width b will lead to a lower reflection coefficient. When b increases, the absolute value of the reflection coefficient increases to surpass the -10dB threshold for $b = 7$ mm. Thus, we decide to fix b at 3 mm.

3.4.3 Optimization of the Step Length t

In this section, the step length t is sequentially optimized so that the frequency bandwidth of the modified Yagi-Uda antenna covers the required DTV frequency band. Figure 3.10 shows the simulated reflection coefficient as a function of frequency for different step lengths t. As expected, the parameter t has a low impact on the lower resonance position (R_1). The higher resonance mode (R_3) is clearly affected and is shifted towards the lower frequency resonance R_2, when the step length t increases.

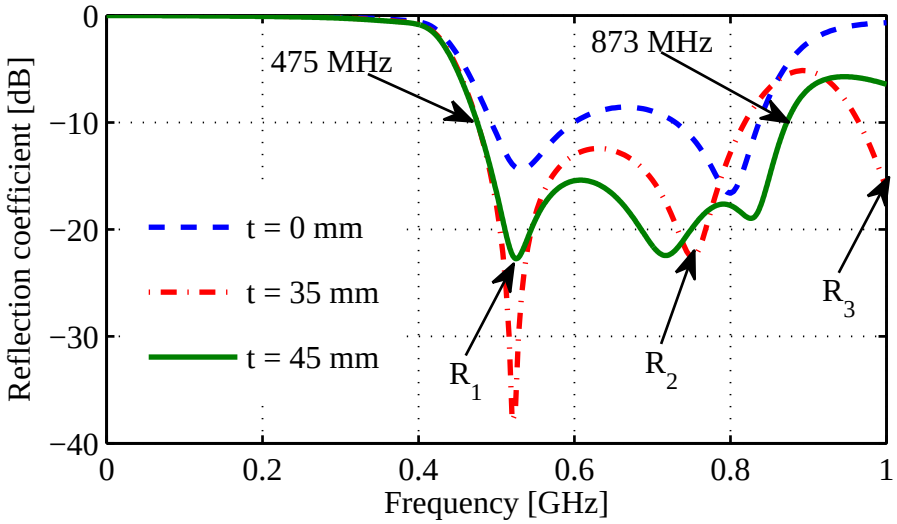

Figure 3.10. Simulated results of the reflection coefficient as a function of frequency for different step length values t. $g = 0.5$ mm, $b = 3$ mm, D-L = 130 mm.

As a result, a wide bandwidth is achieved when t is set to 45 mm. When compared to a standard centre fed Yagi-Uda antenna (dashed curve, $t = 0$ mm) which is characterized by only two resonances, the reflection coefficient of the novel antenna does not exceed the -15 dB level between 595 and 850 MHz, while the reflection coefficient of the standard Yagi-Uda antenna reaches -8.7 dB at a frequency of 680 MHz.
The sequentially optimized parameters for covering the DTV bandwidth are as follows: gap width $g = 1$mm, step length $t = 45$ mm, arm width $b = 3$mm and director length D-L = 130 mm. For these parameters, the antenna impedance bandwidth reaches 398 MHz (475 MHz - 873 MHz) or about 61 % in 2.0:1.0 VSWR centered at 650 MHz, compared to 50 % in 2.5:1.0 VSWR for the wide-band strip dipole antenna in [55].
The gain and the front-to-back ratio as a function of frequency of the optimized antenna are shown in Fig. 3.11.
The novel antenna shows a gain above 4.3 dBi in the operating bandwidth. The front-to-back ratio is less than 9.6 dB to reach the DTV broadcasting range. Above 810 MHz the front-to-back ratio degrades, and reaches 5.2 dB at a frequency of 875 MHz.

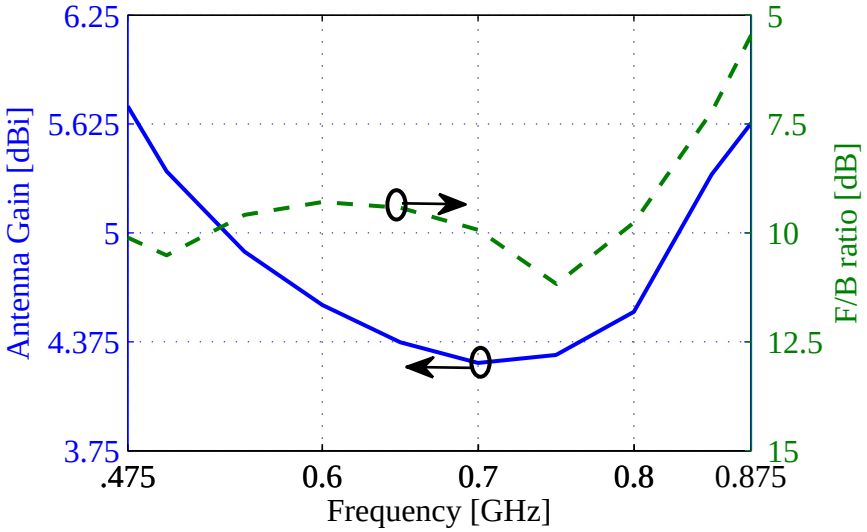

Figure 3.11. Simulated antenna gain and front-to-back ratio as a function of frequency for the novel broad-band Yagi-Uda antenna antenna, $b = 3$ mm, $t = 45$ mm, D-L = 130 mm. Other parameters are listed in Table.3.3.

The antenna gain for the new configuration has almost doubled with respect to the step-shaped-fed strip dipole antenna investigated in Sec. 3.2, which makes the newly proposed antenna well suitable for RF energy harvesting from DTV broadcast signals. In Table. 3.4 the comparison between the performances of a standard Yagi-Uda antenna and the modified Yagi-Uda antenna are presented.

Table 3.4. Comparison between a standard Yagi-Uda antenna and the modified broadband Yagi-Uda antenna.

	Standard Yagi-Uda (See Fig. 3.5(a)-solid curve)	Modified Yagi-Uda [This work]
Gain	5.7 dBi	4.2 dBi
F/B ration	10 dBi	5.2 dB
Bandwidth	80 MHz	398 MHz
Antenna size	290 mm x 295 mm	290 mm x 190 mm

Compared to a standard printed Yagi-Uda antenna (See Sec. 3.3) where the bandwidth around the resonance frequency is limited to 80 MHz (See Fig. 3.5(a)-solid curve), the novel antenna operating bandwidth is increased by a factor of four. The antenna gain over the wide band is only reduced by an average of 1.5 dBi. The front-to-back ratio

for a standard Yagi-Uda antenna is 5 dB lower, which makes the standard Yagi-Uda antenna more directive. However, the novel antenna (290 mm x 190 mm) is 35 % smaller when compared to a standard Yagi-Uda antenna (290 mm x 295 mm). The antenna gain of the novel broadband Yagi-Uda antenna can be improved at the expense of the antenna bandwidth and size.

3.4.4 Fabricated Antenna

Based on the previous results, an antenna is fabricated as shown in Fig. 3.12.

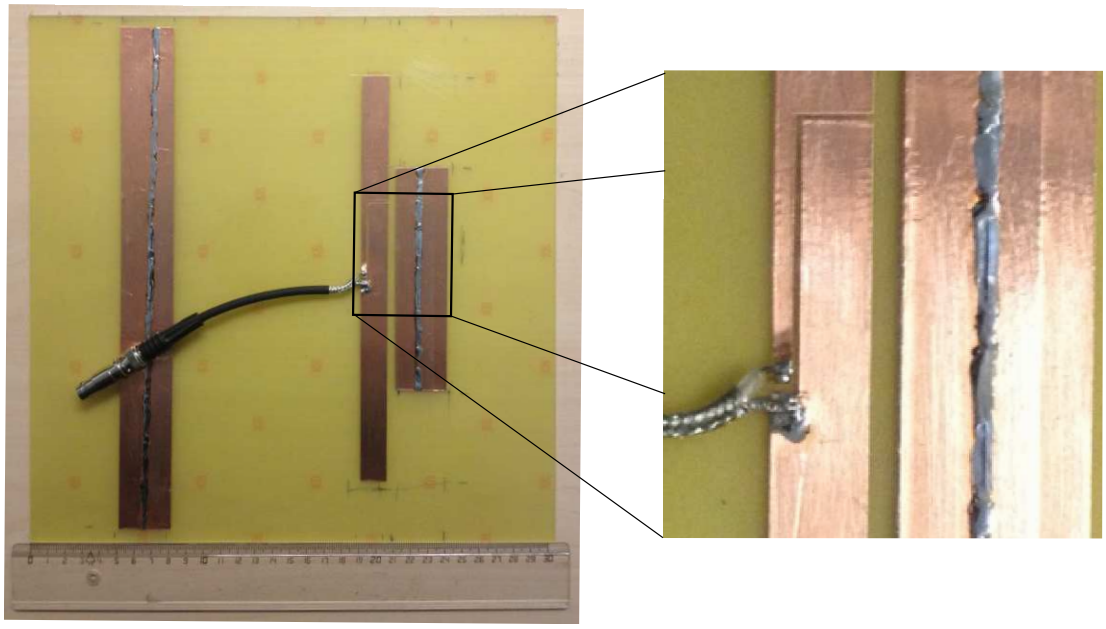

Figure 3.12. Fabricated antenna on a 1.6 mm thick FR4 substrate.

The antenna is printed on a 1.6 mm thick FR4 substrate. The reflection coefficient of the fabricated antenna is measured between 10 MHz and 1 GHz with the aid of the PNA-X Network Analyser [45]. The measured reflection coefficient as a function of frequency is shown in Fig. 3.13. It is clear form the figure the measured results of the reflection coefficients are lower than -10 dB for the frequency band between 475 MHz and 950 MHz which validates the broadband characteristics for the novel antenna.

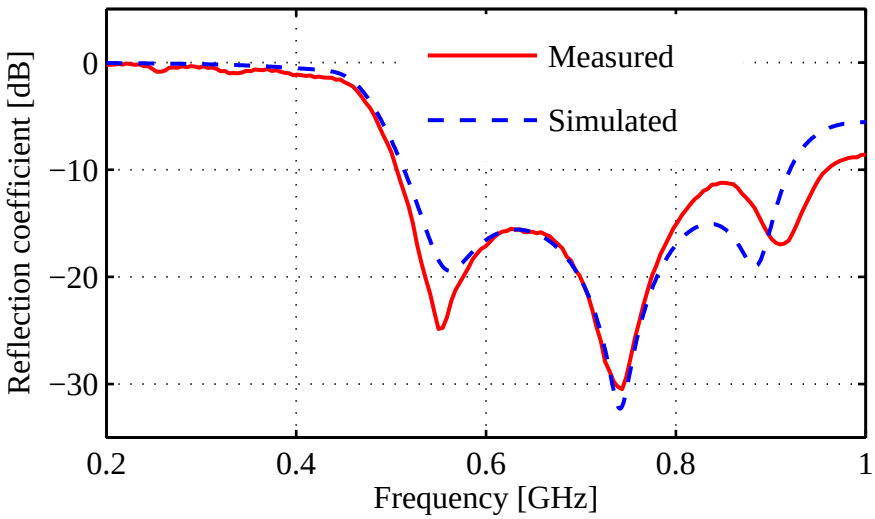

Figure 3.13. Simulated and measured reflection coefficient as a function of frequency.

Radiation diagrams in the E-plane of the fabricated prototype are measured at three different frequencies, 470 MHz, 650 MHz and 800 MHz. The E-plane and H-plane are indicated in Fig. 3.14.

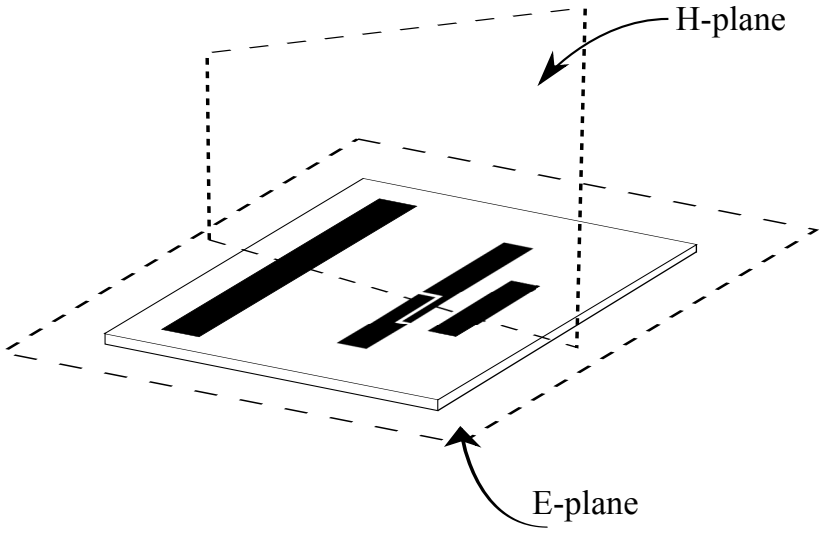

Figure 3.14. E-plane and H-plane.

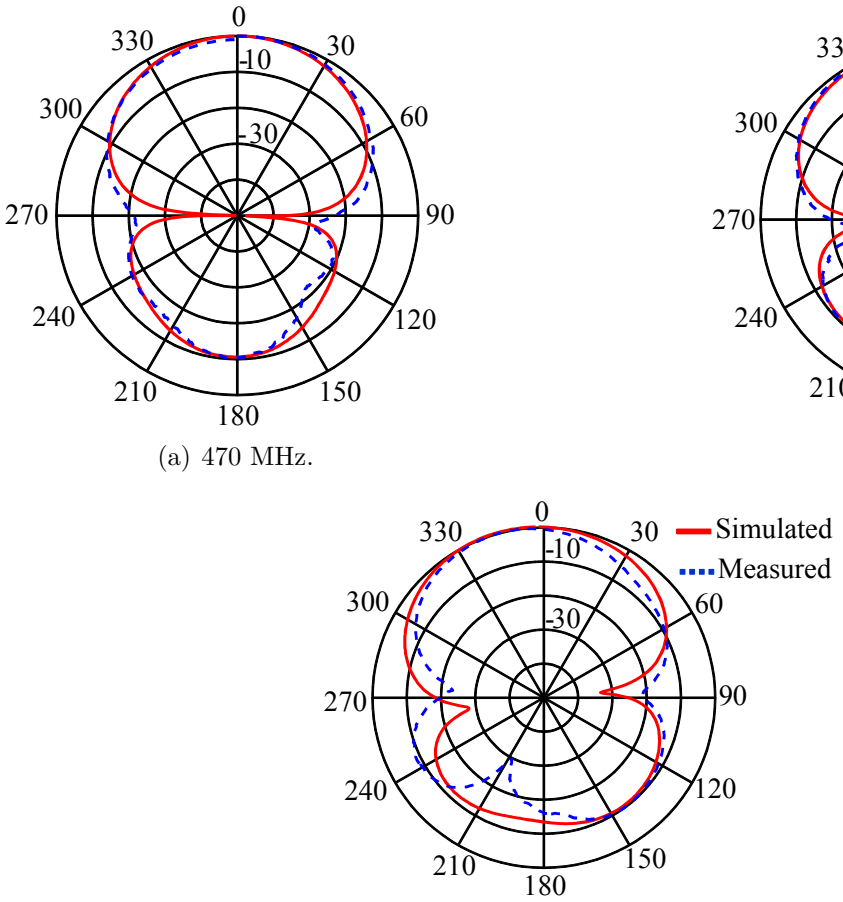
Figure 3.15 shows the simulated and the measured radiation diagrams in the E-plane at the three different frequencies. The solid curve represents the simulated radiation diagrams while the dashed curve represents the measured ones. It is clearly indicated in the figure that the simulated radiation diagrams are validated by measurements with less than 0.5 dB difference in the direction of the main beam between $\theta = 330°$ and $\theta =$

30° at 470 MHz and 650 MHz. At 800 MHz, the difference increases to 2.5 dB at 30°, but note that both in simulations and measurements the main beam has been tilted to the left.



(a) 470 MHz.

(b) 650 MHz.

(c) 800 MHz.

Figure 3.15. Simulated and measured normalized radiation diagrams in the E-plane of the broad-band Yagi-Uda antenna.

3.5 Triple-Band Modified Yagi-Uda Antenna

The exponential increase in the usage of wireless communication devices, especially mobile phones, increases the presence of electromagnetic radiation in the environment. The dominant communication systems are as follows: GSM (890-910 MHz), DCS/PCS/UMTS (1800-2100 MHz) and WiFi (2.446 - 2.454 GHz). RF energy harvesting from these transmitting sources has gained a lot of attention recently. A multi-band RF power harvesting system was introduced in [64]. In this section, the triple-band antenna suggested in [64] to have the possibility to harvest RF power at three different frequencies (900 MHz, 1800 MHz and 2.45 GHz), is presented.

Using the same design procedures as in the previous section, the antenna parameters can be optimized to produce a triple-band or a dual-band antenna. This section introduces a triple-band modified Yagi-Uda antenna. The following section introduces a dual-band modified Yagi-Uda antenna. The optimized parameters (see Fig. 3.7) for the triple-band antenna prototype are shown in the first two columns of Table 3.5.

Table 3.5. Optimized parameters for the triple-band and for the dual-band prototypes. The antenna is fabricated on a 1.6 mm thick FR4 substrate.

Parameter	Triple-band (mm)	Dual-band (mm)
D-L	42	38
F-L	130	119
F-W	10	10
R-L	170	160
R-W	5	5
R-D	20	20
D-D	6	5
D-W	8	5
g	1.2	0.5
b	1.35	2
t	13	11

The triple-band antenna (see column 1 and 2 in Table 3.5) is designed, simulated and manufactured on a 1.6 mm thick FR4 substrate. The simulated (solid curve) and the measured (dashed curve) reflection coefficients as a function of frequency are shown in Fig. 3.16.

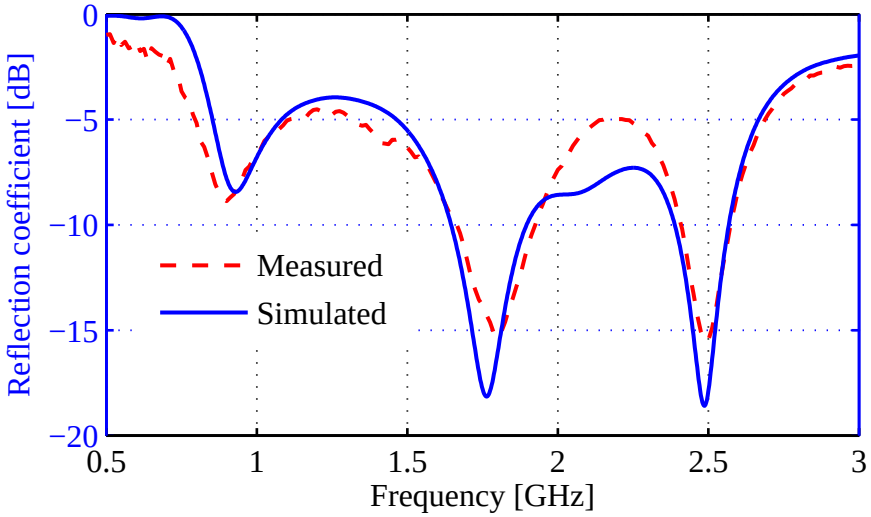


Figure 3.16. Measured and simulated reflection coefficients versus frequency of the triple-band Yagi-Uda antenna

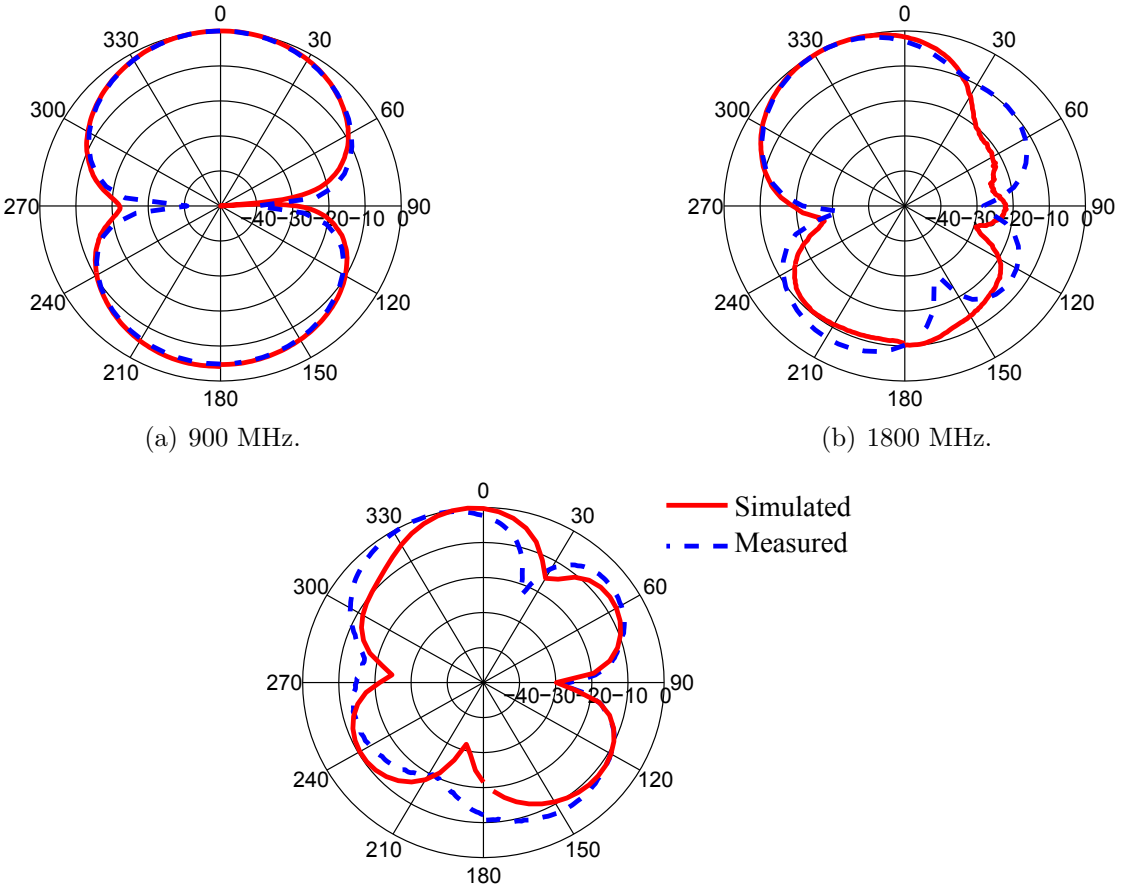
It is observed in the figure that the measured reflection coefficients agree well with the simulated ones. The differences between the simulated and the measured results are less than 1 dB at 900 MHz, the difference increase to less than 3 dB at 1800 MHz and 2.45 GHz. The measured reflection coefficient is -8.6 dB, -16 dB and -13.25 dB at 900 MHz, 1800 MHz and 2.45 GHz respectively. This validates the triple-band characteristics for the antenna.
The normalized power radiation diagrams in the E-plane (see Fig. 3.14) have been simulated and measured at the three desired frequencies and are shown in Fig. 3.17.



(a) 900 MHz.

(b) 1800 MHz.

(c) 2.45 GHz.

Figure 3.17. Simulated and measured normalized power radiation diagrams in the E-plane of the triple-band modified Yagi-Uda antenna.

Figures 3.17(a), 3.17(b) and 3.17(c) show the simulated and the measured normalized power radiation diagrams at 900 MHz, 1800 MHz and at 2.45 GHz respectively. It is shown that the simulated and the measured results agree well with less than 0.5 dB difference in the direction of the main beam between $\theta = 330°$ and $\theta = 30°$ at 900 MHz. It should be mentioned that the direction of the maximum propagation is shifted 30

degrees at 1800 MHz and at 2.45 GHz. This shift is due to the asymmetry in the driven element for the modified Yagi-Uda antenna (see Fig. 3.7). In the direction of the shifted main beam at 1800 MHz, between $\theta = 300°$ and $\theta = 0°$, the difference between the simulated radiation diagram and the measured one is 1 dB at 1800 MHz.
At 2.45 GHz, in the direction of the main beam $\theta = 330°$, the difference increases to 3 dB. Here the radiation pattern is more complex, showing multiple lobes explaining the higher differences.

3.6 Dual-Band Modified Yagi-Uda Antenna

To demonstrate the reconfigurability of the novel antenna geometry, a third prototype is presented in this section. The antenna here is designed to be a dual-band antenna resonating at 900 MHz and at 2.45 GHz. The optimized parameters for the novel dual-band antenna are listed in Table 3.5 (column 1 and 3).
Figure 3.18 shows the simulated (solid curve) and the measured (dashed-dotted curve) reflection coefficient versus frequency as well as the simulated antenna gain (dashed curve) as a function of frequency.

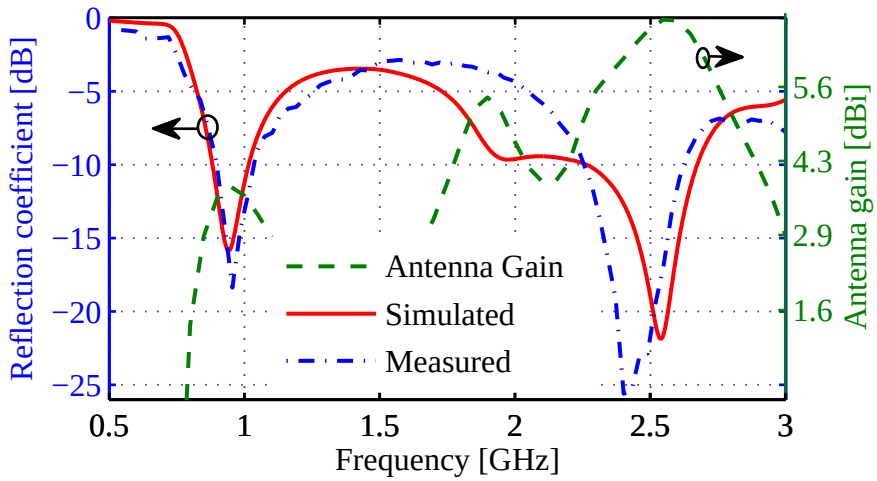


Figure 3.18. Simulated and measured results of the reflection coefficient and antenna gain as a function of frequency for the dual band antenna.

It is shown in the figure that a frequency shift of 100 MHz is present between the simulated and the measured reflection coefficients at the second resonance. This shift is due to fabrication tolerances due to the narrow gap width g of 0.5 mm. The simulated antenna gain reaches 3.2 dBi at 900 MHz and 6.45 dBi at 2.45 GHz.
The radiation diagrams in the E-plane have been simulated and measured for the dual-

band modified Yagi-Uda antenna. Figures 3.19 and 3.20 show the simulated and the measured normalized power radiation diagrams in the E-plane at the frequencies 900 MHz and 2.45 GHz respectively. The differences between simulations and measurements are less than 1 dB in the direction of the main beam between $\theta = 330°$ and $\theta = 30°$ at 900 MHz and at 2.45 GHz.

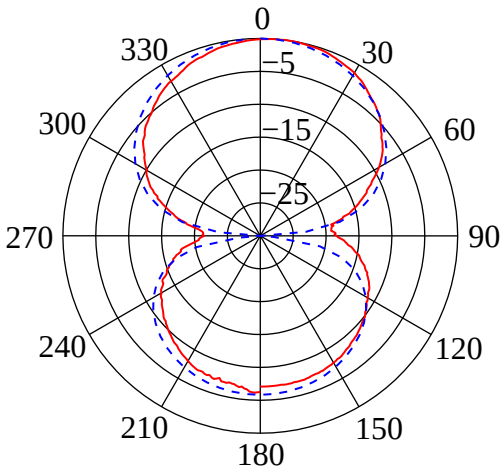

Figure 3.19. Simulated (dashed curve) and measured (solid curve) normalized power radiation diagrams in the E-plane of the dual-band modified Yagi-Uda antenna at 900 MHz.

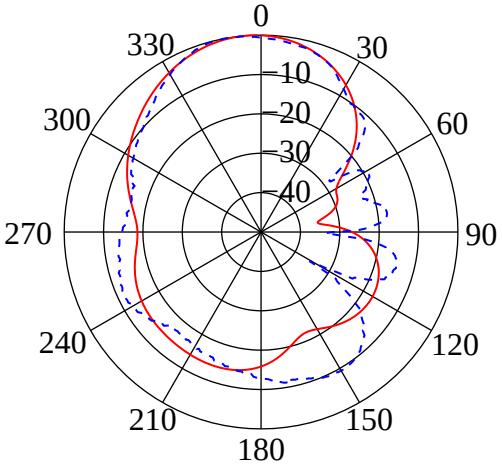

Figure 3.20. Simulated (dashed curve) and measured (solid curve) normalized power radiation diagrams in the E-plane of the dual-band modified Yagi-Uda antenna at 2.45 GHz.

3.7 RF Power Transport at 868 MHz

In this section, the receiving part of the RF power transport system is discussed. Design and measurement results will be described. The DC output voltage and the power conversion efficiency are measured for different values of the load resistance and for different input power levels.

3.7.1 Lumped-Element Matching Network

As is apparent from Fig. 3.1, a rectifier is needed to transform the RF input power into DC power. For a maximum power transfer between the antenna and the rectifier, an impedance matching network is designed, simulated, manufactured, and measured. Commercially available, discrete Schottky diodes HSMS-2852 [43] are used for power rectification.

Figure 3.21 shows a voltage doubler configuration. C_1 and C_2 are set to 100 pF. This value of C_1 and C_2 is not critical for the voltage doubler functioning. The capacitors need to function as 'DC-blockers'. R_L is set to 10 kΩ. The main reason behind choosing $R_L =$ 10 kΩ is that the measured power conversion efficiency peaks around 10 kΩ. Moreover, this value is around the optimum input impedance of the power management circuit [65] that will follow the rectifier part (see Fig. 3.1). $Z_{rectifier}$ is the input impedance of the voltage doubler.

The diode is a nonlinear device and its impedance changes as a function of frequency and as a function of input power level. A fixed input power level and a fixed operating frequency are chosen. Based on the results from previous chapters, we choose $P_{in} = -10$ dBm and the operating frequency $f = 868$ MHz (see Sec. 2.7). A lumped-element matching network is designed to match the input impedance of the rectifier to the input impedance of the antenna (50 Ω).

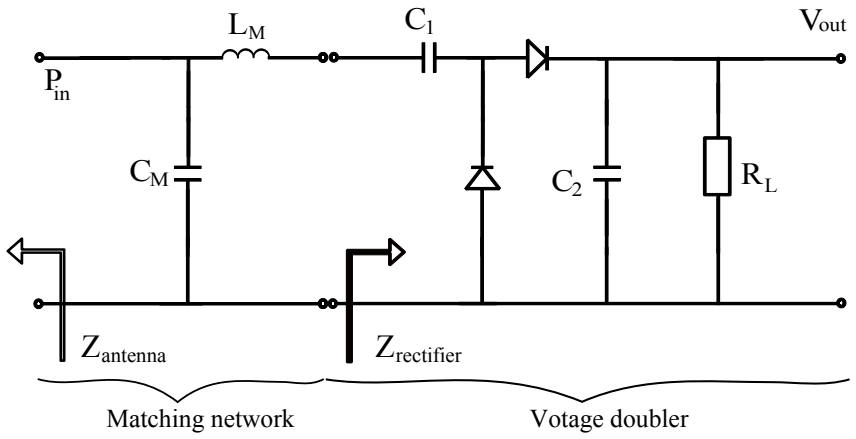

Figure 3.21. Voltage doubler configuration used to rectify the RF power harvested.

Agilent ADS [44] harmonic balance is used for impedance simulations. Figure 3.22 shows the Printed Circuit Board (PCB) footprint layout of the voltage doubler and the lumped-elements matching network. The components used to realize the circuit are summarized in Table 3.6. The circuit is printed on a 1.6 mm thick FR4 substrate.

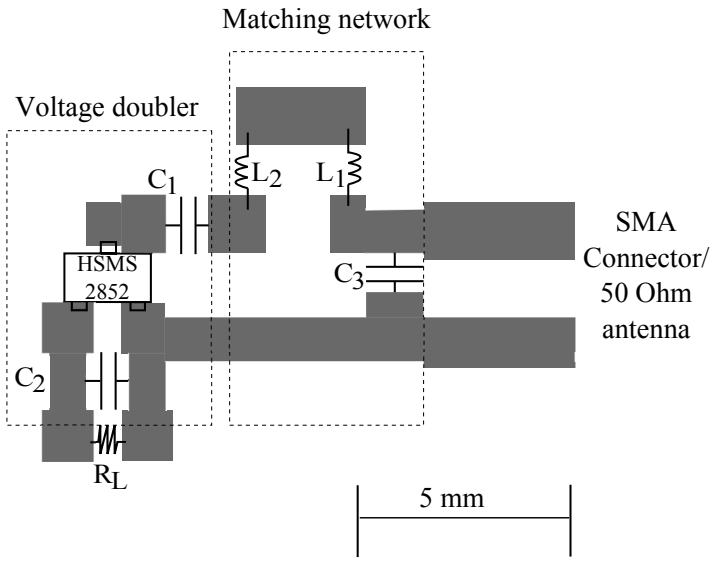

Figure 3.22. Layout of the PCB footprint of the voltage doubler and the matching network.

Table 3.6. Used lumped elements components.

Reference	Value	Manufacturer Ref.

HSMS 2852	-	AVAGO TECHNOLOGIES HSMS-2852-TR1G

The reflection coefficient as a function of frequency for the realized network is measured for different input power levels, and the results together with the simulated ones are plotted in Fig. 3.23.

From the figures, it is observed that the simulated results agree reasonably well with the measured ones with a difference less than 3 dB between the simulated and the measured results. The designed matching networks match the impedance of the rectifier at 868 MHz for different power levels. At 868 MHz and using a 10 k Ω load the measured reflection coefficients are equal to -9.2 dB, -11.9 dB, -13.9 dB and -28.9 dB at -20 dBm, -15 dBm, -10 dBm and at -5 dBm, respectively. From the Figures, it is clear that the rectifier is matched to the antenna for the input power range -15 dBm $\leq P_{in} \leq -5$ dBm with a measured reflection coefficients less than -10 dB.

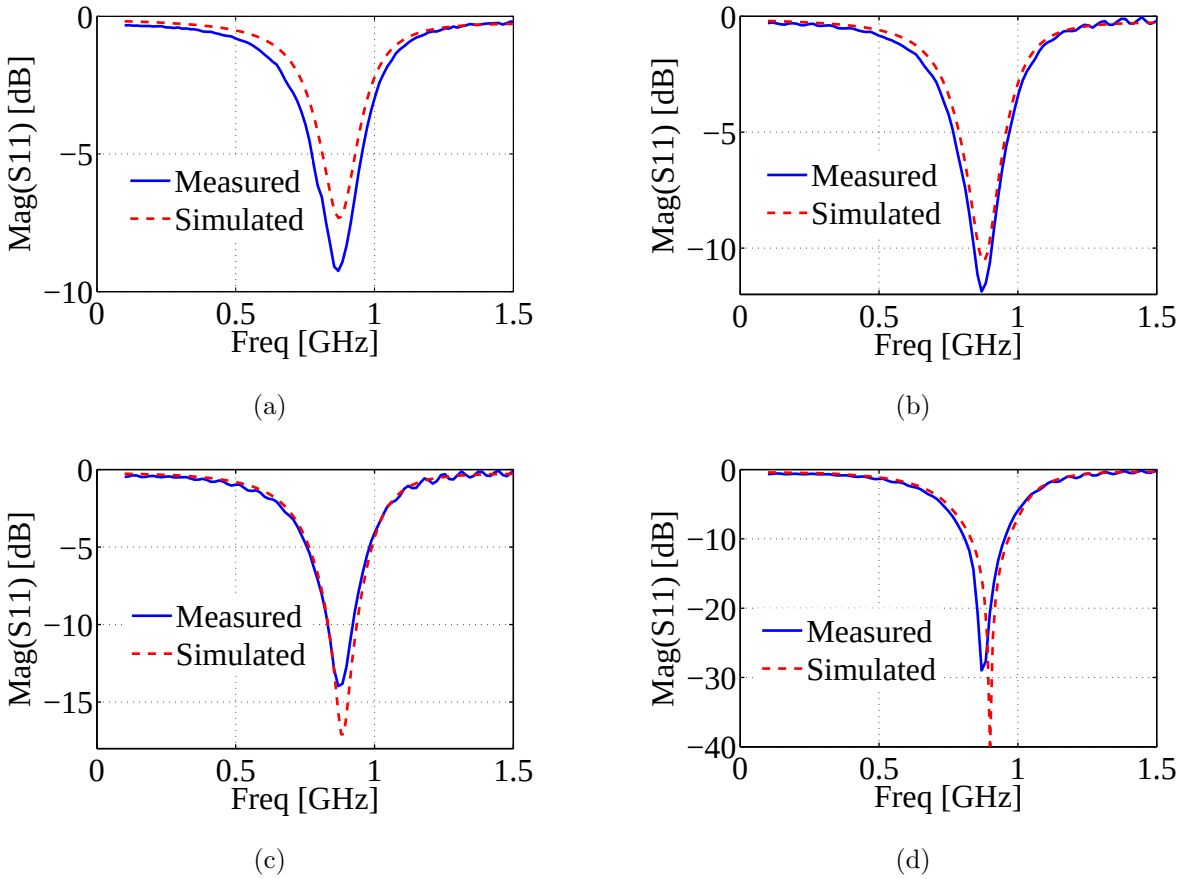

Figure 3.23. Reflection coefficients versus frequency for different input power levels. $R_L = 10$ kΩ. (a) $P_{in} = -20$ dBm . (b) $P_{in} = -15$ dBm. (c) $P_{in} = -10$ dBm . (d) $P_{in} = -5$ dBm.

3.7.2 RF Power Transport Measurement Results

For RF power transport, a system as shown in Fig. 3.1 is being used. In this section, we describe how the rectenna is used for wireless RF power transfer. The power

transfer measurement setup is shown in Fig. 3.24. The setup is calibrated by using two antennas with a known gain, G_r and G_t (see Fig. 3.24) at 868 MHz separated by 1 meter. With the choice of the antenna, we ensures that far-field conditions are satisfied for both antennas. The power density (S) at the receiving side is dictated by the effective isotropic radiated power, $EIRP = P_t G_t$, where P_t is the transmitted power and G_t is the transmit antenna gain, and by the distance R between the transmitting and the receiving antennas.

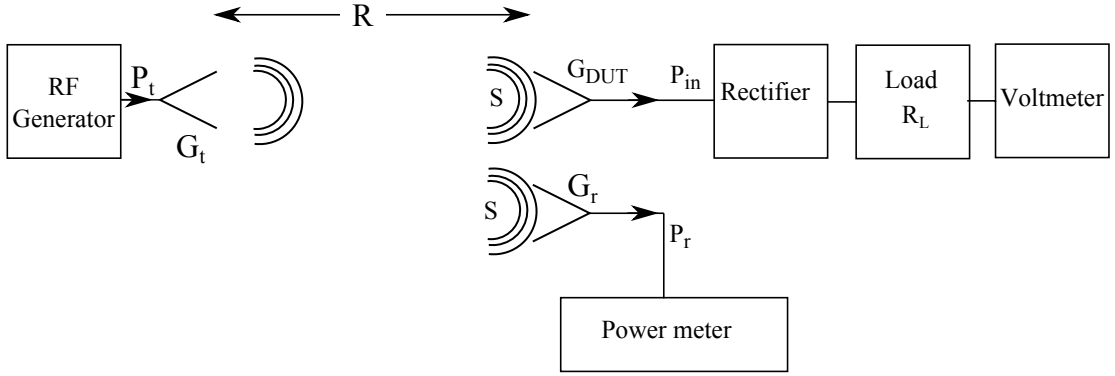

Figure 3.24. Power transfer measurement setup.

The power density is calculated by

$$S = \frac{EIRP}{4\pi R^2} = \frac{P_t G_t}{4\pi R^2}. \tag{3.1}$$

The antenna at the receiving side captures part of this power density with an effective aperture A_r. The received power P_r (see Fig. 3.24) is given by:

$$P_r = A_r S, \tag{3.2}$$

where A_r is the effective aperture of the receiving antenna in the direction of the transmitting antenna. According to [50], the effective aperture is related to the antenna gain by

$$A_r = G_r \frac{\lambda_0^2}{4\pi}, \tag{3.3}$$

where λ_0 is the wavelength of transmitted signal. Substituting Eq. (3.3) in Eq. (3.2) in Eq. (3.1) leads to the Friis transmission equation where the received power at the

terminals of the power meter is expressed as

$$P_r = P_t G_t G_r \left(\frac{\lambda_0}{4\pi R}\right)^2 = P_t G_t G_r \left(\frac{c}{4\pi f_0 R}\right)^2, \tag{3.4}$$

where c is the free-space speed of light and f_0 is the operating frequency of the transmitted signal.

A power meter is used to measure the received RF power P_r. The measured power P_r is then compared to the theoretically calculated value based on Eq. (3.4). The measured power appeared to be within ± 0.5 dB agreement with the theoretically calculated power, which ensures an accurate measurement setup. The rectenna is then placed for wireless power transport. The antenna gain of the rectenna is denoted by G_{DUT} as shown in Fig. 3.24. G_{DUT} is simulated with the aid of CST Microwave Studio. The input power level P_{in} at the clamps of the rectifier (see Fig. 3.24) is then calculated from

$$P_{in} = P_t G_t G_{DUT} \left(\frac{c}{4\pi f_0 R}\right)^2, \tag{3.5}$$

so that

$$P_{in} = \frac{P_r G_{DUT}}{G_r}. \tag{3.6}$$

The receiving rectenna system is connected to a variable load resistor R_L. The DC output voltage is measured with the aid of a voltmeter for different load resistances and for different input power levels.

The antenna of the receiving rectenna system shown in Fig. 3.24 consists of the modified Yagi-Uda antenna introduced in the previous section. The antenna is optimized to resonate at 868 MHz [37]. Then the antenna is connected to the rectifier through the impedance matching network and to a variable load resistor R_L. The DC output voltage is measured for different load resistances at three different input power levels -20 dBm, -10 dBm and -5 dBm calculated according to Eq. (3.6).

Figure 3.25 shows the measured output voltage versus load resistance at the three input power levels at an operating frequency f_0 of 868 MHz. The solid curve represents the output voltage as a function of R_L at an input power level of -20 dBm. The dashed curve and the dotted-dashed curve represent the measured output DC voltage at -10 dBm and -5 dBm respectively. The system output voltage reaches 0.17 V, 0.7 V and 1.3 V over a 10 kΩ load resistance at an input power level of -20 dBm, -10 dBm and -5 dBm, respectively.

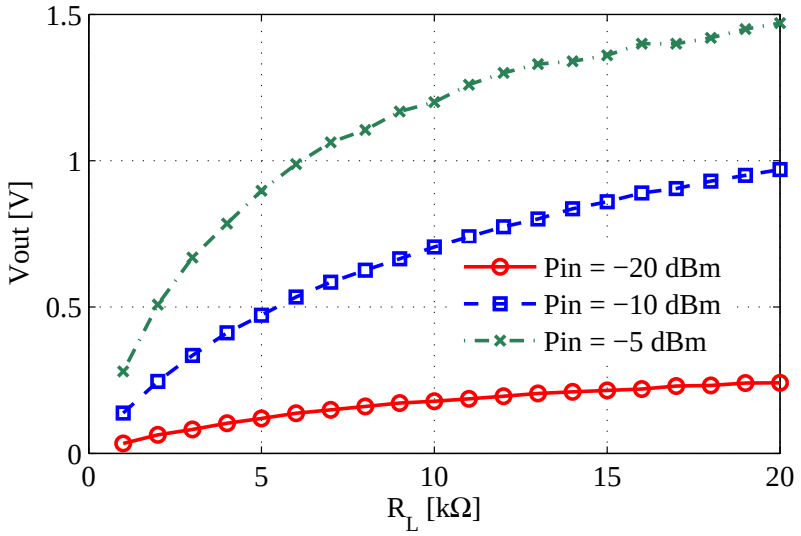

Figure 3.25. Measured DC output voltage versus load resistance R_L for different input power levels. Operating frequency f_0= 868 MHz.

The measured power conversion efficiency (PCE) is calculated using the following equation:

$$\mathrm{PCE}\,(\%) = \frac{P_{load}}{P_{in}} = \frac{V_{out}^2}{R_L}\frac{1}{P_{in}}. \tag{3.7}$$

The PCE is calculated for different input power levels from Eq. (3.7) and the results are plotted in Fig. 3.26.

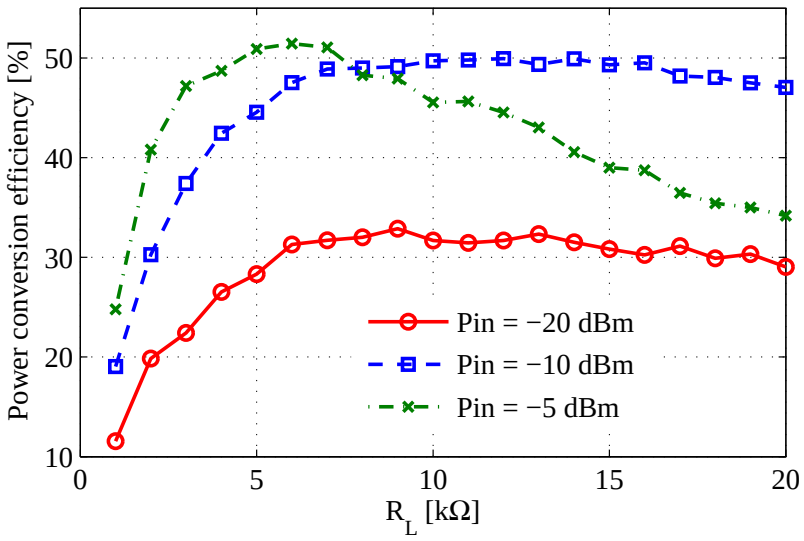

Figure 3.26. Measured power conversion efficiency (PCE) as a function of load resistance R_L for different input power levels. Operating frequency f_0 = 868 MHz.

The system PCE reaches 31.6% and 49.7 % over a 10 kΩ load resistance at an input power level of -20 dBm and -10 dBm, respectively. The PCE decreases to 45.5 % at an input power level of -5 dBm across the same load resistance. Table 3.7 compares the presented results in this section to the state-of-the-art reported results [19, 66–68] that use commercially available discrete rectifiers.

Table 3.7. Comparison of rectenna systems in literature that uses commertially available discrete rectifers

Reference	Pin [dBm]	Frequency [MHz]	Resistive Load kΩ	Discrete rectifier	Power Conversion Efficiency
[66]	-10	866.5	3	HSMS285C	24*%
[19]	-10 -20	1800	2.4	HSMS2850	38*% 15*%
[67]	-10	830	10^4	HSMS286Y	44%
[68]	-20	850 1850	-	SMS7630	14*% 13*%
This work	-10 -20	868	10	HSMS2852	49.7% 31.6%

∗calculated from figure

The authors in [66] and [19] use the same Schottky rectifier as was used in this section. The peak measured power conversion efficiency is 24 % across a 3 kΩ load in [66] and is 38% across a 2.4 kΩ load in [19] which is lower than the 49.7 % achieved by using the suggested matching network.

In [67], the authors use the commercial rectifier HSMS-286Y in combination with an impedance matching circuit and a resonant circuit. The maximum measured PCE at 830 MHz and at -10 dBm is 44 %. Compared to the results reported in Fig. 3.26, the system suggested in this chapter is 5 % more efficient. It is clearly indicated in Table 3.7 that the rectenna presented in this chapter shows a higher efficiency performance at -20 dBm and at -10 dBm.

3.8 Conclusion

A novel modified Yagi-Uda antenna is presented in this chapter. The main advantage of the presented antenna is that, by tuning its parameters, the antenna can be reconfigured to behave as either a broad-band, triple-band or dual-band antenna. Three prototypes are designed to validate the reconfigurability of the antenna. The antennas are simulated, manufactured and measured. The simulated results are in line with the

measured ones. Agilent ADS harmonic balance simulations are used to design a voltage doubler and a matching network to match the impedance of the rectifier to 50Ω.

The DC output voltage and the power conversion efficiency as a function of load resistance at three input power levels are measured for a frequency of 868 MHz. The system output voltage reaches 0.17 V, 0.7 V and 1.3 V over a 10 kΩ load resistance at an input power level of -20 dBm, -10 dBm and -5 dBm respectively. The system PCE reaches 31.6 % and 49.7 % over a 10 kΩ load resistance at an input power level of -20 dBm and -10 dBm, respectively.
The 50Ω rectenna system presented in this chapter exhibits an increased PCE of at least 5 % at -10 dBm and at least 10 % at -20 dBm, compared to the reported state-of-the-art results.

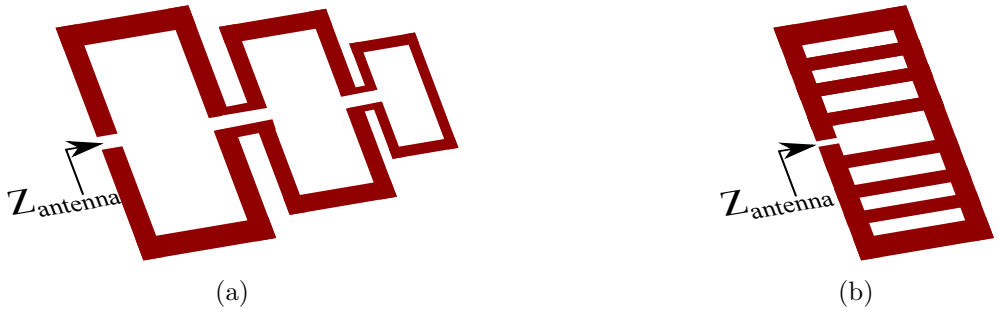
Chapter four

Compact and Conjugate-Matched Antenna Design

In this chapter we investigate different antenna topologies. These are the strip dipole, the folded strip dipole and a modified loop antenna. Novel, simple and accurate empirical expressions are introduced to calculate the input impedance of a strip dipole antenna. Next these expressions are employed to calculate the input impedance of a strip folded dipole antenna. A modified rectangular loop antenna with additional geometrical structures is introduced. The additional geometrical structures will make it possible to tune the antenna input impedance to the complex conjugate of that of a rectifier.

4.1 Introduction

To design an antenna with a specific input impedance, the geometry of the antenna should have enough parameters to be able to tune the input impedance. One such antenna is the strip-folded dipole array antenna shown in Fig. 4.1(a) [69]. This antenna is characterised by its broad bandwidth when the resonant frequencies of the individual elements are close together. If used for RFID applications and RF power harvesting, the strip folded-dipole array antenna has enough geometrical features to tune its input impedance. Another antenna that has ample geometrical features is the modified loop antenna shown in Fig. 4.1(b). Horizontal inner strips are added to the loop to tune the antenna input impedance. The main advantage of this modified loop antenna is its compact size compared to the strip-folded-dipole-array antenna.



(a) (b)

Figure 4.1. (a) Strip folded-dipole array antenna configuration and (b) the suggested modified loop antenna configuration.

The core of a strip folded-dipole array antenna is the folded dipole antenna. It is worthwhile therefore to put some effort into calculating the characteristics of the strip folded dipole antenna with a high degree of accuracy, without resorting to full-wave methods. The core of a folded dipole antenna is a dipole antenna. In this chapter, new empirical equations are introduced to calculate the input impedance of a strip dipole antenna. The proposed design equations are very accurate and can be easily implemented in standard computing tools, e.g. Matlab. The simulation results are validated by measurements. Next, updated analytical equations are presented to calculate the input impedance of an asymmetric strip folded dipole antenna. In addition, a novel and compact modified loop antenna configuration is introduced for which the antenna impedance can be tuned independently from its radiation efficiency. The impedance tuning ability eliminates the need for a matching network between the antenna and the rectifier which makes the rectenna system more compact, power-efficient, and cheaper to produce. The modified loop antenna will be used in Chapter 5 for RF power transport applications.

4.2 Strip Dipole Antenna

The basic element of the folded dipole antenna is the single dipole antenna [70]. A folded dipole antenna is commonly analyzed by recognizing a transmission line mode and a dipole antenna mode. The strip folded dipole antenna will be investigated in Sec. 4.3. In this section we present a strip dipole antenna analysis, using accurate and easy-to-use design equations to calculate the input impedance.

The input impedance of a dipole antenna can be calculated using full-wave analysis techniques, e.g. the method of moments (MoM) [71], and the finite integration technique (FIT) [72]. These methods are potentially very accurate for solving the Maxwell equations without a-priori approximations, but in general are time consuming. An alternative way is to use dedicated analytical-equation methods. Analytical equations may be derived by employing, among other methods, the induced EMF method, Hallén's

integral equation (HIE) method, and the King-Middleton second-order method [70]. While the resulting equations are easy-to-use, they appear to be insufficiently accurate to design antennas with a specific non-standard input impedance, especially when the radius of the cylindrical dipole antenna increases as shown in Appendix A. In this section, we present a simple but highly accurate analysis method that improves upon the known analytical expressions.

From a realization perspective, strip dipole antennas are more convenient than cylindrical wire dipole antennas. Strip dipole antennas may be implemented on foil, e.g. for RFID tags and even on-chip realizations are feasible.
A printed dipole antenna of width W can be analyzed by treating it as an equivalent cylindrical dipole antenna with a radius $r = \frac{W}{4}$ [73].

4.2.1 Equivalent Radius of a Strip Dipole Antenna

Cylindrical and strip dipole configurations are shown in Fig. 4.2(a).

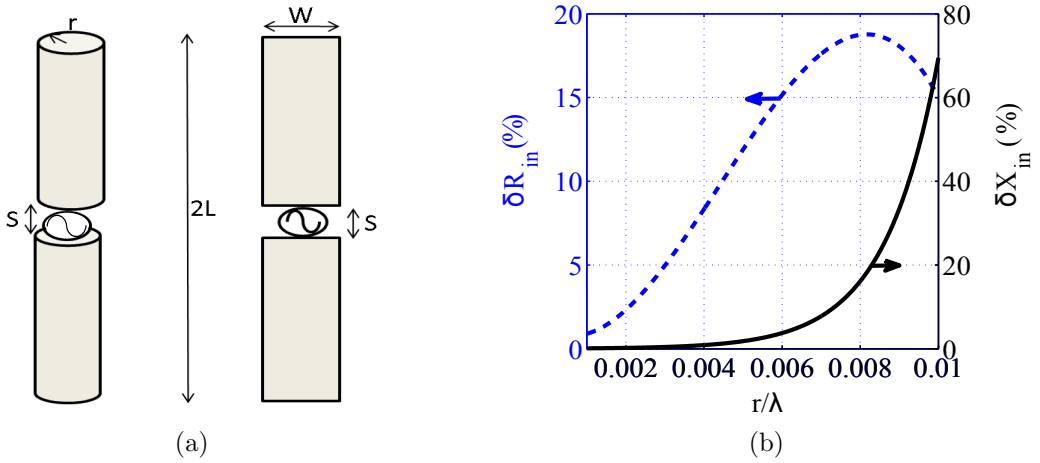


Figure 4.2. (a) Cylindrical and strip dipole configuration and (b) relative difference between the real and imaginary parts of the input impedance as a function of dipole radius over wavelength. L = 237 mm, S = 2 mm. $\lambda = 1$ m.

To investigate the accuracy of the equivalence $r = \frac{W}{4}$, the radius r of the cylindrical dipole is set to a quarter of the strip dipole width W, and CST Microwave Studio [57] is used to calculate the input impedance of the strip dipole and its equivalent cylindrical dipole. The feeding gap S is set to 0.002λ for the cylindrical dipole and for the strip dipole. This procedure is repeated for different dipole radii. Figure 4.2(b) shows the relative difference errors $\delta R_{in} = (R_{Cylindrical} - R_{Strip}) / R_{Cylindrical}$ (dashed curve) and $\delta X_{in} = (X_{Cylindrical} - X_{Strip}) / X_{Cylindrical}$ (solid curve) as a function of dipole

radius. It is shown in the figure that, for larger dipole radii, the deviation increases, which makes the quasi-static approach $\left(r = \frac{W}{4}\right)$ not accurate especially for larger dipole radii. Therefore, it should be used only for very thin cylindrical radii ($\frac{r}{\lambda} \leq 0.004$ for $\epsilon_{\delta_{R_{in},X_{in}}} \leq 10\,\%$). It should be mentioned that the frequency solver employed by CST Microwave Studio has been used for simulations which proved to be the most accurate compared to measurements.

4.2.2 Input Impedance of a Strip Dipole Antenna

Since the quasi-static approach $\left(r = \frac{W}{4}\right)$ is not accurate enough to calculate the input impedance of a practical strip dipole, a new analytical solution to calculate the impedance of a strip dipole of length $2L$ and a width of W as shown in Fig. 4.2(a) is derived. The input impedance of the strip dipole antenna is calculated for different lengths and widths at a frequency of 300 MHz. Figure 4.3 shows the simulated results of the real (a) and imaginary (b) parts of the input impedance for $1.0 \leq \left(\frac{2\pi L}{\lambda}\right) \leq 2.0$ and $0.003 \leq \left(\frac{W}{\lambda}\right) \leq 0.04$ at an operating frequency of 300 MHz.
Different data fitting methods, using polynomial models, exponential models, Fourier series and power series have been investigated to best fit the results shown in Fig. 4.3. It has been found that the polynomial models match the simulated results with the lowest relative errors (less than 10 %). Matlab has been used to investigate the optimum fitting method. Since the strip dipole antenna has two parameters: the width W and the half-length length L, a two dimensional fitting expression is needed. Performing surface fitting on the full-wave calculated real an imaginary parts of the input impedances shown in Fig. 4.3, results in

$$R_{in}\left(\frac{L}{\lambda}, \frac{W}{\lambda}\right) = \sum_{m=0}^{5}\sum_{n=0}^{5} R_{mn}\left(\frac{L}{\lambda}\right)^{m}\left(\frac{W}{\lambda}\right)^{n}, \tag{4.1}$$

$$X_{in}\left(\frac{L}{\lambda}, \frac{W}{\lambda}\right) = \sum_{m=0}^{5}\sum_{n=0}^{5} X_{mn}\left(\frac{W}{\lambda}\right)^{m}\left(\frac{L}{\lambda}\right)^{n}, \tag{4.2}$$

where the coefficients R_{mn} and X_{mn} are listed in Table 4.1 and Table 4.2, respectively. The width of the feeding gap S is set to 0.002λ. The effect of the feeding gap is limited and will be discussed in detail in Sec. 4.2.3. The impedance equations are valid for $1.0 \leq \left(\frac{2\pi L}{\lambda}\right) \leq 2.0$ and $0.003 \leq \left(\frac{W}{\lambda}\right) \leq 0.04$, where they show a relative error less than 10 % for both real and imaginary parts. Compared to King-Middleton second-order fitting equations as described in Appendix A [70], which are valid only for $1.3 \leq \left(\frac{2\pi L}{\lambda}\right) \leq 1.7$ and $0.001 \leq \left(\frac{W}{\lambda}\right) \leq 0.01$, the novel expressions are valid for longer

and wider strip dipole antennas, as will be shown in Sec. 4.2.3. These equations can be used for a feeding gap width S in the range of 0.001λ to 0.005λ.

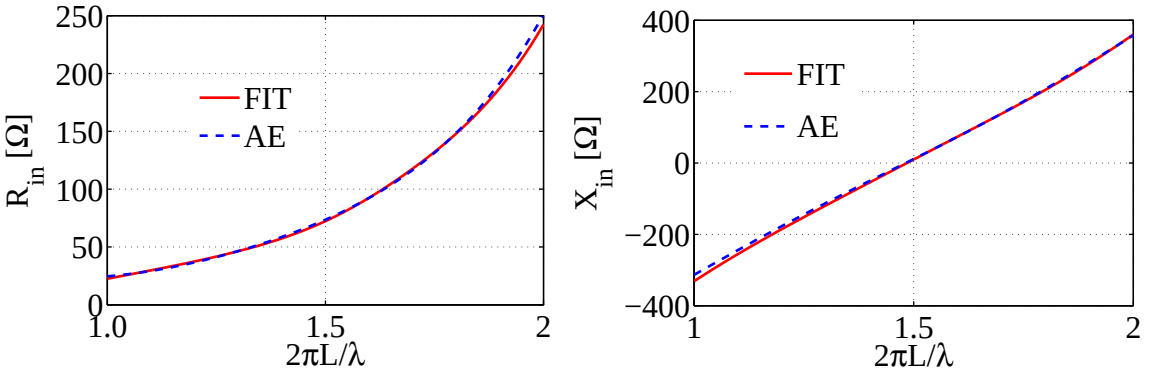
4	-8.8e8	2.709e9	0	0	0	0
5	1.873e9	0	0	0	0	0

Figure 4.4 shows the real (a) and imaginary (b) parts of the input impedance of a strip dipole as a function of frequency calculated using the finite integration technique (FIT) and the analytical equations for strip dipoles (AE). The electrical length of the dipole is set to $\frac{2\pi L}{\lambda}$ =1.5 ($L = 11.93\,\text{cm}$), the width W is set to 0.003λ ($W = 1.5\,\text{mm}$). It is clear from Fig. 4.4(a) and Fig. 4.4(b) that the results obtained by the new empirical equations overlap the results obtained by the electromagnetic simulation software, which shows the accuracy of these fitting equations.

For this example, the relative difference error is calculated for both the real and imaginary parts. For the real part, the highest relative difference error occurs at a frequency of 800 MHz and it is equal to 8 %. For the imaginary part the highest relative difference error occurs at a frequency of 400 MHz and it is equal to 6 %. These equations have been verified for different strip widths and for different strip lengths as a function of frequency within the validity range. They show a relative error less than 10 % for both real and imaginary parts.



(a) (b)

Figure 4.4. Real (a) and imaginary (b) parts of the input impedance of a strip dipole antenna as a function of frequency calculated by the Finite Integration Technique (FIT) and by the novel Analytical equations (AE). $L = 11.93$ cm, $W = 1.5$ mm, $S = 1$ mm.

4.2.3 Feeding Gap S Dependence

The presented equations are developed for a fixed feeding width S of 0.002λ but may be valid over a range of S-values. The 0.002λ constraint may be too specific for general use. To investigate the effect of the feeding width, the FIT is used to calculate the reflection coefficients and the input impedance of two strip dipole antennas A1 and A2 with a length $L_1 = 225$ mm and a width $W_1 = 20$ mm for antenna A1. The length and width for antenna A2 are $L_2 = 115$ mm and $W_2 = 10$ mm, respectively.
Figures 4.5(a) and 4.5(b) show the reflection coefficients relative to 50Ω as a function of frequency for different feeding width values S for antennas A1 and A2, respectively. It is shown in the figures that the antenna resonance is shifted when the feeding width is changed. However, for practical values $(0.001\lambda - 0.005\lambda)$ the change in the reflection coefficient is negligible (see Figs. 4.5(a) and 4.5(b)). Consequently, for these practical values, the change in the impedance may be neglected.

To calculate the deviations between the input impedance calculated by the Analytical Equations (AE) and calculated by the Finite Integration Technique (FIT), the Figure of Merit (FoM) introduced in Sec. 1.6 is used. Using the FoM, the validity of the presented formulas for different feeding widths S are expressed in a single number having the characteristics of a power wave reflection coefficient. The input impedance of a strip dipole is calculated from the presented empirical expressions and by using the FIT for different feeding width values S. The FoM accounts for the mismatch due to feed gap errors in the analytical calculations.
Figure 4.6 shows the FoM for the analytical equations as a function of feeding gap width S referred to the outcome of the FIT analysis for antennas A1 (solid curve) and antenna

A2 (dashed curve). It is clear from the figure that the presented expressions are valid for a feeding width up to 0.02λ (Threshold$\leq -10\,\mathrm{dB}$), which validates the accuracy of the novel empirical expressions for the practical values of the feeding gap ($0.001\lambda - 0.005\lambda$) with a FoM $\leq$-20 dB.

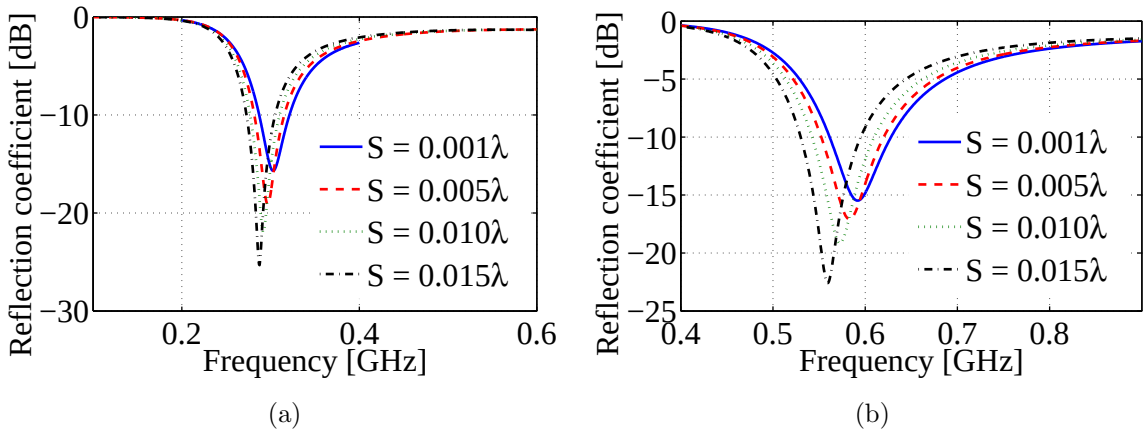


Figure 4.5. Reflection coefficients relative to 50Ω as a function of frequency for different feeding width S for antenna A1 (a) and antenna A2 (b). $L_1 = 225\,\mathrm{mm}$, $W_1 = 20\,\mathrm{mm}$, $\lambda_1 = 1\,\mathrm{m}$. $L_2 = 115\,\mathrm{mm}$, $W_2 = 10\,\mathrm{mm}$, $\lambda_2 = 0.5\,\mathrm{m}$

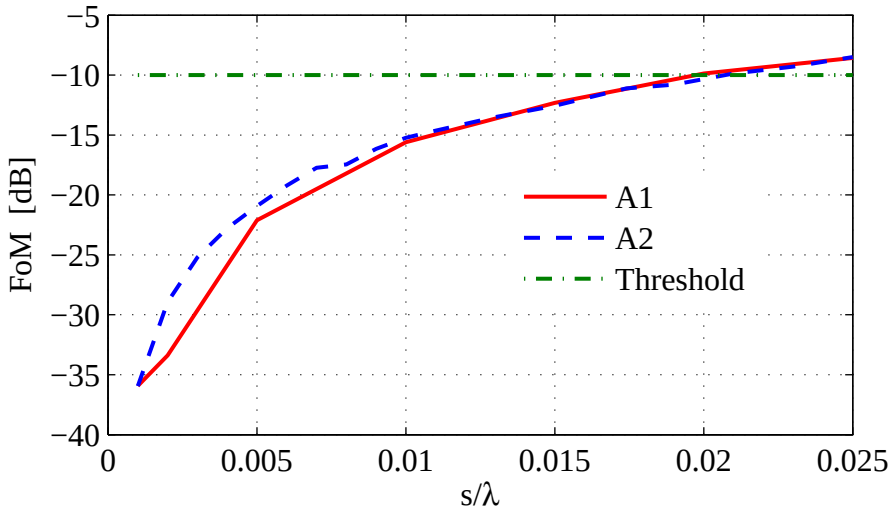

Figure 4.6. Figure of Merit (FoM) to calculate the deviations between the presented equations and the FIT for different feeding width for antenna A1 and antenna A2.

4.2.4 Fabricated Antenna

So far, we have used the results of CST Microwave Studio as a reference. To verify the real accuracy of the novel empirical equations, a strip dipole antenna is designed, simulated using AE and FIT, manufactured and tested. The antenna is designed to cover the GSM900 frequency bands: 890-915 MHz (uplink) and 935-960 MHz (downlink) [74]. The designed length and width of the strip dipole are $2L = 15\,\text{cm}$, $W = 1\,\text{cm}$. Figure 4.7 shows the simulated (AE & FIT) and the measured reflection coefficients as a function of frequency. It is clear from the full-wave analysis results and the measurement results that the novel empirical equations can predict the input impedance behavior and the resonance of the strip dipoles with less than 2 dB difference in the reflection coefficients in the specified GSM900 frequency bands.

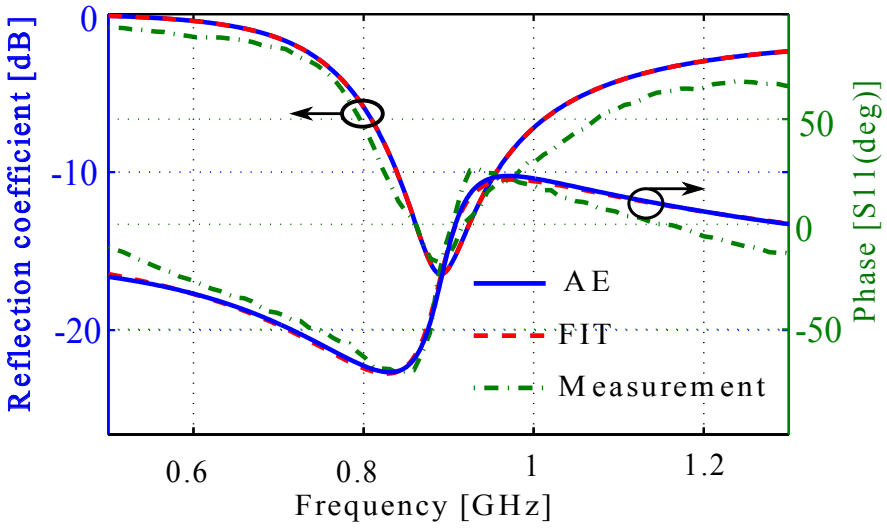

Figure 4.7. Simulated and measured reflection coefficients as a function of frequency.

4.3 Folded-Strip Dipole Antenna

The main limitation of the strip dipole antenna investigated in the previous section is its restricted number of geometrical features. This will make it hard to directly conjugate impedance match the antenna to a complex impedance. The impedance tuning ability of the strip dipole antenna depends only on the strip width W, the strip length $2L$ and - to a lesser extent - the feed gap width S (see Fig. 4.2(a)). Another antenna with more geometrical features that can be used for RF power harvesting applications is the strip folded dipole antenna [75] shown in Fig. 4.8(a). The strip folded dipole antenna may

be regarded as an evolution of the strip dipole antenna.

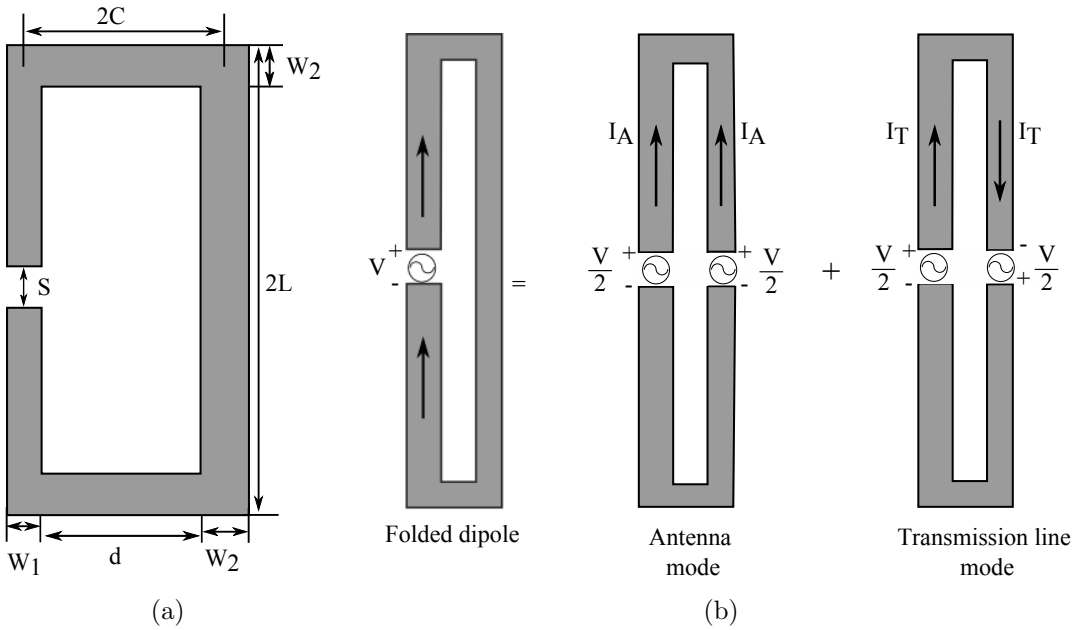

Figure 4.8. Strip folded dipole antenna configuration (a) and the decomposition of the current distribution into an antenna mode and a transmission line mode(b).

The main advantage of the strip folded dipole antenna over the strip dipole antenna is that it introduces two additional geometrical features, W_2, the width of the parallel, short-circuited dipole, and d, the inter-element distance between the CoPlanar Strips (CPS), (see Fig. 4.8(a).

In this section we will discuss an updated design procedure to calculate the input impedance of an asymmetric strip folded dipole antenna. Compared to the state of the art [76, 77], the design procedure in this section does not use the equivalence between a strip and a circular cross section wire to calculate the input impedance of a strip dipole. Instead it directly uses the empirical equations (Eq. (4.1) and Eq. (4.2)) for the strip dipole antenna introduced in the previous section.

The folded dipole antenna analysis by Thiele and Ekelman [75] will be followed. The currents in the folded dipole are decomposed into two fundamental modes: the transmission-line mode and the antenna mode as visualized in Fig. 4.8(b), where I_A is the antenna current flowing on the surface of the dipole and I_T is the transmission line current.

4.3.1 Input Impedance of a Strip Folded Dipole

Figure 4.8(a) shows the configuration of an asymmetric strip folded dipole antenna in free space. By decomposing the current into two modes, the input impedance of the strip folded dipole has become a function of three variables, the input impedance of the strip dipole, the input impedance of the coplanar strip transmission line stubs that may be recognized in the antenna configuration and the step-up impedance ratio [78,79] accounting for the difference in strip widths. The input impedance of the folded dipole antenna is then found to be [33]:

$$Z_{in} = \frac{2(1+q)^2 Z_D Z_T}{(1+q)^2 Z_D + 2Z_T}, \tag{4.3}$$

where Z_D is the input impedance of a strip dipole antenna with length $2L$ and width W_1. Z_T is the input impedance of the asymmetric coplanar strip transmission line stub of length L. The CPS line widths are W_1 and W_2, respectively, and $(1+q)^2$ is the step-up impedance ratio [75]. q will be specified in the next subsection.

4.3.2 Transmission Line Analytical Equations

The input impedance of a short circuited length of coplanar strip transmission line Z_T is calculated from the general transmission line theory as [80]:

$$Z_T = jZ_C \tan\left(\frac{\beta L}{2}\right), \tag{4.4}$$

where $Z_C = \left[\frac{120\pi}{\sqrt{\epsilon_r}} \frac{K(k)}{K'(k)}\right]$ is the characteristic impedance of the CPS transmission line [76]. $K(k)$ is the complete elliptic function of the first kind where $K'(k) = K(k')$ and $k'^2 = 1 - k^2$. The ratio of the complete elliptic functions $\frac{K(k)}{K'(k)}$ may be approximated by [81],

$$\frac{K(k)}{K(k')} \approx \begin{cases} \frac{1}{2\pi} \ln\left[2\frac{\sqrt{1+k}+\sqrt[4]{4k}}{\sqrt{1+k}-\sqrt[4]{4k}}\right] & \text{for } 1 \le \frac{K}{K'} \le \infty, \quad \frac{1}{\sqrt{2}} \le k \le 1 \\ \frac{2\pi}{\ln\left[2\left(\frac{\sqrt{1+k'}+\sqrt[4]{4k'}}{\sqrt{1+k'}-\sqrt[4]{4k'}}\right)\right]} & \text{for } 0 \le \frac{K}{K'} \le 1, \quad 0 \le k \le \frac{1}{\sqrt{2}} \end{cases} \tag{4.5}$$

The argument k is given by [78,79],

$$k = \frac{\left(\frac{d}{2}\right)\left(1 + e\left(\frac{d}{2} + W_1\right)\right)}{\left(\frac{d}{2}\right) + W_1 + e\left(\frac{d}{2}\right)^2}, \tag{4.6}$$

and

$$e = \left[\frac{W_1 W_2 + \frac{d}{2}(W_1 + W_2) - \sqrt{W_1 W_2 (d + W_1)(d + W_2)}}{\left(\frac{d}{2}\right)^2 (W_1 - W_2)} \right], \tag{4.7}$$

where W_1 is the width of the strip dipole, W_2 is the width of the parallel, short circuited dipole and d is the distance between the CPS strips as shown in Fig.4.8(a). The step-up impedance ratio $(1+q)^2$, is calculated from [78],

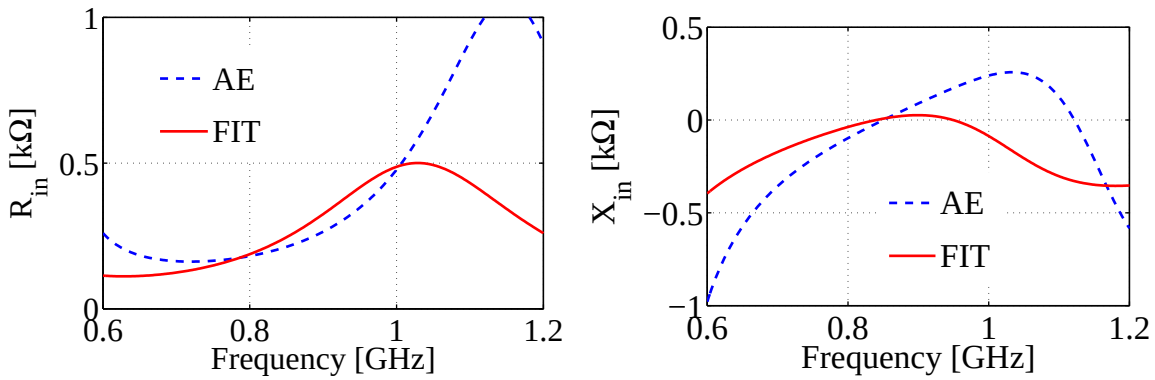
$$q = \left[\frac{\ln\left\{4C + 2\sqrt{(2C)^2 - \left(\frac{W_1}{2}\right)^2}\right\} - \ln\{W_1\}}{\ln\left\{4C + 2\sqrt{(2C)^2 - \left(\frac{W_2}{2}\right)^2}\right\} - \ln\{W_2\}} \right], \tag{4.8}$$

where $2C$ is the distance from the middle of the strip dipole to the middle of the parallel dipole as shown in Fig.4.8(a). ($C = \frac{d}{2} + \frac{W_1}{4} + \frac{W_2}{4}$). Now, we will follow the existing analysis for the strip folded dipole antenna and replace the dipole input impedance with the newly derived expressions.

4.3.3 Validation of the New Analytical Procedures

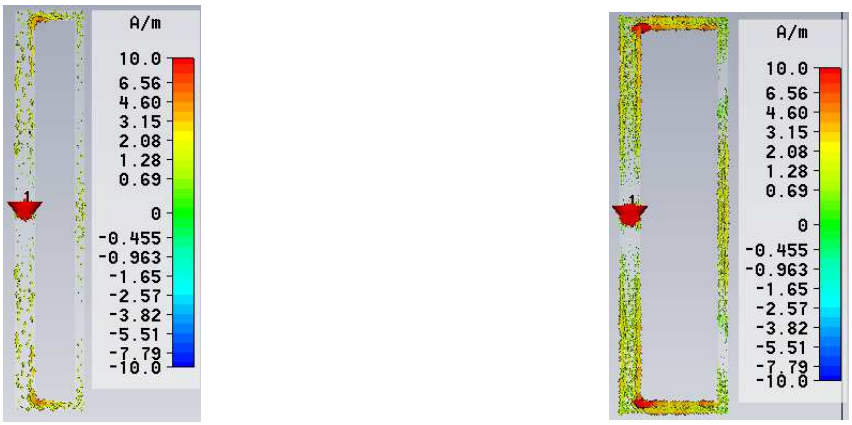
To verify the accuracy of the updated analytical expressions, the real and imaginary parts of the input impedance of a strip folded dipole are calculated using CST Microwave Studio (FIT). These results are compared to the results of the proposed analytical expressions (AE). Figure 4.9 shows the input impedance (real and imaginary parts) as a function of frequency for a strip folded dipole calculated by both the FIT and the AE. The strip widths are $W_1 = 8\,\text{mm}$, and $W_2 = 4\,\text{mm}$, the separation between strips is $d = 16\,\text{mm}$, the strip folded dipole length is $2L = 16\,\text{cm}$ and the feeding width is $S = 2\,\text{mm}$.

It is clear from the figure that the results obtained by the AE deviate from the results obtained by the FIT. Both curves (for the real and imaginary parts) show more or less the same behavior, but a frequency shift is visible as well as a change in the impedance level. To investigate possible sources of errors in the analytical expressions, the surface current distribution is simulated with the aid of CST Microwave Studio. Figure 4.10 shows the surface current distribution on a strip folded dipole antenna for two different separation distances, $d = 16\,\text{mm}$ and $d = 32\,\text{mm}$, at an operating frequency of 1.2 GHz.



(a) (b)

Figure 4.9. Real (a) and imaginary (b) parts of the input impedance versus frequency for an asymmetric strip folded dipole antenna calculated using the Finite Integration Technique (FIT) and the Analytical Equations (AE).$W_1 = 8\,\text{mm}$, $W_2 = 4\,\text{mm}$, $d = 16\,\text{mm}$, $2L = 16\,\text{cm}$.



(a) (b)

Figure 4.10. Surface current distribution on a strip folded dipole antenna for a separation between strips of (a) $d = 16\,\text{mm}$ and of (b) $d = 32\,\text{mm}$. $W_1 = 8\,\text{mm}$, $W_2 = 4\,\text{mm}$, $2L = 16\,\text{cm}$. Frequency $= 1.2\,\text{GHz}$

It is observed in Fig. 4.10 that a considerable amount of current flows along the short-horizontal strips. Moreover it is shown that when the separation distance is increased to $d = 32\,\text{mm}$ (Fig. 4.10(b)) the surface current density in these strips increases.
When the input impedance of the coplanar strip transmission line Z_T is calculated, it is assumed that the coplanar strip lines are connected with an infinitely thin horizontal strip, but in reality they are interconnected with a strip that has the same width as the transmission line W_2. Consequently, the deviations shown in Fig. 4.9 are assumed

to be due to the connecting strips of length d. In order to compensate for the distance between the CPS and the current flowing in the connecting strips, a correction to the transmission line length is required.
To derive the correction factor analytically, the input impedance of the antenna is calculated and compared to the results obtained by FIT. Then the length of the transmission line in the transmission line mode is increased until the resonance frequency of the AE coincides with that of the FIT. This procedure is repeated for different separation widths d.

The correction to the transmission line length L_T is calculated as:

$$L_T = 2L + \Phi(d)\,\lambda d, \tag{4.9}$$

where the correction factor $\Phi(d)$ for the separation width is found to be

$$\Phi(d) = \left(0.06243 d^{(-1.038)} + 3.071\right). \tag{4.10}$$

The results after using this correction factor are shown in Fig. 4.11. It is shown in the figure that when the correction factor is used, the proposed analytical equations can predict the impedance behavior of the strip folded dipole antenna within reasonable accuracy as will be explained in the following.

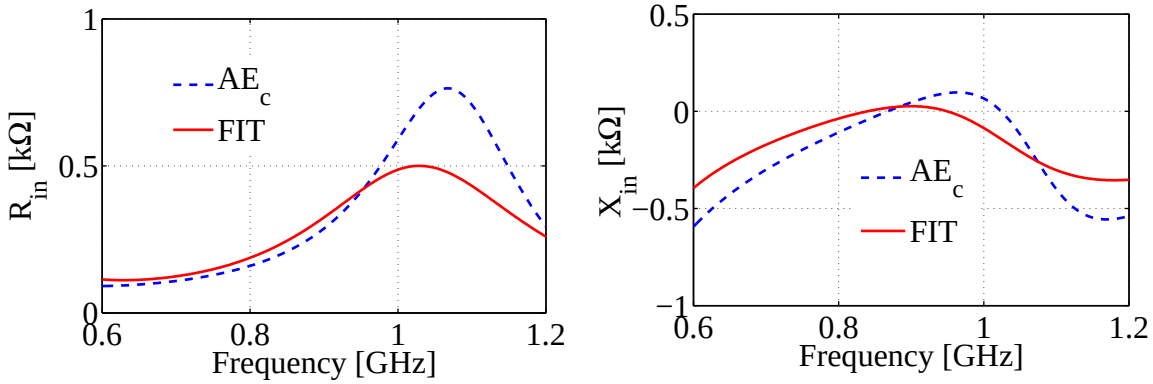


Figure 4.11. Real (a) and imaginary (b) parts of the input impedance versus frequency for the same asymmetric strip folded dipole antenna as analyzed in Fig. 4.9. The correction factor for the transmission line length is introduced in the analytical expressions.

To quantify the improvement of using the correction factor in terms of a single Figure of Merit, Eq.(1.2) is used to transform the deviations into power reflection coefficients. Using the suggested Figure of Merit, the deviations between the input impedance calculated by the FIT and by AE without a correction factor (Fig. 4.9) and when the

correction factor is employed (Fig. 4.11) are casted into a single plot. The higher the deviations between FIT and AE are, the higher the reflection coefficients (FoM) will be.

Figure 4.12 shows the Figure of Merit as a function of frequency for the two simulations. The dashed curve represents the FoM for the uncorrected Analytical Expressions (AE), while the solid curve represents the FoM for the corrected Analytical Expressions (AE_c). It is shown in the figure that, when the correction factor is used, the validity range of the corrected analytical expressions (0.75 GHz - 1.05 GHz) is extended by approximately 50 % compared to a validity range of the uncorrected analytical expressions (0.75 GHz - 0.95 GHz). The validity range is determined by a FoM not exceeding -10 dB. Two more validation examples, one for an antenna resonant at 300 MHz and one for an antenna resonant at 1.5 GHz, are presented in [82], and are shown in Appendix A.

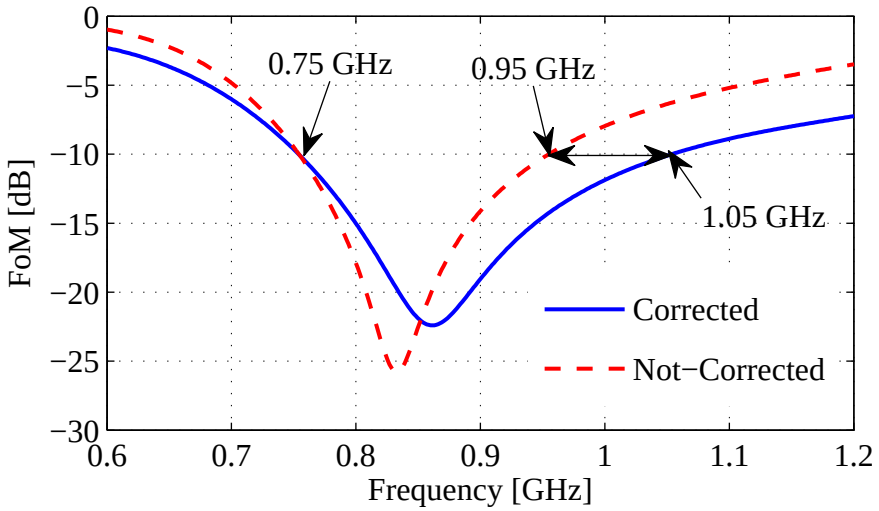

Figure 4.12. FoM as a function of frequency for the AE and corrected AE

The analytical expressions for the folded strip dipole antenna are valid within the range $1.3 \leq \left(\frac{2\pi L}{\lambda}\right) \leq 1.7$ ensuring a FoM $\leq$ -10 dB. The validity range of these expressions is also limited for d, being less than 1/20th of a wavelength.
Although we now have an antenna type with more possibilities to tune its input impedance than a strip dipole antenna, the tuning possibility may still be too limited for a practical use. Moreover, the size of the antenna (about half a wavelength long) might be too large for some applications, especially for Smart Building Integration (SBI). The following section therefore introduces a compact modified rectangular loop antenna.

4.4 Modified Rectangular Loop Antenna

In this section, a novel and compact antenna configuration is introduced to be conjugately matched to the impedance of the rectifier. The antenna is a modified rectangular loop antenna. The modification consists of adding additional arms to control its input impedance. The suggested antenna configuration is shown in Fig. 4.13 and consists of metal printed on a substrate. The radiation characteristics (radiation efficiency and radiation pattern) of the antenna are dictated by the outer antenna length and width L_1 and L_2, respectively, while adding additional arms to the antenna allows tuning its input impedance without affecting the radiation characteristics much. The width of each arm W_1 to W_n and the distance between the arms E_1 to E_n are fine tuned to obtain the exact desired input impedance.

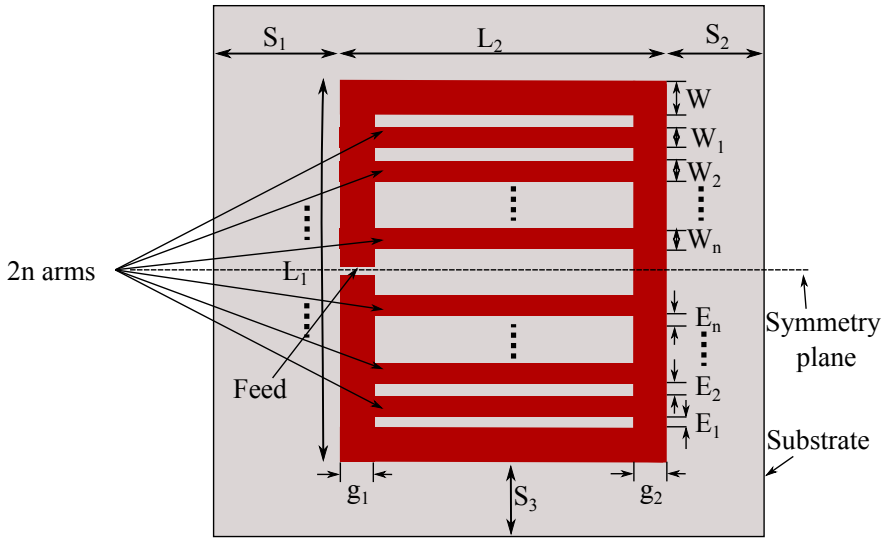

Figure 4.13. Compact antenna topology and dimensional parameters.

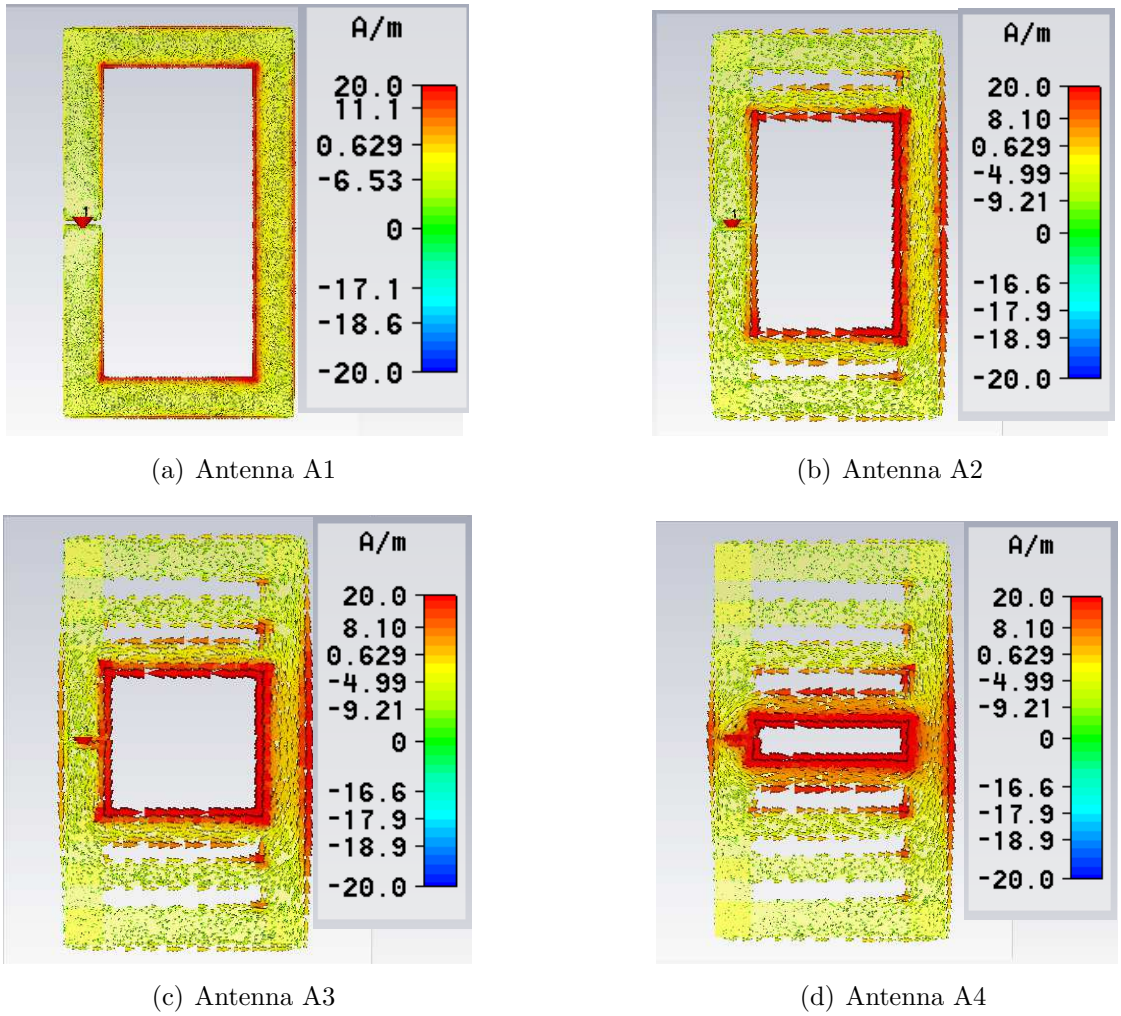
In order to understand the physical behavior of the suggested antenna, CST Microwave Studio is used to simulate the surface current density for four different antenna configurations that possess the same outer dimensions L_1 and L_2 (see Fig. 4.13). The parameters of the four simulated antennas denoted by A1, A2, A3 and A4 are listed in Table. 4.3.

Table 4.3. Antenna parameters used to calculate the input impedance and the radiation efficiency. All dimensions are in millimeters.

W_1, W_2, W_3, E_1, E_2	E_3	W, g_1, g_2	L_2	L_1	S_1	S_2	S_3
3	4	5	32	54	10	7	8

The first simulated antenna (A1) is a loop antenna without any additional arm see Fig. 4.14(a). The outer dimensions of the loop antenna are L_1 and L_2. The width of the strips are W, g_1 and g_2. The second simulated antenna (A2), with $n = 1$, has exactly the same outer dimensions as antenna A1 but with two additional arms added as shown in Fig. 4.14(b). The additional needed parameters to simulate antenna A2 are W_1 and E_1. In the same way the third antenna (A3) and the fourth antenna (A4) are designed and simulated. Antenna (A3) with $n = 2$, possesses the same outer characteristics as antenna A1 but has four additional arms while antenna A4 ($n = 3$) has 6 additional arms compared to antenna A1.



(a) Antenna A1

(b) Antenna A2

(c) Antenna A3

(d) Antenna A4

Figure 4.14. Surface current density on the suggested compact loop antenna for different numbers of additional arms. Frequency = 868 MHz.

Figure 4.14(a) shows the surface current distribution for antenna A1. It is clear from the figure that the surface current density is distributed along the loop. When two

arms are added to antenna A1 to form antenna A2, the maximum current density is concentrated in the inner loop as shown in Fig. 4.14(b). Similarly, when more internal arms are added to the loop, the maximum current density is drawn by the inner loops as shown in Fig. 4.14(c) and Fig. 4.14(d). Using the suggested configuration, the antenna input impedance and its radiation efficiency can be tuned separately. Since the surface current density is concentrated in the inner loop, consequently the inner loop dictates the input impedance of the antenna, while the outer loop dimensions L_1 and L_2 determine the antenna radiation efficiency. The arms between the inner loop and the outer loop are used to fine tune the antenna input impedance.

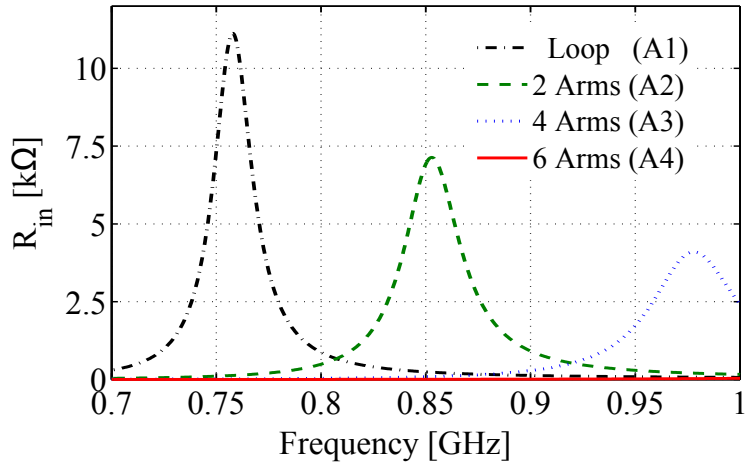
4.4.1 Impedance Tuning Capability

To verify the tuning capability of the suggested antenna configuration, the antenna input impedance and the radiation efficiency are simulated using CST Microwave Studio for the antennas A1, A2, A3 and A4. Figure 4.15 shows the real (a) and imaginary (b) parts of the input impedance as well as the radiation efficiency (c) as a function of frequency for the four simulated antennas. We see, as we expected, that the inner loop dominates the impedance and we see that the resonance shifts toward higher frequencies with the addition of more internal arms. Since the outer arms do draw currents but these currents are much smaller than those in the inner loop, we only observe a slight variation in the radiation efficiency. This demonstrates the impedance-tuning ability of the suggested compact-modified-loop antenna by tuning the variables E_i and W_i, where $i = 1, 2, \cdots, n$, without deteriorating the radiation efficiency of the antenna much. The in-between arms are needed to fine tune the required input impedance.
Table 4.4 summarizes the input impedances and the radiation efficiencies of the four simulated antennas at the design frequency of 868 MHz.

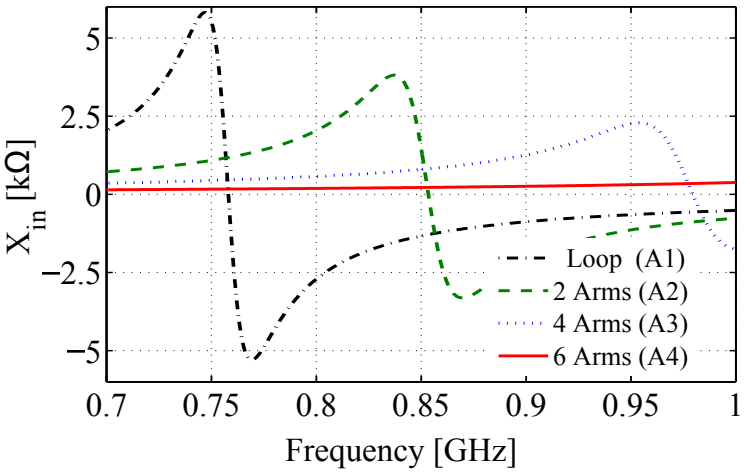
Table 4.4. Simulated input impedance and radiation efficiency at an operating frequency of 868 MHz.

Antenna	A1	A2	A3	A4
$R_{in}(\Omega)$	187.2	3945	129.7	7.08
X_{in} (Ω)	-112.4	-3294	922.3	239.9
$Radiation_{eff}$ (%)	71.51	73.14	74.1	70.7

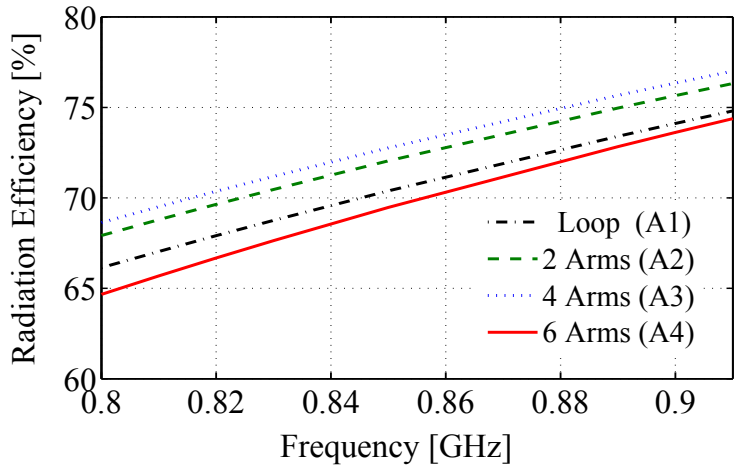
The table shows a large change in the real and imaginary parts of the input impedance when inner arms are added, while the radiation efficiency difference is less than 3.4% over all configurations. In Subsecection 4.4.3 we will further discuss the radiation efficiency simulation results.



(a)



(b)



(c)

Figure 4.15. Real (a) and imaginary (b) parts of the input impedance and the radiation efficiency (c) as a function of frequency of the four simulated antennas.

The main benefits of the suggested novel antenna topology are its compact size ($0.16\lambda \times 0.093\lambda \times 0.0046\lambda$) and the ability to tune its input impedance while maintaining a constant radiation efficiency.

4.4.2 Validation of the Simulation Results

To cross-verify the simulation results two different simulation software packages have been employed: CST Microwave Studio [57] and Empire XCcel [83] that use two different computational methods. CST uses the Finite Integration Technique (FIT) [72] and Empire XCcel uses the Finite Difference Time Domain Method (FDTD) [84]. Antenna A4 (Fig. 4.14(d)) is selected for simulation. The simulated real and imaginary parts of the input impedance are plotted versus frequency in Fig. 4.16. It is shown in the figure that the two different simulation methods converge to almost identical values in the shown frequency range. At a frequency of 868 MHz, the input impedances are found to be: $Z_{in,\,FDTD,\,868\,MHZ} = 8.49 + j237\Omega$ and $Z_{in,\,FIT,\,868\,MHZ} = 7.08 + j239.9\Omega$. The power wave reflection coefficient is calculated using the figure of merit (FoM) introduced in Sec. 1.6. The FoM results in -13.8 dB power reflections at 868 MHz ensuring accurate simulation results.

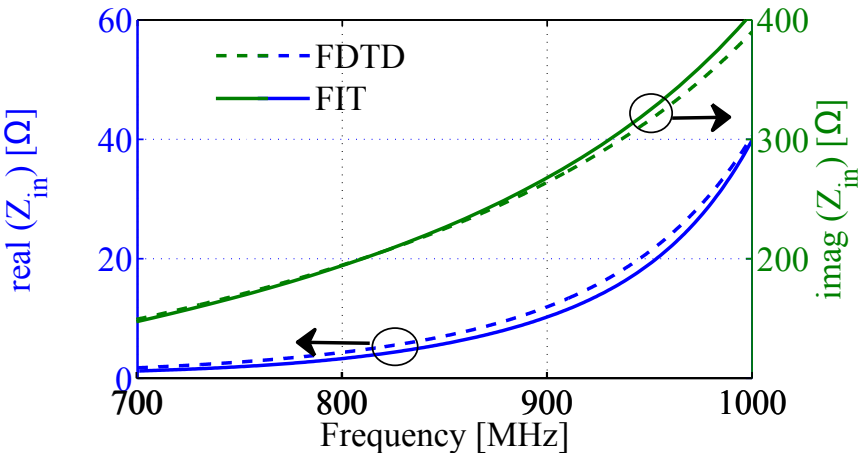


Figure 4.16. Real (a) and imaginary (b) parts of the input impedance as a function of frequency simulated using the Finite Difference Time Domain (FDTD) method and the Finite Integration Technique (FIT).

To verify the simulated results by measurements, a monopole version of the antenna has been fabricated by cutting the antenna through its symmetry plane (see Fig.4.13), and soldering this monopole to a large ground plane as shown in Fig. 4.17. In this way, the antenna can be measured using a single-ended (SMA) connection, which matches with the use of a standard Vector Network Analyser (VNA). The input impedance of the fabricated antenna is measured and compared to the simulated results. Figure 4.18 shows the simulated and measured real (Fig. 4.18(a)) and imaginary (Fig. 4.18(b)) parts

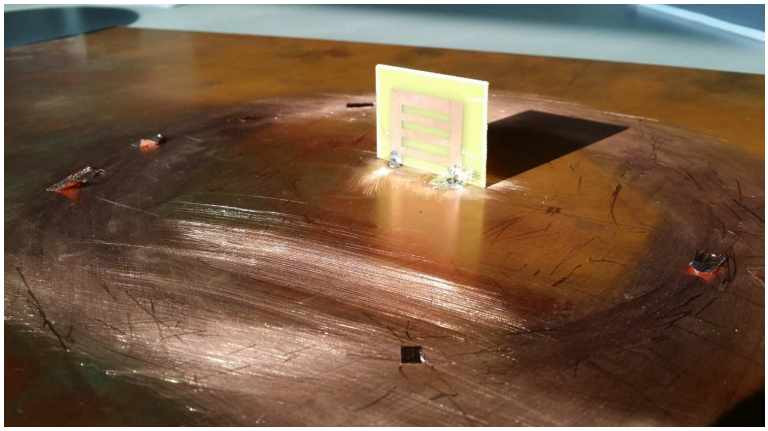

Figure 4.17. Fabricated monopole prototype for impedance measurements.

of the input impedance as a function of frequency. The measured values are multiplied by two to give results that apply for the actual antenna. It is shown in the Figure that the measurement results verify the simulated ones.

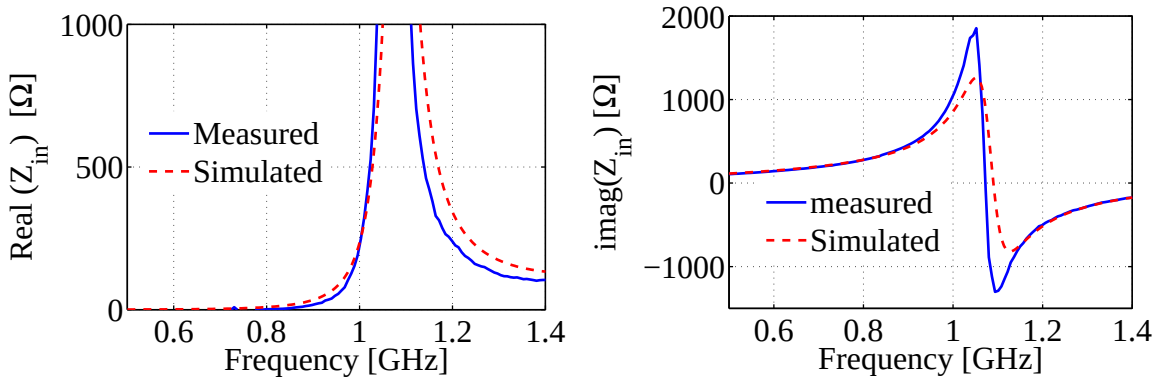

Figure 4.18. Simulated and measured real (a) and imaginary (b) parts of the input impedance of the fabricated prototype antenna versus frequency.

4.4.3 Radiation Efficiency and Radiation Pattern

The antenna radiation efficiency η is defined as [50]:

$$\eta = \frac{R_{rad}}{R_{rad} + R_{loss}}, \tag{4.11}$$

where R_{rad} is the radiation resistance and R_{loss} is the loss resistance.

The Wheeler cap method [85, 86] enables separate measurements of the radiation resistance (R_{rad}) and loss resistance (R_{loss}) by enclosing the antenna with a radiation shield.

The radiation shield is a conducting sphere enclosing the near-field of the antenna at a radius $r = \lambda/2\pi$ [85] as shown in Fig. 4.19(b).
The input impedance of the antenna (Z_{in}) is first measured as indicated in the previous section and illustrated in Fig. 4.19(a).

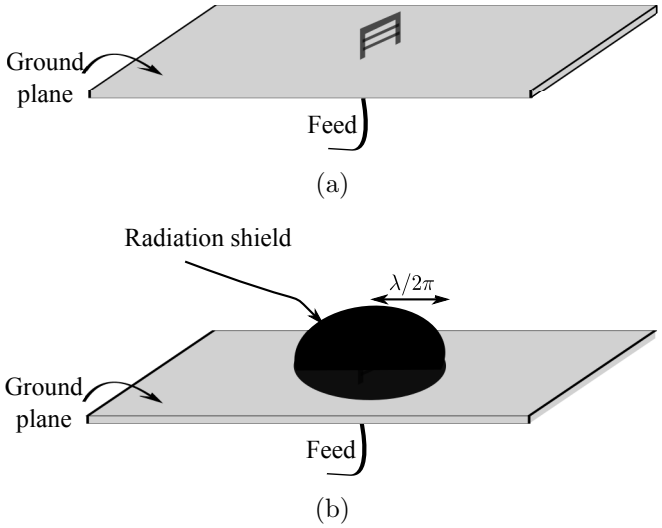

Figure 4.19. Input impedance measurement setup (a) and Wheeler cap measurement setup (b).

The real part of the input impedance is expressed as:

$$Re\{Z_{in}\} = R_{rad} + R_{loss}. \tag{4.12}$$

By placing the radiation shield over the antenna, the radiation resistance (R_{rad}) can be eliminated and consequently the Wheeler cap input impedance (Z_{wc}) can be measured where the real part is expressed as:

$$Re\{Z_{wc}\} = R_{loss}. \tag{4.13}$$

Substituting Eqs. (4.13) and (4.12) in Eq. (4.11), the antenna radiation efficiency is expressed as:

$$\eta = \frac{R_{rad}}{R_{rad} + R_{loss}} = \frac{Re\{Z_{in}\} - Re\{Z_{wc}\}}{Re\{Z_{in}\}} \tag{4.14}$$

The shape of the cap is not critical and need not be spherical [87], [88] and [89]. In this section, a cylindrical cap with a radius of 10.5 cm and a height of 7.5 cm will be used to measure the radiation efficiency of the manufactured prototype. The cylindrical cap

measurement setup is shown in Fig. 4.20. During the measurements, the lid in Fig. 4.20 is placed to enclose the near field of the antenna.

Figure 4.20. Radiation efficiency measurement setup using a cylindrical cap.

The simulated and the measured radiation efficiencies are plotted in Fig. 4.21. It is shown in the figure that the measured results exhibit two major resonances around 1.1 GHz and 1.8 GHz. These resonances are due to the cutoff frequencies of the TM_{01} (1.12 GHz) and TE_{01} (1.78 GHz) propagating modes of the used cylindrical waveguide [80].

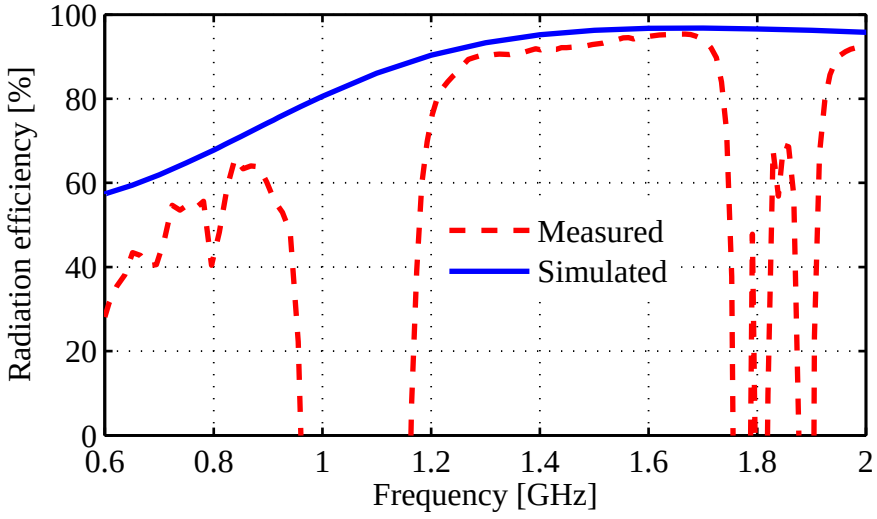

Figure 4.21. Simulated and measured radiation efficiency as a function of frequency using the Finite Integration Technique (simulation) and the Wheeler cap method (measurement).

It should be mentioned that for frequencies below 1 GHz, the height of the cylindrical

cap (7.5 cm) does not satisfy the radian sphere criterion ($r = \lambda/2\pi$) and consequently an extension of the cap height is needed. The cap height is extended by 5 cm using a 5 mm-thick copper plate. The measured radiation efficiency as a function of frequency below 1 GHz using the extended cap is shown in Fig. 4.21. It is clearly indicated in the figure that the deviations between the simulated and the measured radiation efficiencies increase at low frequencies. The deviations are less than 2 % at 1.6 GHz, while they are almost 30% at 0.6 GHz. This behaviour is mainly due to the small value of the input resistance at low frequencies as shown in Fig. 4.16. At low frequencies ($\leq$ 1GHz) accurate small input resistance measurement is quite a challenge due to the imperfections of the calibration standards used which leads to higher deviations in the measured radiation efficiency [90]. Another source of errors at lower frequencies is the non-perfect galvanic contact of the extension of the cylindrical cap.
Excluding the resonant modes of the cylindrical cap, the radiation efficiency has been measured between 1.3 GHz and 1.6 GHz for antennas A1, A2, and A4 (see Fig. 4.14). The simulated and the measured radiation efficiency as a function of frequency are shown in Fig. 4.22. It is indicated in the figure that the deviations between the simulated and the measured radiation efficiency do not exceed 5 % in the measured frequency band. The simulated radiation efficiency has been verified also by employing full-wave Wheeler cap simulations [91].

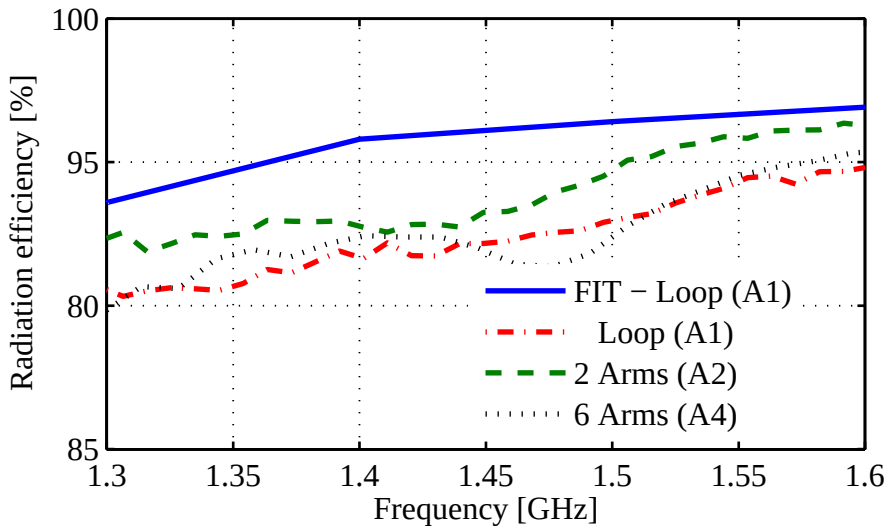

Figure 4.22. Simulated and measured radiation efficiency as a function of frequency for antennas A1, A2 and A4.

The antenna radiation efficiency reaches 70.7 % at the design frequency (868 MHz), see Fig. 4.21. This radiation efficiency can be increased by using a thinner and a lower-loss substrate. The substrate optimization will be presented in the following chapter.

The rectifier is connected on the top side of the antenna, directly to the antenna feeding points, see Fig. 4.23 for the rectifier layout. Figure 4.23 shows the 3D directivity pattern, where the rectifier is placed in the direction of the maximum directivity ($\theta = -90°$, $\phi = 0°$). It is clear from the figure that the layout position of the rectifier does not visibly affect the 3D radiation pattern of the antenna. The directivity D_r and the radiation efficiency $\eta_{radiation}$ determine the antenna gain G_r. $G_r = \eta_{radiation} D_r$, with $D_r = 1.74$ dBi and $\eta_{radiation} = 0.707$, the simulated antenna gain is $G_r = 0.23$ dBi.

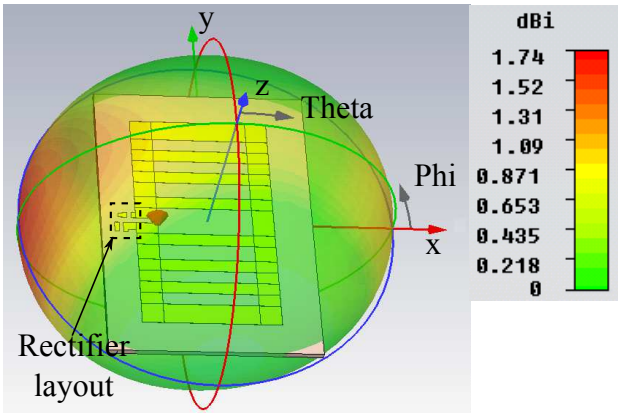

Figure 4.23. 3D directivity pattern at an operating frequency of 868 MHz, simulated using CST Microwave Studio.

As the input impedance of the modified compact loop antenna can be tuned to satisfy the conjugate complex design criterion (i.e. be the complex conjugate of the rectifier input impedance), and the presence of the rectifier does not affect the radiation characteristics of the antenna, this antenna topology will be used in the following chapter to harvest RF power and convert it to usable DC power.

4.5 Conclusion

In this chapter, new design expressions and updated analytical procedures are introduced to calculate the input impedance of strip dipoles and strip folded dipole antennas. The development is driven by the necessity to match the input impedance of the rectifier in a rectenna for maximum power transfer. Simulation and measurement results have shown that the proposed equations satisfy the Figure of Merit criterion and are easily implementable in standard computing tools. Compared to the state-of-the-art analytical solutions, the validity range for the dipole length is extended by 150 % which allows for the modeling of longer strip dipole antennas.
In addition, a novel and compact modified loop antenna configuration has been intro-

duced. The modification consists of adding additional horizontal arms to the loop antenna, which results in a higher degree of freedom to tune the antenna's input impedance. The main advantage of the introduced antenna topology is that the antenna impedance can be tuned without affecting its radiation efficiency much. The simulation results of the input impedance are validated by measurements.

Chapter five

RF Power Transport Using Conjugate-Matched Rectenna System

In this chapter, the modified compact loop antenna introduced in the previous chapter is tuned to eliminate the commonly used matching network between the antenna and the rectifier, since this antenna will be conjugately matched to the rectifier. Two rectenna prototypes are presented in this chapter. The first prototype consists of a rectenna using commercially available, discrete rectifiers. At an incident RF power level of -20 dBm, the Power Conversion Efficiency (PCE) reaches 33.8 % for a resistive load of 10 kΩ. The PCE increases to 54.7 % for a power level of -10 dBm. Compared to the state-of-the-art, the PCE is at least 10 % higher for the same input power levels.
For the second prototype, an integrated 5 stage cross-connected bridge rectifier with a capacitor bank, implemented in standard 90-nm CMOS technology has been used. The PCE reaches 30 % at an input power level of -20 dBm and it increases to 36.6 % at an input power level of -17 dBm over a 0.33 MΩ resistive load. Measurements show a -27 dBm sensitivity for 1 V DC output. At an input power level of -20 dBm, the peak output voltage is measured at an operating frequency of 855 MHz reaching 1.73 V. The suggested prototype is smaller in size than those reported in the literature.

5.1 Introduction

Figure 5.1 shows the configuration of the wireless power transmission system being used in this chapter.

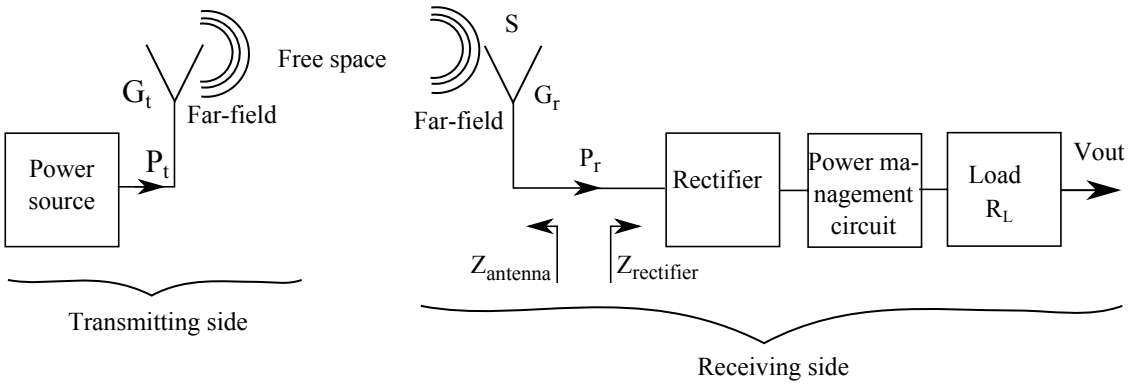

Figure 5.1. Wireless power transmission system.

The system consists of a transmitter that transmits RF power and a receiver that collects part of the transmitted power.
When the transmitter is not dedicated for wireless power transmission, e.g. a TV broadcasting or a GSM base station, the power collection and conversion is defined as wireless power *harvesting* [22], [92]. When the power is intentionally transmitted using a dedicated source, this is defined as wireless power *transport* [93], [94]. For both, the receiving side consists of a *rectenna* (*rec*tifying an*tenna*) which is an antenna connected to a rectifier and a load. The load can be an ultra-low power sensor. A power management circuit between the rectifier and the load is needed to transfer and store the DC power. In order to achieve a compact rectenna system, the commonly employed impedance matching network between the antenna and the rectifier is removed as shown in Fig. 5.1 and the antenna is conjugately matched to the rectifier ($Z_{antenna} = Z^*_{rectifier}$). The compact antenna configuration introduced in the previous chapter is used to capture part of the transmitted RF power.

5.2 Design Methodology

In this section[1], a design methodology is presented to optimize the power transfer between the antenna and the rectifier [95]. The optimal impedance matching network with

[1]This section is based on the work by Hubregt J. Visser that is published in [95]. For the completeness of the work, this section is included in the thesis.

respect to power efficiency, rectifier input voltage maximization and rectifier sensitivity improvement is investigated. It should be mentioned that the impedance matching may be accomplished by a (discrete) lumped-element matching network and by a distributed network integrated into the antenna. Figure 5.2 shows the equivalent circuit model of a generalized rectenna system.

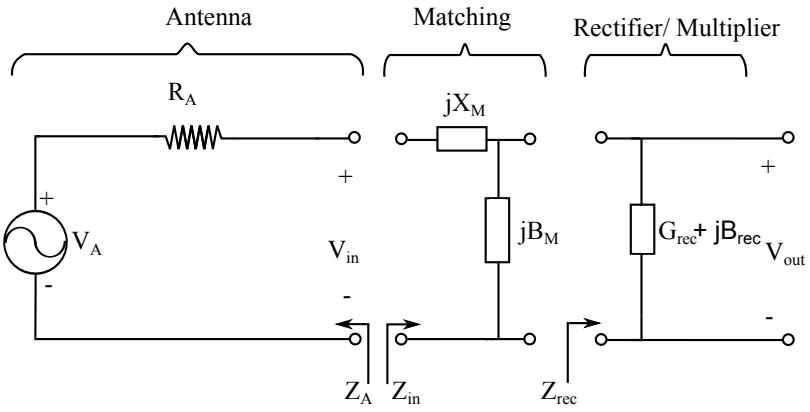

Figure 5.2. Equivalent circuit model of a rectenna system.

The antenna in the figure is represented by its Thévenin equivalent circuit of a voltage source $\mathrm{V_A}$, with an internal resistance R_A. The Thévenin equivalent voltage V_A is:

$$V_A = \sqrt{8 R_A P_{in}}, \tag{5.1}$$

where P_{in} is the maximum power available at the clamps of the antenna.

For the generalized rectenna system shown in Fig. 5.2, an 'L-network' impedance matching is introduced between the antenna and the rectifier/multiplier.
The input power P_{in} at the input of the matching network is described as

$$P_{in} = \frac{1}{2} |V_{in}|^2 \, \Re \{Y_{in}\}, \tag{5.2}$$

where $Y_{in} = \frac{1}{Z_{in}}$ is the input admittance as indicated in Fig. 5.2. The function $\Re\{x\}$ denotes the real part of x. V_{in} is the voltage across the input impedance Z_{in} see Fig. 5.2. V_{in} is calculated as

$$V_{in} = \left(\frac{Z_{in}}{Z_{in} + R_A} \right) V_A = \left(\frac{1}{1 + Y_{in} R_A} \right) V_A. \tag{5.3}$$

Substituting Eq. (5.3) in Eq. (5.2) results in

$$P_{in} = \frac{1}{2}\left|\frac{1}{1+Y_{in}R_A}\right|^2 V_A^2 \Re\left\{Y_{in}\right\}. \tag{5.4}$$

The output power P_{out} across the rectifier terminals is given by

$$P_{out} = \frac{1}{2}\left|V_{out}\right|^2 \Re\left\{Y_{rec}\right\}, \tag{5.5}$$

where Y_{rec} is the input admittance of the rectifier $Y_{rec} = G_{rec} + jB_{rec} = \frac{1}{Z_{rec}}$ and V_{out} is the output voltage across the rectifier terminals. V_{out} and Z_{rec} are indicated in Fig. 5.2.

5.2.1 Antenna Matched to the Rectifier

The 'L-network' shown in Fig. 5.2 is used to conjugately match the antenna impedance to that of the rectifier. If a lossless network is assumed, the output power P_{out} is equal to input power P_{in} and, consequently, the voltage gain G_v is given by

$$G_v = \frac{|V_{out}|}{|V_A|} = \frac{1}{2}\sqrt{\frac{\Re\left\{Y_{in}\right\}}{\Re\left\{Y_{rec}\right\}}}. \tag{5.6}$$

The input impedance Z_{in} is calculated using the network model shown in Fig. 5.2 as

$$\begin{aligned} Z_{in} &= jX_M + \frac{1}{G_{rec} + j\left(B_M + B_{rec}\right)} \\ &= \frac{G_{rec}}{G_{rec}^2 + \left(B_M + B_{rec}\right)^2} + j\left(X_M - \frac{B_M + B_{rec}}{G_{rec}^2 + \left(B_M + B_{rec}\right)^2}\right). \end{aligned} \tag{5.7}$$

In order to conjugately match the antenna to the rectifier, the following conditions apply

$$R_A = \frac{G_{rec}}{G_{rec}^2 + \left(B_M + B_{rec}\right)^2}, \tag{5.8}$$

$$X_M = \frac{B_M + B_{rec}}{G_{rec}^2 + \left(B_M + B_{rec}\right)^2}. \tag{5.9}$$

From Eqs. (5.7) and (5.9), the real part of the input admittance is calculated as

$$\Re\{Y_{in}\} = \frac{G_{rec}^2 + (B_M + B_{rec})^2}{G_{rec}}, \tag{5.10}$$

and, since $Y_{rec} = G_{rec} + jB_{rec}$, the real part of the rectifier's admittance is

$$\Re\{Y_{rec}\} = G_{rec}. \tag{5.11}$$

Substituting Eq. (5.10) and Eq. (5.11) in Eq. (5.6) leads to the voltage gain

$$G_v = \frac{|V_{out}|}{|V_A|} = \frac{1}{2}\sqrt{\frac{\Re\{Y_{in}\}}{\Re\{Y_{rec}\}}} = \frac{1}{2}\sqrt{1 + \left(\frac{B_M + B_{rec}}{G_{rec}}\right)^2} = \frac{1}{2}\sqrt{1 + (Q)^2}, \tag{5.12}$$

where $Q = \frac{B_M + B_{rec}}{G_{rec}}$ is the quality factor at the output of the matching circuit.

G_{rec} and B_{rec} are defined by the rectifier's impedance. Eq. (5.12) leaves the impression that, by a proper choice of the matching network susceptance B_M, one can choose the output voltage V_{out} and then design the antenna having an impedance R_A and take X_M as dictated by Eq. (5.8) and Eq. (5.9), respectively.

The error made in this reasoning is that it is implicitly assumed that V_A and R_A can be chosen independently, while in fact they are related through the available power from the antenna as specified in Eq. (5.1).

5.2.2 Maximizing the Output Voltage

Assuming a lossless network, one can express the available power from the antenna by using Eq. (5.1)

$$P_{in} = \frac{V_A^2}{8R_A}. \tag{5.13}$$

By the substitution of Eq. (5.8) in Eq. (5.13), V_A is expressed as

$$V_A = \sqrt{8R_A P_{in}} = 2\sqrt{2P_{in}\frac{G_{rec}}{G_{rec}^2 + (B_M + B_{rec})^2}}. \tag{5.14}$$

The output voltage is calculated by substituting Eq. (5.14) in Eq. (5.12), which results in

$$V_{out} = G_v V_A = \sqrt{\frac{2P_{in}}{G_{rec}}}. \tag{5.15}$$

As described in Eq. (5.15), the output voltage is thus dictated by the available power from the antenna and the real part of the input admittance of the rectifer/multiplier.

G_{rec} is the real part of the rectifier admittance as shown in Fig. 5.2.

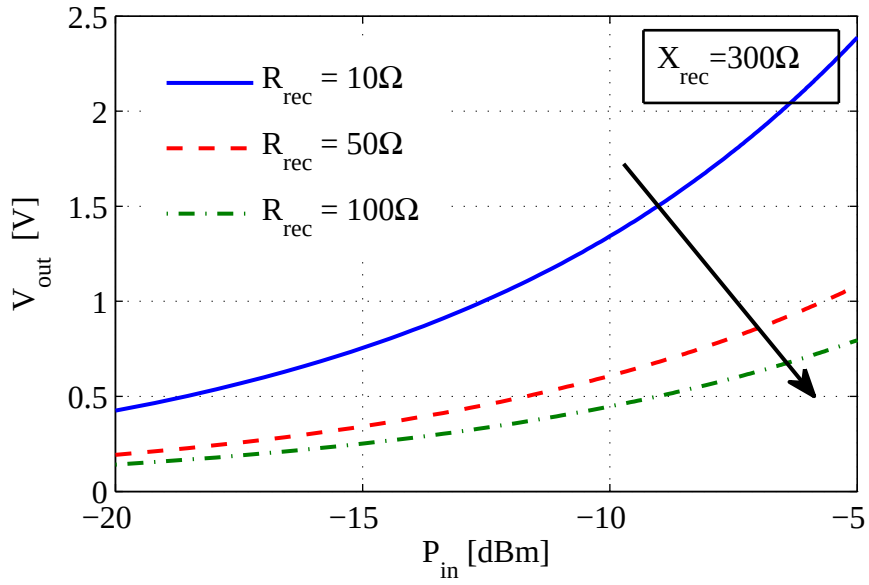
$$\begin{aligned} G_{rec} &= \Re\{Y_{rec}\} \\ &= \frac{R_{rec}}{R_{rec}^2 + X_{rec}^2}. \end{aligned} \tag{5.16}$$

After substituting Eq. (5.16) in Eq. (5.15), the output voltage is described in terms of the input impedance of the rectifier as follows:

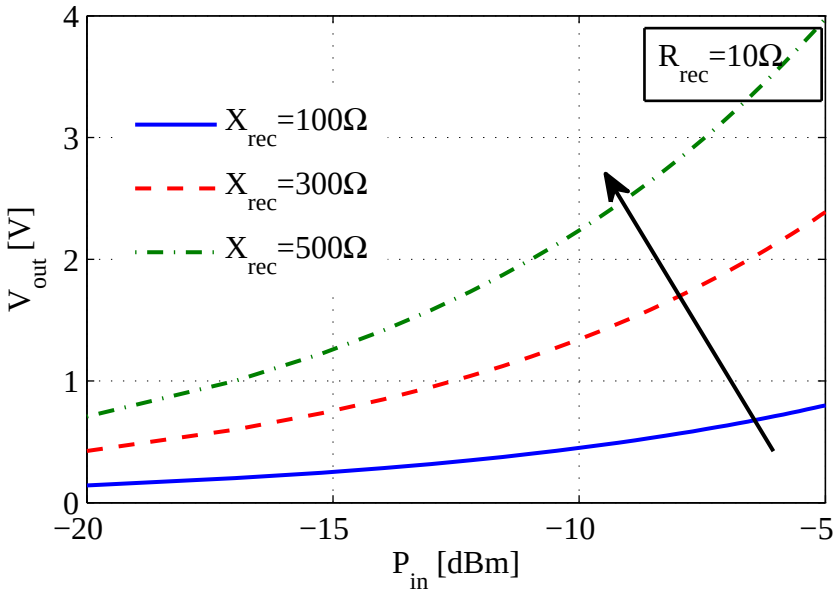
$$V_{out} = \sqrt{2P_{in}\frac{R_{rec}^2 + X_{rec}^2}{R_{rec}}}. \tag{5.17}$$

To maximize the output voltage V_{out} (i.e. the sensitivity) and the power transfer between the antenna and the rectifier, Eq. (5.17) should be satisfied. The real part of the input impedance should be as high as possible while the imaginary part should be as low as possible or the other way around. Since most Schottky diodes show an input impedance having a low resistance in series with a high capacitance we choose for the latter method. Figure 5.3 shows the DC output voltage for different input power levels for different rectifier impedances following Eq. (5.17). Figure 5.3(a) shows the output voltage for different values of the real part of the rectifier impedance while the rectifier reactance is set to 300 Ω. Figure 5.3(b) shows the output voltage for different values of the imaginary part of the rectifier impedance while the rectifier resistance is set to 10 Ω.

It is clear from the figure that when $X_{rec} \gg R_{rec}$, the voltage decreases with increasing real part of the rectifier's input impedance. A voltage of 0.5 V is generated at an available power level of -9 dBm (dotted-dashed curve) when R_{rec} is set to 100 Ω. The same output voltage is generated at an available power level of -18.5 dBm (solid curve) when R_{rec} is decreased to 10 Ω, which results in a 8.5 dB sensitivity improvement. Figure 5.3(b) clearly indicates that the output voltage increases with increasing reactive part of the input impedance when the real part is set to 10 Ω.



(a)



(b)

Figure 5.3. Output voltage for different input power levels P_{in} for different rectifier impedances. (a) $X_{rec} = 300\Omega$, (b) $R_{rec} = 10\Omega$.

A voltage of 0.7 V is generated at an available power level of -6 dBm (solid curve) when X_{rec} is set to 100 Ω. The same output voltage is generated at an available power level of -20 dBm (dotted-dashed curve) when X_{rec} is increased to 500 Ω, which results in a 14 dB sensitivity improvement. This knowledge will be used in Sec. 5.4 where a 5 stages rectifier implemented in TSMC 90-nm CMOS technology with an input impedance of

$Z_{in} = 7.6 + j418$ has been designed, realized and measured.

Through the presented analysis and our results for a compact loop antenna, it has been shown that the steps to maximize the output voltage and thus improve the rectifier's sensitivity for a given low power level are:

- conjugate match the antenna to the rectifier;
- design the rectifier circuit for a minimum real part and maximum absolute value of the imaginary part $|X_{rec}| \gg R_{rec}$;
- use antenna miniaturization up to a level that the radiation resistance still dominates the loss resistance;
- use a small loop antenna as a basis.

5.3 Power Transport Using Commercially Available Diodes

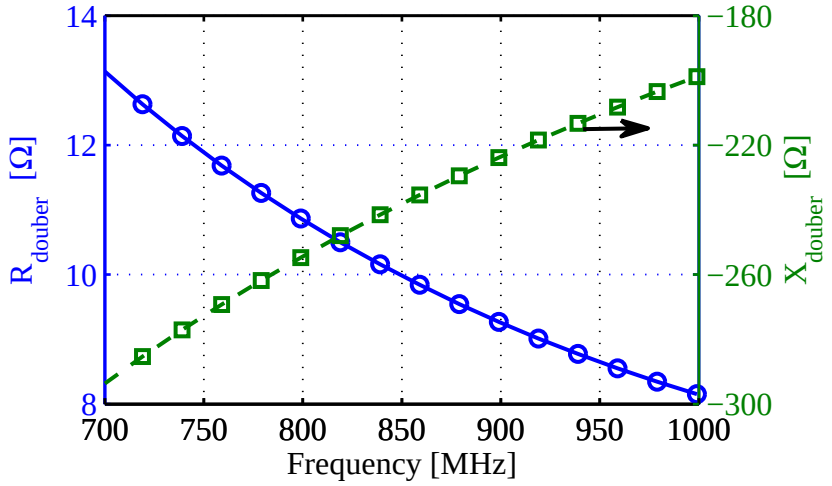
In this section, the modified loop antenna introduced in the previous chapter is combined with commercially available diodes. A voltage doubler rectifier is used. The output voltage is measured for different input power levels at an operating frequency of 868 MHz.

5.3.1 Rectenna Design

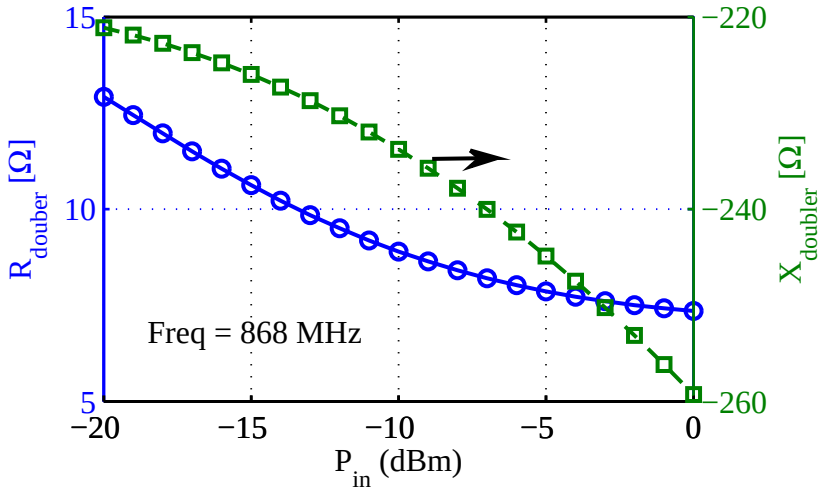
The design frequency and the design input power level have been investigated in Sec. 2.7.1 and Sec. 2.7.2, respectively. The output voltage and the input impedance of a single rectifier (Schottky diode) have been investigated in [41] and have been presented in Chapter 2. In this section we will investigate the input impedance of the voltage doubler (see Fig. 3.21) as a function of frequency for different RF input power levels. The main reason to choose a voltage doubler is that it provides a higher DC output voltage than the single rectifier and it eliminates the need for a return-current coil. In addition, it provides a compact size due to the commercially available double-packaged-diodes. ADS harmonic balance and Momentum [44] have been used for simulations.

For a voltage doubler circuit made with an Avago HSMS-2852 [43] Schottky-diode pair, the input impedance is calculated as a function of frequency and as a function of input power level. Figures 5.4(a) and 5.4(b) show the real and imaginary parts of the input impedance as a function of frequency and as a function of input power level, respectively. For Fig. 5.4(a), the input power level is set to -10 dBm while for Fig. 5.4(b) the operating frequency is 868 MHz. It is observed in the figure that the

impedance of the voltage doubler changes as a function of frequency and as a function of input power level. At the design frequency (868 MHz) and input power level (-10 dBm) the input impedance of the voltage doubler is $Z_{doubler} = 8.9 - j234\,\Omega$.



(a)



(b)

Figure 5.4. Simulated real and imaginary parts of the input impedance of the voltage doubler based on the AVAGO HSMS-2852 as a function of frequency for an input power level of -10 dBm (a) and as a function of input power level at an operating frequency of 868 MHz (b).

The modified compact loop antenna introduced in the previous chapter is tuned, so that its input impedance is equal to the conjugate complex of that of the voltage

doubler, at an input power level of -10 dBm, and an operating frequency of 868 MHz. Figure 5.5 shows the real (a) and imaginary parts of the input impedance as a function of frequency for the voltage doubler and for antenna A4 introduced in Sec. 4.4. It is shown in the figure that the real parts of the input impedance for the antenna and the rectifier intersect around 868 MHz. The imaginary parts of the input impedance for the antenna and the voltage doubler are plotted in Fig. 5.5(b). It is indicated in the figure that $\mathrm{imag}(\mathrm{Z_{rectifer}}) = -\mathrm{imag}(\mathrm{Z_{antenna}})$ around 868 MHz.

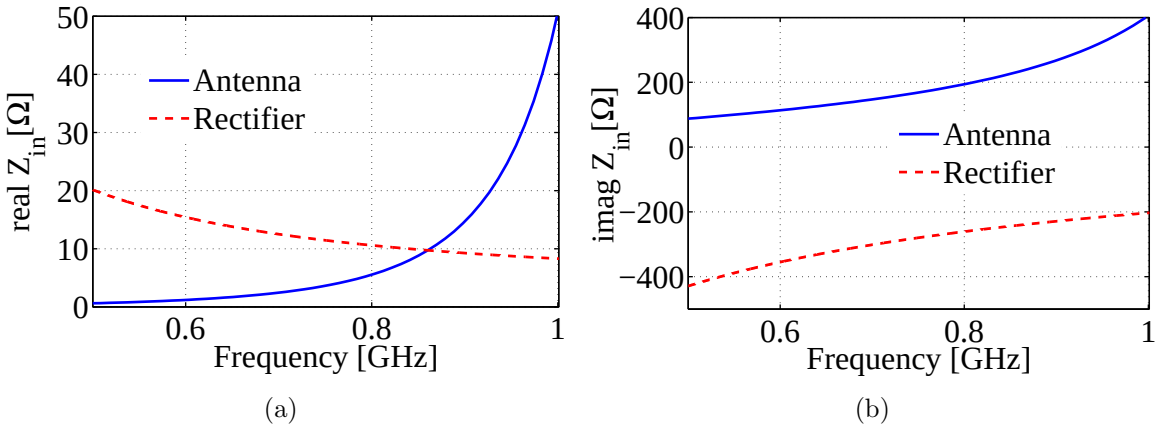


Figure 5.5. Simulated real (a) and imaginary (b) parts of the input impedance of the voltage doubler as well as the antenna as a function of frequency, for P_{in}= -10 dBm.

To investigate the complex conjugate matching, the power wave reflection coefficient concept [34] [51] introduced in Sec. 1.6 is used to calculate the power reflection coefficient between the input impedance of the rectifier and the input impedance of the antenna.

$$\mathrm{FoM} = 20\log\left|\frac{\mathrm{Z_{rectifier}} - \mathrm{Z^{*}_{antenna}}}{\mathrm{Z_{rectifier}} + \mathrm{Z_{antenna}}}\right|, \tag{5.18}$$

where * denotes the complex conjugate of the input impedance. Figure 5.6 shows the power wave reflection coefficient (FoM) as a function of frequency calculated using Eq. 5.18. The figure shows that the antenna is matched to the rectifier with $S_{11} = -16$ dB at the design frequency 868 MHz.
At the design frequency (868 MHz) and at the design input power level (-10 dBm), the input impedance of the voltage doubler is conjugately matched to that of the antenna, which results in a power wave reflection coefficients of -16 dB as indicated in Fig. 5.6. A first rectenna prototype is realized on a 1.6 mm thick FR4 substrate. A photograph of the fabricated rectenna is shown in Fig. 5.7.

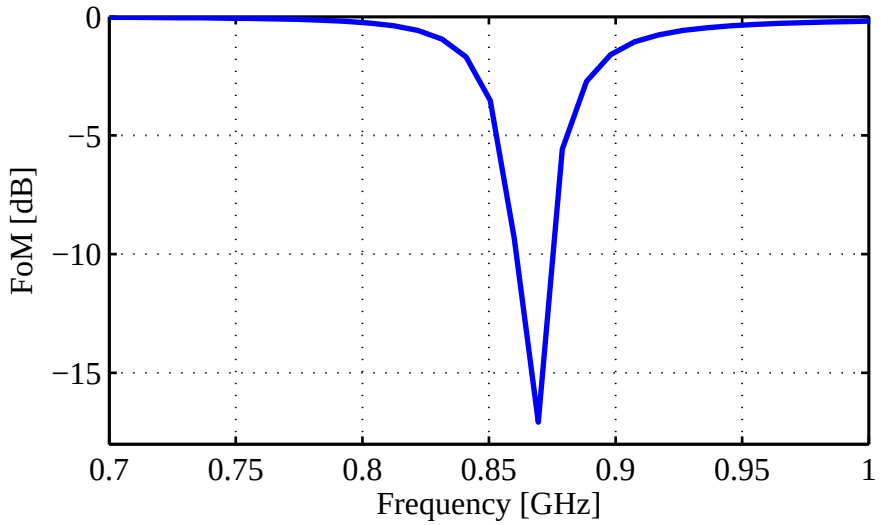

Figure 5.6. Power wave reflection coefficient as a function of frequency calculated using the input impedance of the voltage doubler and the input input impedance of the antenna.

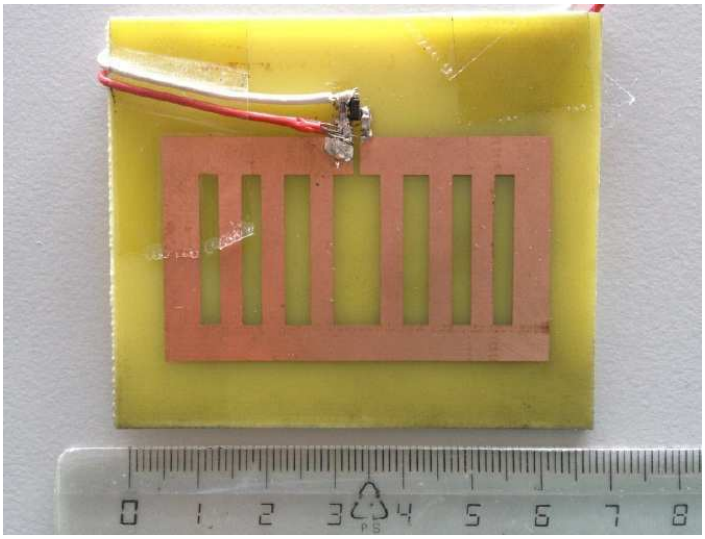

Figure 5.7. Photograph of the fabricated rectenna.

5.3.2 RF Power Transport Measurement Results

For RF power transport, a system as shown in Fig. 3.1 is being used. In this section, we describe how the rectenna is used for wireless RF power transfer. The power transfer measurement setup is shown in Fig. 5.8. The setup is calibrated using two antennas with a known gain, G_r and G_t (see Fig. 5.8), at 868 MHz separated by a distance R.

R is chosen to ensure that far-field conditions are satisfied for both antennas. The power density (S) at the receiving side is dictated by the effective isotropic radiated power, $EIRP = P_t G_t$, where P_t is the transmitted power and G_t is the transmit antenna gain, and by the distance R between the transmitting and the receiving antennas.

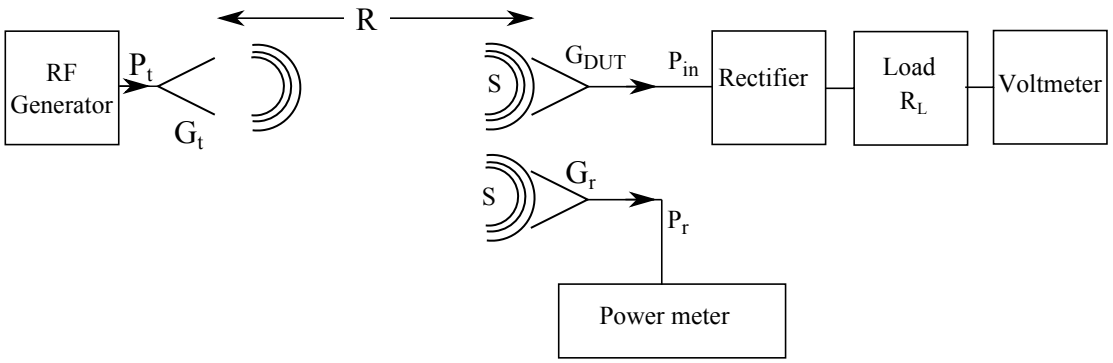

Figure 5.8. Power transfer measurement system.

Using the same procedures as introduced in Sec. 3.7.2 in Chapter 3, the received power at the terminals of the power meter is expressed as

$$P_r = P_t G_t G_r \left(\frac{\lambda_0}{4\pi R}\right)^2 = P_t G_t G_r \left(\frac{c}{4\pi f_0 R}\right)^2, \tag{5.19}$$

where c is the free-space speed of light and f_0 is the operating frequency of the transmitted signal. A power meter is used to measure the received RF power P_r. The measured power P_r is compared to the theoretically calculated value based on Eq. (5.19). The measured power appeared to be within ± 0.5 dB agreement with the theoretically calculated power, which ensures an accurate measurement setup. The rectenna is then placed at the position of the test receiving antenna for wireless power transport. The antenna gain of the rectenna is denoted by G_{DUT} as shown in Fig. 5.8. The input power level Pin at the clamps of the rectifier (see Fig. 5.8) is then calculated as

$$P_{in} = \frac{P_r G_{DUT}}{G_r}. \tag{5.20}$$

The receiving rectenna system is connected to a variable load resistor R_L. The DC output voltage is measured using a voltmeter for different load resistances and for different input power levels using a voltmeter.

The antenna of the receiving rectenna system shown in Fig. 5.8 consists of the modified loop antenna shown in Fig. 5.7. This antenna is connected to the rectifier having a variable load resistor R_L. The DC output voltage is measured for different load resistances

at three different input power levels -20 dBm, -10 dBm and -5 dBm calculated according to Eq. (5.20).

The output voltage is first measured as a function of frequency at an input power level P_{in} (see Fig.5.8) of -10 dBm where a 1 MΩ load resistance is used to terminate the rectenna. Figure 5.9 shows the measured output voltage versus frequency. It is clear from the measurement results that the system output voltage peaks at 868 MHz and reaches 1.36 V. Centered at 868 MHz, the -3dB voltage bandwidth is approximately 30 MHz as indicated in the same figure.

The Power Conversion Efficiency (PCE) is calculated as:

$$\mathrm{PCE}\,(\%) = \frac{P_{load}}{P_{in}} = \frac{V_{out}^2}{R_L}\frac{1}{P_{in}}. \tag{5.21}$$

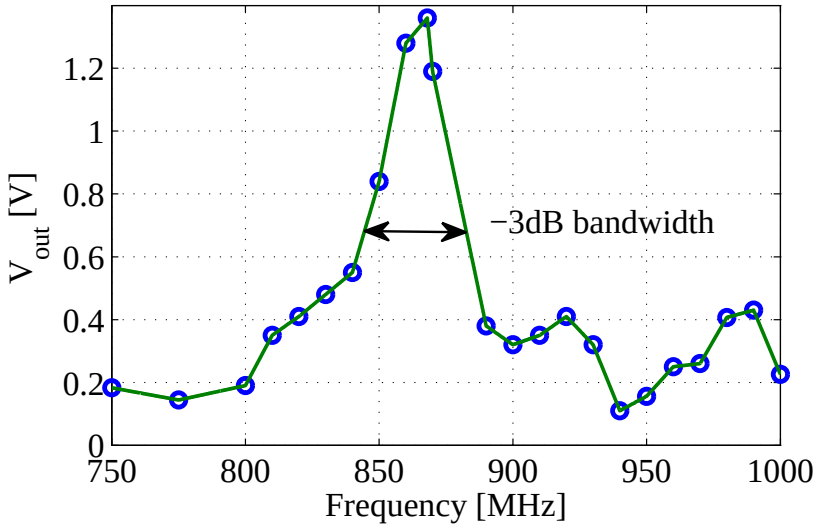

Figure 5.9. Measured output voltage (V_{out}) over a 1 MΩ load resistance as a function of frequency at an input power level P_{in} of -10 dBm.

To measure the power conversion efficiency (PCE), the output voltage is measured over different load resistances and for different input power levels; the results are shown in Fig. 5.10. Over a 10 kΩ resistive load, the DC output voltage reaches 0.19 V at an input power level of -20 dBm. V_{out} increases to 0.76 V and 1.41 V at an input power level of -10 dBm and -5 dBm, respectively.

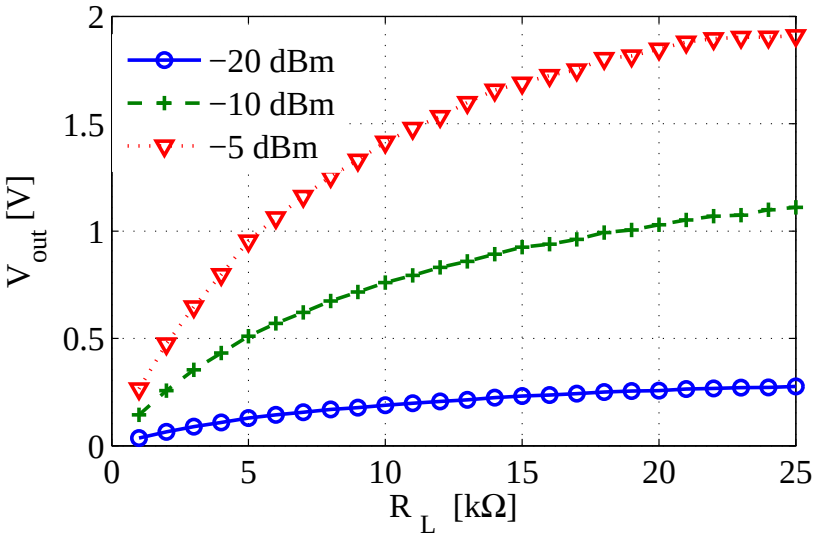

Figure 5.10. Measured output voltage (V_{out}) for different input power levels (P_{in}) versus R_L.

Figure 5.11 shows the measured PCE as a function of R_L for different input power levels (P_{in}) at the design frequency, 868 MHz.

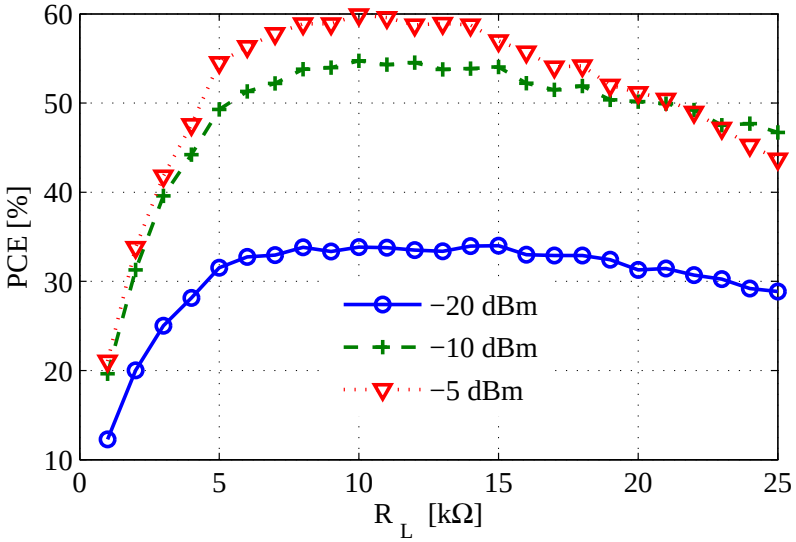

Figure 5.11. Measured power conversion efficiency (PCE) for different input power levels (P_{in}) versus R_L.

At an input power level of -20 dBm, the PCE reaches 33.8 % for a resistive load for 10 kΩ. For the same load resistance, the PCE increases to 54.7 % and 60 % at an input power level of -10 dBm, and -5 dBm, respectively.

Table 5.1 gives a short overview of the state of the art reported for rectennas in the literature that use commercially available rectifiers for RF to DC power conversion.

Table 5.1. Overview of rectenna performances from literature.

Reference	Pin [dBm]	Frequency [MHz]	Load R_L [Ω]	$\frac{Size}{\lambda^2}$	Power Conversion Efficiency (PCE)
[19]	-10 -20	1800	2.4×10^3	-	38*% 15*%
[67]	-10	830	1×10^7	0.027	44 %
[96]	-20	550	2×10^3	0.035	18* %
[20]	0*	1960	460	0.192	54 %
This work	-10 -20	868	10×10^3	0.028	54.7% 33.8%

*calculated from figure

Compared to [67], where a 4 stage rectifier has been used, the presented rectenna in this paper is more efficient at the same input power level and has approximately the same size. At an input power level of -20 dBm, the measured PCE in [96] is 18 %. At the same input power level, the measured PCE of the rectenna presented in this paper reaches 34%. When compared to the measured PCE in [20], our rectenna shows approximately the same performance at an input power level that is 10 times lower. In addition, the rectenna in this chapter is more than five times as compact and operates at a lower frequency. Thus, through a co-design of the antenna and the rectifier, we are able to significantly improve the performance compared to the state of the art.

5.4 Five Stage CMOS Rectifier with a Control Loop

In the previous section a voltage doubler using commercially available diodes has been used to convert the RF incident power into DC power. To further increase the output voltage, a 5 stage rectifier[2] implemented in TSMC 90-nm CMOS technology is designed and realized and the rectifier output voltage and sensitivity are measured.

5.4.1 Design and Implementation

The CMOS rectifier to be presented has been first introduced in [98] and is optimized to harvest power at low input power levels, around -20 dBm. Fig. 5.12 shows the principle

[2]This section is the result of the cooperation between Holst Centre/imec and Delft University of Technical (TUD). The 5 stage CMOS rectifier with the control loop was designed, developed and realized by Mark Stoopman from TUD. The antenna design as well as the connector layout are realized by Shady Keyrouz from TU/e. The reported results in this section are published in [97].

of the multi-stage RF harvester as introduced in [98].

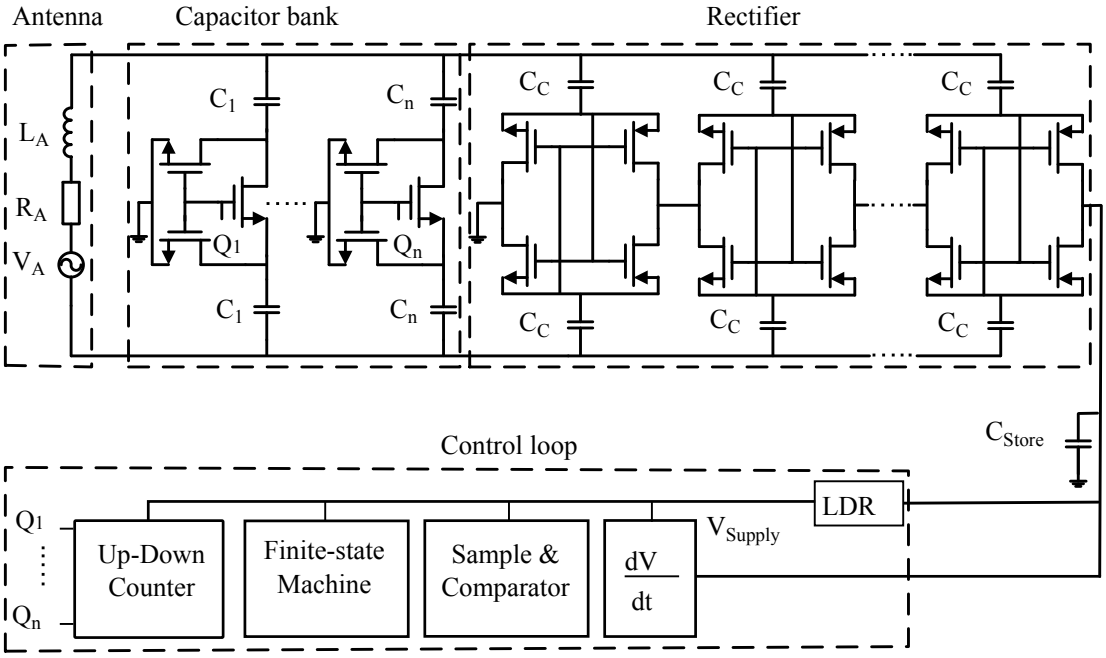

Figure 5.12. Muli-stage RF harvester implemented using CMOS technology.

The harvester consists of a 5 stage cross-connected bridge rectifier. For maximizing the output voltage, the rectifier is connected to a purely capacitive load C_{Store}. A control loop is added to maximize the output voltage on the capacitive load by tuning the reactive part of the rectifier's input impedance such that it is conjugately matched to the antenna. The antenna is connected to a capacitor bank that is controlled by an up-down counter. The 7-bit capacitor bank consists of 128 capacitor switches where C_{max} = 256 fF and C_{min} = 116 fF. By using the control loop, the input impedance of the rectifier as seen from the antenna can be tuned between C_{min} and C_{max} to be conjugately matched to that of the antenna, provided that the real parts of the antenna and rectifier are identical.

The control loop implementation in combination with the multi-stage rectifier is also shown in Fig. 5.12. The harvester initially charges the storage capacitor to the turn-on voltage of the control loop. Then the energy transfer to the off-chip capacitor (C_{Store}) is optimized by maximizing the slope of the load voltage. The slope information is obtained by using a differentiating network. Then the slope information is compared with the previous sample using the sample and comparator stage that determines whether the slope has increased or decreased. Consequently, the finite-state machine determines if the up-down counter should keep counting or change the count direction.

In this realized first prototype, the control loop is implemented off chip by using a micro-

controller. Once the loop is calibrated, it can be turned off so that it is not loading the rectifier for very low input power levels. The input impedance seen from the antenna is found to be $Z_{in,0} = 7.6 - j418\,\Omega$ for C_{min} and $Z_{in,1} = 4.3 - j310\,\Omega$ for C_{max}. This self-calibrating RF rectifier has been implemented in [39] where the rectifier was printed on a FR4 substrate connected to the modified square loop antenna introduced in the previous chapter. In this section, the substrate material and the substrate thickness are optimized for maximum antenna radiation efficiency. A prototype realized on a low-loss and thin substrate will be presented.

5.4.2 Antenna Optimization and Chip Integration

The same antenna topology as introduced in Sec. 4.4 is used for realizing a rectenna based on the just discussed rectifier. In this design the antenna reactance part $X_{Antenna}$, should be between 310 Ω and 418 Ω. Then, the control loop will optimize the rectifier impedance to be conjugately matched to the antenna. The real part should be a fixed value between 4.3 Ω and 7.6 Ω. So an exact, critical value of the reactive part of the antenna impedance is not required. This gives another degree of freedom in maximizing the antenna radiation efficiency.
The antenna radiation efficiency is improved by choosing a thin and a low-loss substrate instead of the so far used lossy FR4 PCB material. Figure 5.13 shows the simulated antenna radiation efficiency versus frequency for different substrate materials for the structure shown in Fig. 5.15.

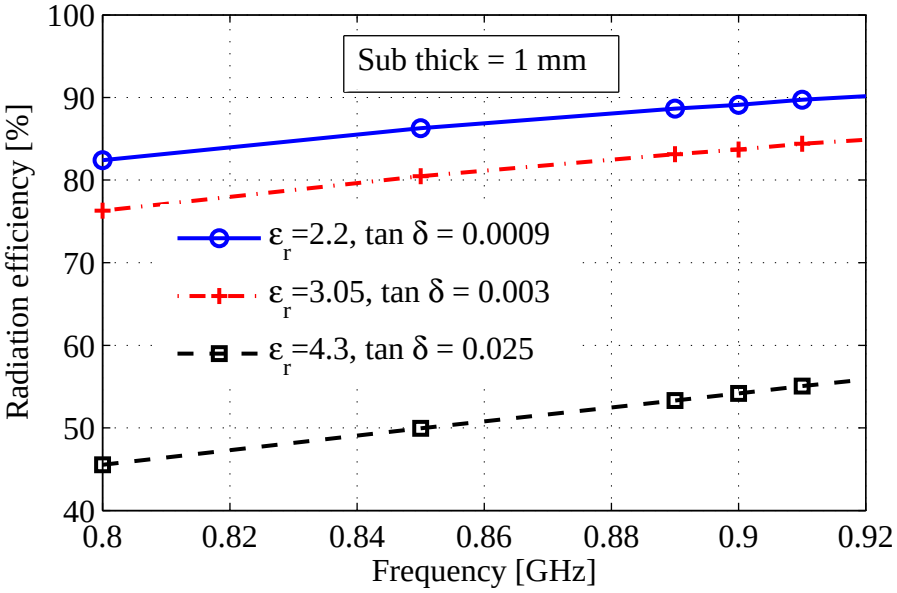

Figure 5.13. Antenna radiation efficiency versus frequency for different substrate materials. Substrate thickness is 1 mm.

In this Figure the substrate height is set to 1mm and the radiation efficiency is simulated for three different substrate materials, FR4 dashed curve ($\epsilon_r = 4.3$, $\tan\delta = 0.025$), GML 1000 dashed-dotted curve ($\epsilon_r = 3.05$, $\tan\delta = 0.003$) and Rogers RT-5880 solid curve ($\epsilon_r = 2.2$, $\tan\delta = 0.0009$). It should be mentioned that the antenna size is kept constant for the three simulations. It is shown in the figure that the radiation efficiency increases when the substrate loss ($\tan\delta$) decreases.

Figure 5.14 shows the antenna radiation efficiency as a function of frequency for varying substrate thickness. In this figure the substrate material is chosen to be GML 1000. The figure shows that a thinner substrate has a limited effect on the radiation efficiency and will result in a slightly higher radiation efficiency. The antenna radiation efficiency is improved by less than 4% when choosing a 0.5 mm thick substrate instead of a 1.5 mm thick substrate.

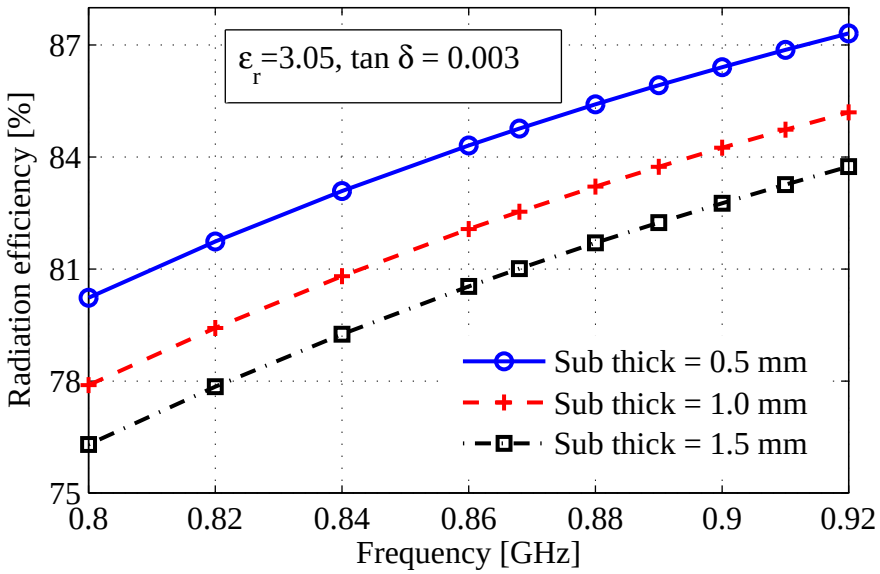

Figure 5.14. Antenna radiation efficiency as a function of frequency for different substrate thickness.

For the prototype realized in this section using the 5 stage CMOS rectifier, a 0.5 mm thick GML 1000 substrate is chosen. At the design frequency, the simulated radiation efficiency is presented in the solid curve of Fig. 5.14. At an operating frequency of 868 MHz, the antenna radiation efficiency is 84.7 %.

The real part of the antenna should be a fixed value between 4.3 Ω and 7.6 Ω. Based on the rectenna design criterion presented in Sec. 5.2.2, the real part of the input impedance of the rectifier is chosen to be 4.4 Ω. After optimizing all the antenna parameters (see Fig. 4.13), an antenna with one short-circuited arm ($n = 1$) having an input impedance

of $Z_{Antenna} = 4.4+j328\Omega$ is chosen. The geometrical parameters of the designed antenna (see Fig. 4.13) are listed in Table 5.2.

Table 5.2. Optimized antenna parameters for the suggested antenna prototype. All dimensions are in mm.

n	W, W_1	g_1, g_2	E_1	L_1	L_2	S_1	S_2	S_3
1	5	3	2	34	35.25	13.75	2	4.5

The front and the back sides of the designed antenna are shown in Fig. 5.15.

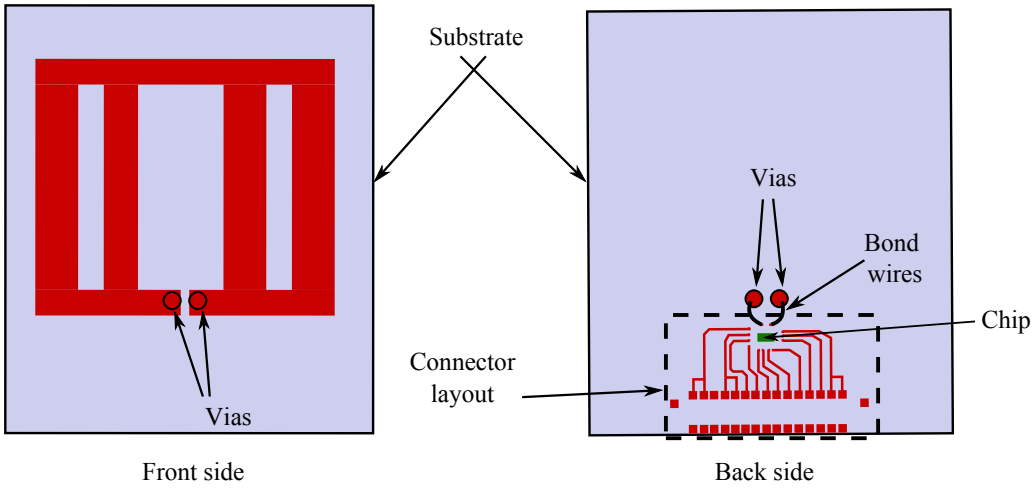

Figure 5.15. Front and back sides of the designed compact antenna structure, including the five stage CMOS chip and the connector layout.

For a proof of principle, the control loop is connected to the chip and antenna using the connector layout shown in Fig. 5.15. The chip is integrated on the backside of the antenna. It should be mentioned that the antenna parameters are optimized in the presence of the connector layout, vias and bond wires. The rectifier inputs are bond-wired to the vias (2 mm in diameter) that connect to the antenna feeding points. The bond wires are modeled using CST Microwave Studio and are having a length of 2.1 mm and a radius of 25 μm.

Due to the self calibrating capability of the circuit and the low real part of the input impedance (R_{in}), the antenna size of the prototype presented in this section is reduced to 21.9 cm^2 compared to 34.3 cm^2 for the first prototype presented in Sec. 5.3.1. Once the external control loop is completely integrated on chip, the connector is no longer required and the antenna board size can be scaled down further without introducing a significant performance loss.

Figure 5.16 shows the simulated 3D directivity pattern of the prototype antenna. The directivity D_r and the radiation efficiency $\eta_{radiation}$ determine the antenna gain G_r. $G_r = \eta_{radiation} D_r$, with $D_r = 1.3$ dBi and $\eta_{radiation} = 0.85$, the simulated antenna gain is $G_r = 0.6$ dBi.

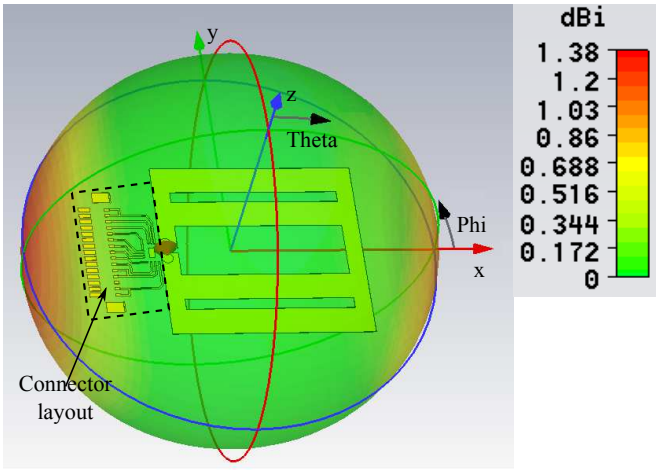

Figure 5.16. 3D directivity pattern of the prototype antenna at an operating frequency of 868 MHz, simulated using CST Microwave Studio.

Figure 5.17 shows a photograph of the manufactured prototype.

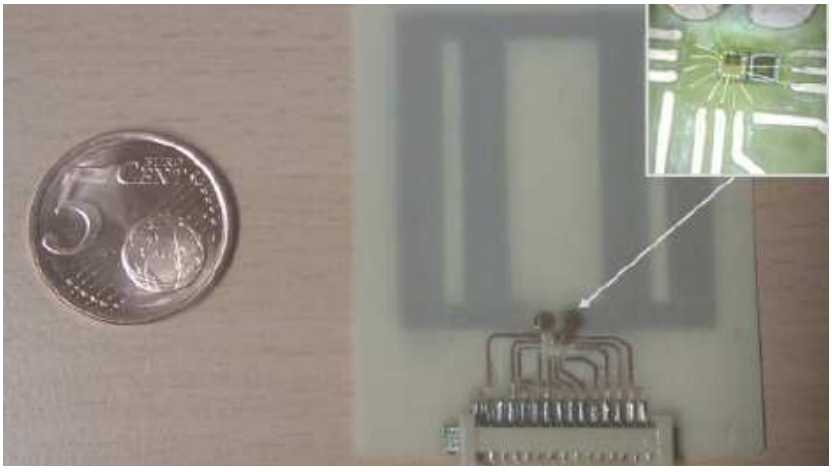

Figure 5.17. Photograph of the manufactured prototype antenna with the integrated circuit. The inset shows the bonded chip in more detail.

5.4.3 Measurement Results

The output voltage and the power conversion efficiency have been measured for different load resistances and for different RF input power levels (P_{in}) at the design frequency (868 MHz).
Figure 5.18 shows the measured DC output voltage (V_{out}) as a function of frequency for a load resistance of 1 MΩ at an input power level of -20 dBm.

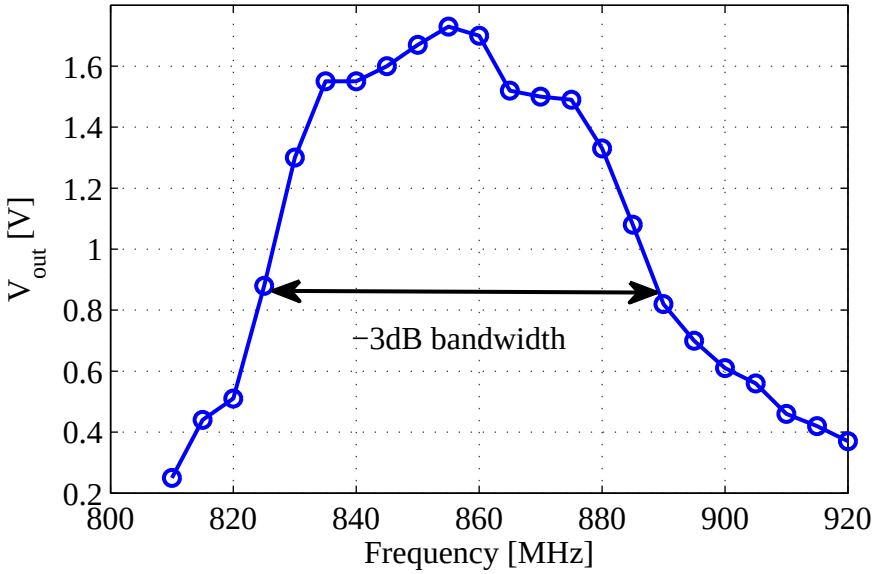

Figure 5.18. Measured output voltage versus frequency for $R_L = 1M\Omega$ and P_{in} = -20 dBm

The peak output voltage is measured at an operating frequency of 855 MHz and reaches 1.73 V. The -3 dB voltage bandwidth is approximately 60 MHz. Compared to the output voltage (measured at Pin = -10 dBm) of the first fabricated prototype, where commercial diodes have been used (see Fig. 5.9), it is clear that this prototype rectenna generates a higher output voltage even at an input power level that is ten times lower (- 20 dBm). In addition, the -3dB voltage bandwidth of this prototype rectenna has almost doubled. This increase in the output voltage was expected and is due to the lower real part and higher imaginary part of the input impedance of the designed CMOS rectifier ($Z_{CMOS-Rectifier} = 4.4 + j328\Omega$) as compared to the input impedance of the discrete diode voltage doubler used for the prototype introduced in the previous section ($Z_{Doubler} = 8.5 + j237\Omega$).

Next, the output voltage has been measured as a function of input power level for different load resistances at 868 MHz; the result is shown in Fig. 5.19. The open circuit output voltage is represented by the dashed-dotted curve in the figure, where the rectenna is able to generate 1 V at an input power level on -27.5 dBm.

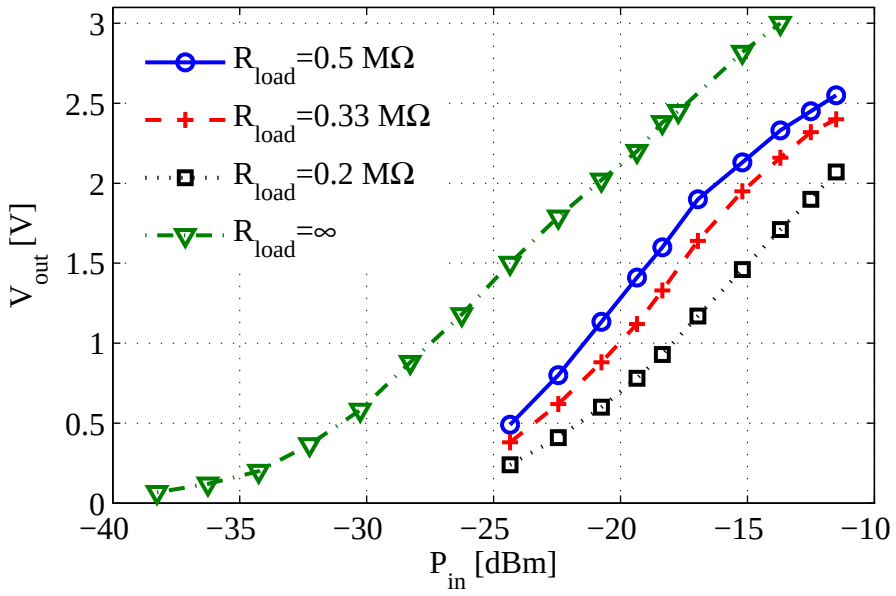

Figure 5.19. Measured output voltage as a function of input power level for different resistive load values.

Based on these voltage levels, and on the simulated antenna gain of 0.6 dBi (D_r = 1.3 dBi, $\eta_{radiation}$ = 0.85), the Power Conversion Efficiency (PCE) is calculated from Eq. (5.21) and plotted in Fig. 5.20 as a function of P_{in} for different load resistance values.

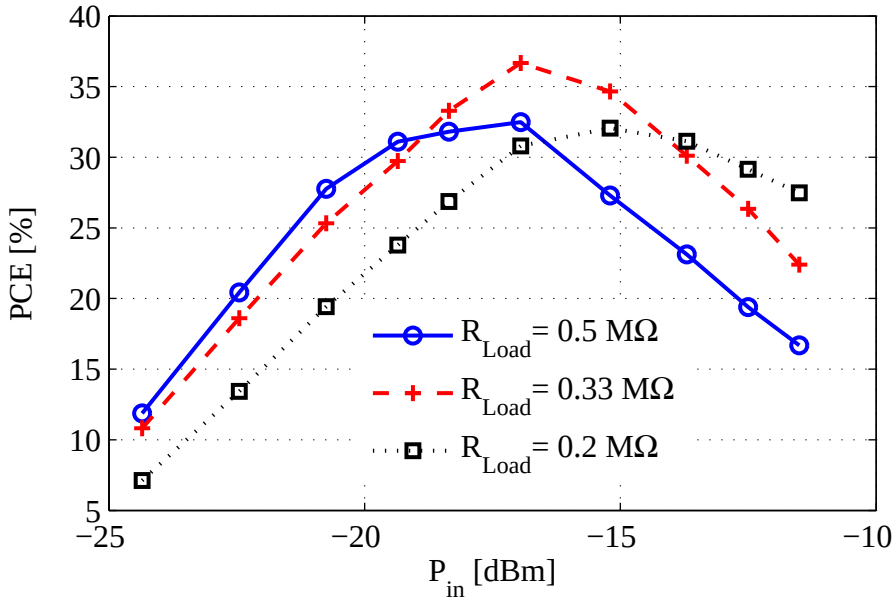

Figure 5.20. Measured power conversion efficiency versus input power level for different resistive load values. Operating frequency = 868 MHz

The power conversion efficiency reaches 30 % at an input power level of -20 dBm and increases to 36.6 % at an input power level of -17 dBm over a 0.33 MΩ resistive load. Compared to the recently reported results in [99, 100], the presented rectenna in this paper has a lower sensitivity and is more compact. Compared to [101] and [102], the proposed rectenna is 70% and 37% more compact respectively. Table 5.3 compares the performances achieved in this work to the state of the art as published in the open literature.

Table 5.3. Overview of rectennas performance with CMOS rectifier in literature.

Ref.	This work	[101]	[102]	[103]

*calculated from the graph

The suggested co-designed antenna-CMOS rectifier is smaller in size than those reported in other publications. Once the control loop is integrated on chip, the size can be even further reduced. Thus, through the co-design of the 5 stage CMOS rectifier and the antenna and following the design criterion from Sec. 5.2.2 we were able to significantly increase the performance of the rectenna with respect to the DC output voltage, power conversion efficiency, sensitivity and size compared to the state of the art.

5.5 Conclusion

A compact rectenna has been presented in this chapter. The design strategy is based on designing an antenna with a input impedance equal to the complex conjugate of that of the rectifier. This allows removing the matching network, which results in a more compact and efficient rectenna system. Two prototypes have been designed, manufactured, and measured. The first prototype consists of a rectenna that uses commercially available diodes, while in the second prototype a CMOS rectifier is used to convert the RF power into DC power.
In the first prototype, a voltage doubler is used that is conjugately matched to the

antenna. At an available power level of -20 dBm, the PCE reaches 33.8 % for a resistive load of 10 kΩ. The PCE increases to 54.7 % when the RF input power level is increased to -10 dBm. The measured results showed an improved performance compared to recently reported results in literature.

For the second prototype, a 5 stage cross-connected bridge rectifier with a capacitor bank implemented in standard 90-nm CMOS technology has been used. A control loop is used to optimize the matching between the antenna and the rectifier. Compared to the output voltage of the voltage doubler of the first fabricated prototype, where commercially available diodes have been used, the 5 stages bridge rectifier generates a higher output voltage even at an input power level that is ten times lower. In addition, the -3 dB voltage bandwidth of the second prototype is almost doubled. Measurements show a sensitivity of -27 dBm for a 1 V DC output.
At an input power level of -20 dBm, the peak output voltage is measured at an operating frequency of 855 MHz and reaches 1.73 V. The radiation efficiency reaches 30 % at an input power level of -20 dBm and it increases to 36.6 % at an input power level of -17 dBm over a 0.33 MΩ resistive load. Compared to the state of the art published results, a better performance of the rectenna has been achieved with respect to the DC output voltage, power conversion efficiency and sensitivity. Moreover the suggested rectenna is smaller in size than those reported in previous publications.

Chapter six

RF Power Transfer - Complete Rectenna System

In this chapter a complete rectenna system, i.e. the receiving part of the RF power transfer system, is described. The system consists of a signal generator connected to a matching network and a rectifier. The signal generator replaces the receiving antenna to ensure an accurate and repeatable signal injection. A commercially available power management circuit is then used to boost the DC voltage and to store the captured energy in a capacitor. The power management circuit is connected to a dynamic load to emulate different radio systems behaviour. The system's DC average output power and the system's power conversion efficiency are measured and compared to those of a commercially available rectenna system.

6.1 System Concept and Measurement Setup

In this section, the matching network and the voltage doubler introduced in Sec. 3.7.1 are combined with the power management circuit TI BQ25570 [104] and a dynamic load that emulates the behaviour of a radio system. The measurement system[1] is shown in Fig. 6.1.

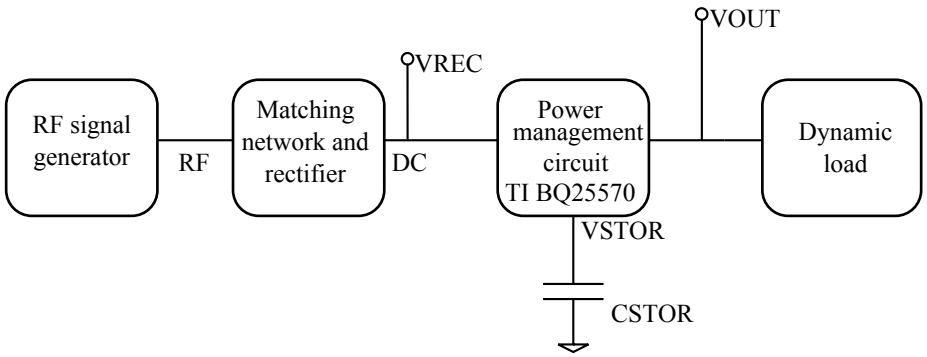

Figure 6.1. Measurement setup using a power management circuit and a dynamic load.

The RF signal generator in this setup replaces the (50Ω) antenna, so that a stable and repeatable measurement setup is created. Since the DC output voltage of the rectifier stage VREC (see Fig. 6.1) is limited and changes with input power level, a power management circuit is needed to store and regulate the system output energy. For our system, the power management circuit TI BQ25570 is used. The connections to the TI BQ25570 are shown in Fig. 6.2. A complete schematic and explanation of the evaluation board used are presented in [105].
The integrated boost controller in the chip amplifies the DC input voltage (VIN_DC=VREC) and controls its output voltage (VSTOR). The boost controller stops when VSTOR reaches a threshold level that is set with the external resistor network shown in Fig. 6.2. The energy is stored in a (super)-capacitor or a rechargeable battery. The integrated buck converter (see Fig. 6.2) is powered from VSTOR and regulates the output voltage to drive different applications. To emulate different radio systems behaviour a dynamic load is connected to the VOUT pin of the evaluation board. This dynamic load will be discussed in more detail in the remainder of this chapter.
The amount of energy stored in a capacitor C, when the voltage increases from V_1 to

[1]The measurement setup as well as the measurement results presented in this chapter were performed at the Holst Centre/imec by Hans Pflug.

V_2 is:

$$W = \frac{1}{2} C \left(V_2^2 - V_1^2 \right). \tag{6.1}$$

The minimum capacitance value, C_{min}, depends on the power drawn by the dynamic load P_L during a discharge time T_p when the capacitor voltage drops from V_2 to V_1 and is given by:

$$C_{min} \geq \frac{P_L T_p}{0.5 \left(V_2^2 - V_1^2 \right)}. \tag{6.2}$$

For example, suppose 60 mW of power is drawn for 40 ms, resulting in a voltage drop from 4.2 V to 1.8 V. This system will have a $C_{min} \geq 333\ \mu F$. To ensure sufficient storage capacitance, a 1000 μF (CSTOR) capacitor is connected to the VSTOR-pin of the TI chip.

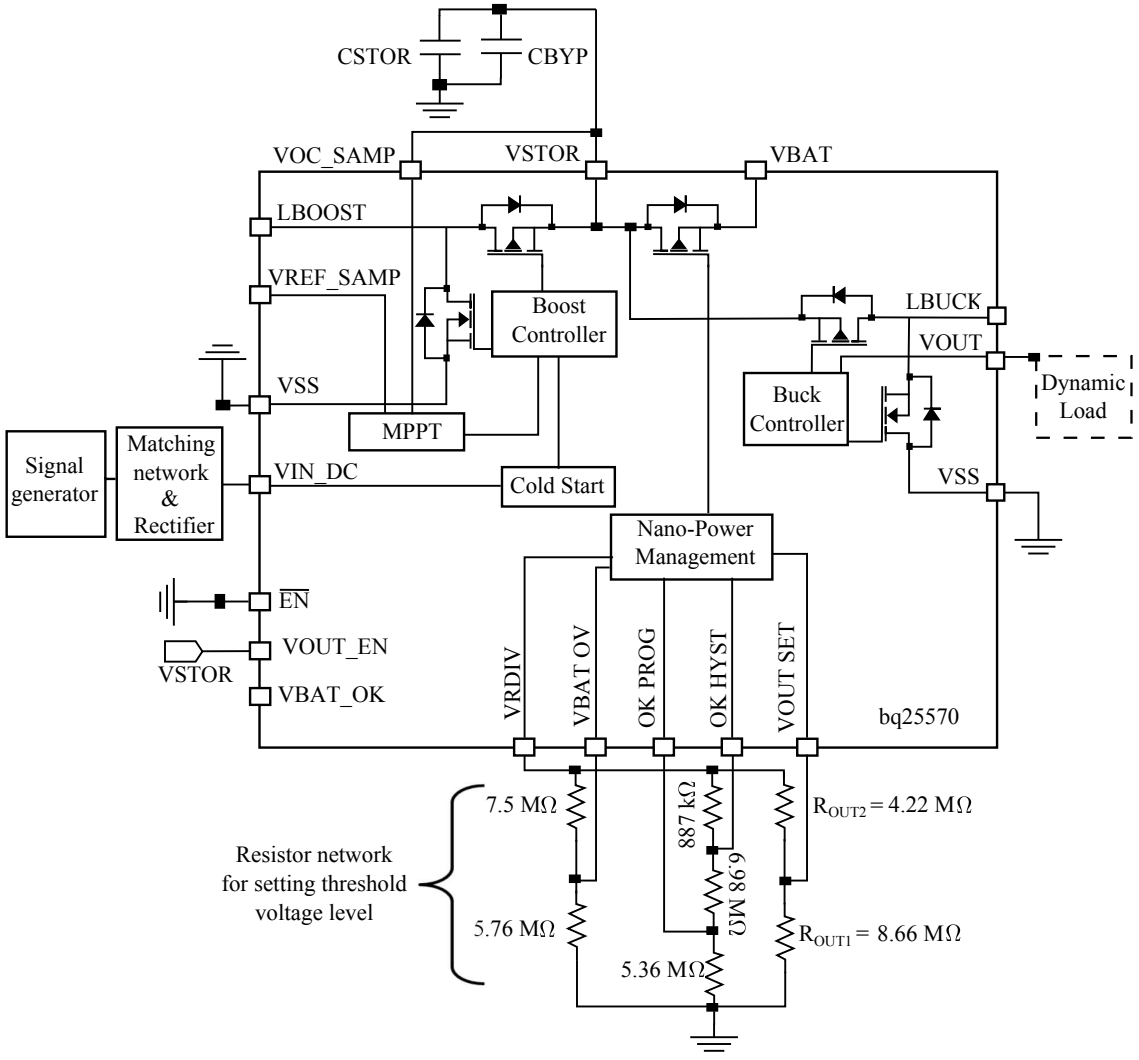

Figure 6.2. Schematic connection to the TI BQ25570 evaluation board.

The integrated boost controller provides 4.2 V at the VSTOR-pin. The buck controller regulates the output voltage VOUT (see Fig. 6.2) at 1.8 V for the chosen values of the resistor network shown in Fig. 6.2. A dynamic load is connected at the VOUT-pin of the TI chip.

The schematic of the dynamic load is shown in Fig. 6.3. It consists of an array of load resistors connected to BJTs that are operated as switches. The switches are controlled by an Arduino Mega board [106] with the ATmega2560 Atmel micro-controller. So, the load resistance and the on-time (T_P) and off-time (T_i) are at the users disposal.

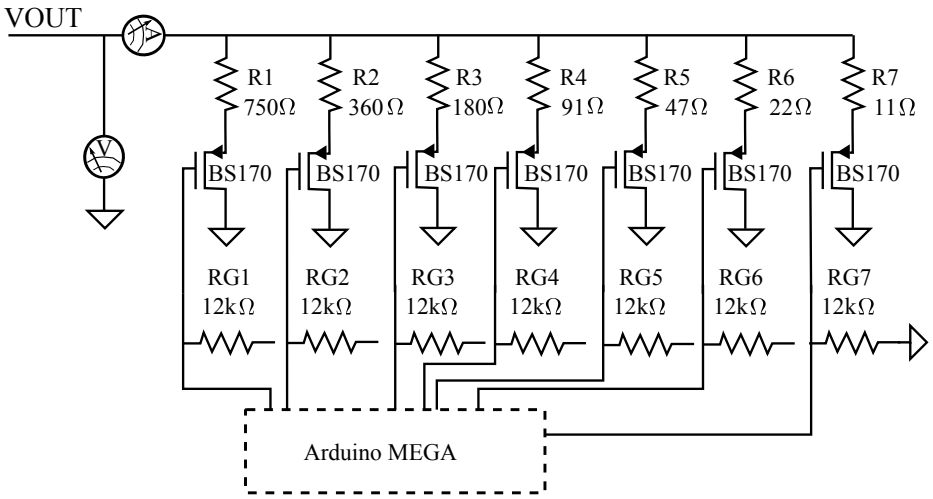

Figure 6.3. Schematic of the used dynamic load connected to the VOUT-pin of the TI BQ25570 chip.

6.2 Measurement Results

The system's average DC output voltage and the system's efficiency are measured, and the results are presented in this section. For the presented measurements, T_P is the pulse duration corresponding to a transmission of a frame and is set to 10 ms. T_i is the time between two consecutive bursts required to recharge the storage capacitor (CSTOR).

The efficiency, η_{system}, of the complete harvesting system is expressed as:

$$\eta_{\text{system}} = \frac{P_{\text{out}}}{P_{\text{RF}}}, \tag{6.3}$$

where P_{RF} is the RF power provided by the signal generator, and P_{out} is the average

DC output power. P_{out} is calculated as:

$$P_{out} = \frac{T_p}{T_p + T_i} P_L. \tag{6.4}$$

The system output voltage is VOUT=1.8 V and 55 mW (P_L = 55mW) of power is drawn by the dynamic load. A commercially available rectenna system [107] has been measured under the same conditions.
Figure 6.4 shows the average DC output power as a function of RF input power level for the commercially available rectenna system and for the presented system. The figure shows that the DC output power of the presented system outperforms that of the commercially available rectenna system, especially at lower input power levels (≤ -6dBm). The presented system is able to generate 10 μW on average at an RF input power level of -12 dBm, while the commercially available rectenna system generates the same output power at an input power level of -6 dBm, which results in 6 dB sensitivity improvement for this average DC output power level.

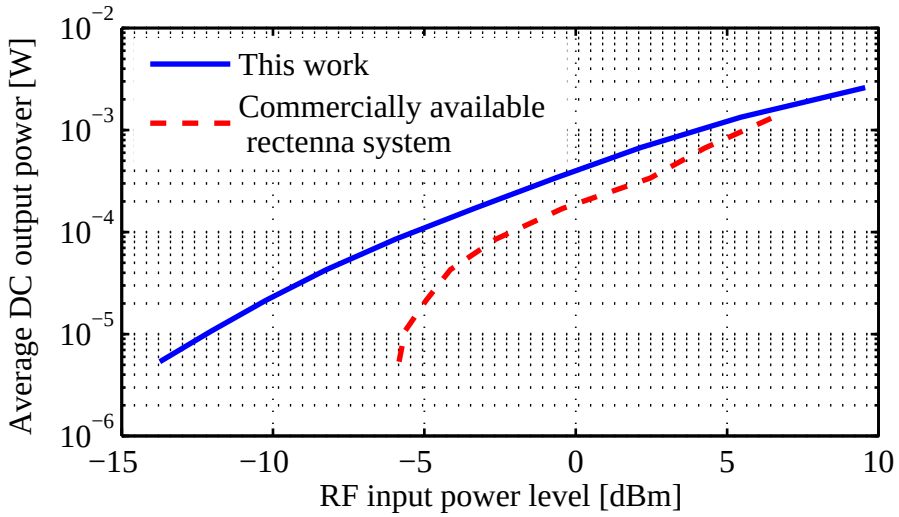

Figure 6.4. Average DC output power as a function of RF input power level using the harvesting system developed in this thesis and the commercially available rectenna system. PL=55mW, T_p = 10ms, T_i varies.

The system's RF to DC conversion efficiency is calculated using Eqs.(6.3) and (6.4) and the results for both systems are plotted in Fig. 6.5. The figure shows that the power conversion efficiency of the presented system is higher than that of the commercially available system in the shown RF power level band. The efficiency of the presented system reaches 23 % at an input power level of -10 dBm, while at the same input power level the commercially available system fails to operate.
At an input power level of 0 dBm, the power conversion efficiency of the commercially

available system is 19 %, while the power conversion efficiency of the presented system reaches 40 % resulting in more than 20 % improvement in power conversion efficiency.

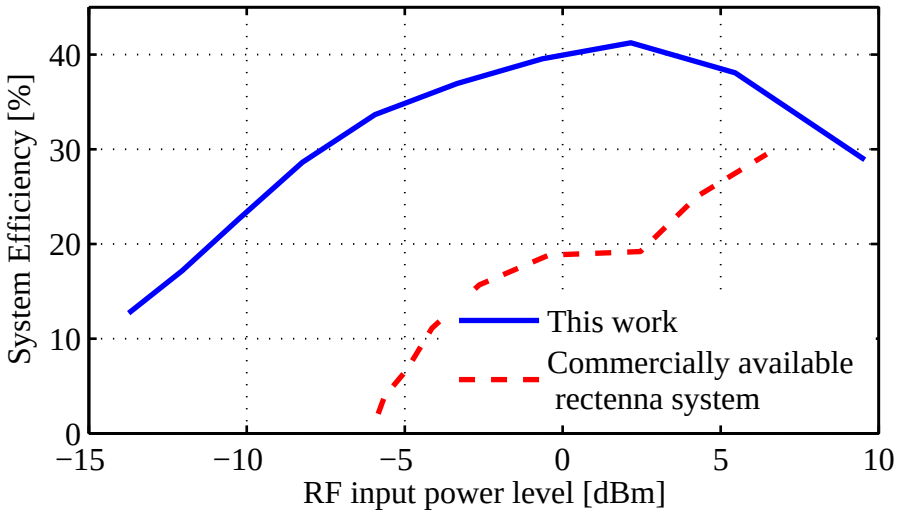

Figure 6.5. System's RF to DC conversion efficiency as a function of RF input power level using the harvesting system developed in this thesis and the commercially available rectenna system. PL=55mW, T_p = 10ms, T_i varies.

Using the measured system efficiency (solid curve in Fig. 6.5), the average DC output power is calculated as a function of rectenna's distance from a 2 W Effective Radiated Power (ERP) source at 868 MHz. Figure 6.6 shows the calculated average DC output power as a function of propagation distance when using a 1 dBi and a 6 dBi receiving antenna.

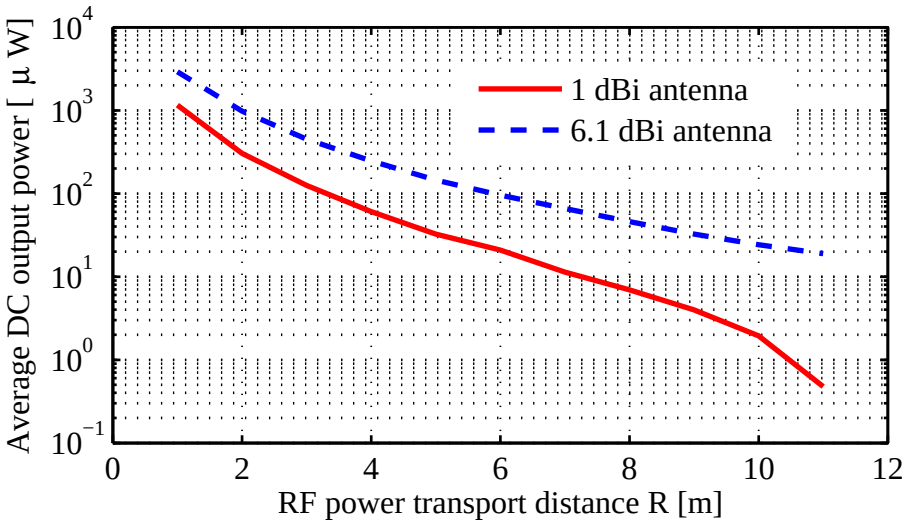

Figure 6.6. Average DC output power as a function of RF power transport distance (R) using a 1 dBi and a 6 dBi receiving antenna.

Figure 6.6 indicates that for an average DC output power of 20 μW, the RF power transport distance increases from 6 meters to 10.5 meters when using a 6.1 dBi gain antenna instead of 1 dBi gain antenna. An average DC output power of 20 μW, having a P_L of 55 mW and a burst time $T_p = 10$ms results in an off-time of $T_i = 27$ seconds.

As a practical application, the commercially available humidity and temperature sensor, Cresta WX688 [108] is used. The Cresta sensor is shown in Fig. 6.7. The sensor uses a 433 MHz transmitter to send data to the main station. The (two AA 1.5 V) batteries of the sensor are removed and the power lines are extended as shown in Fig. 6.7, and connected to the VOUT pin of the TI BQ25570 chip (see Fig. 6.2).

Figure 6.7. Cresta humidity and temperature sensor.

To provide 3.0 V at the VOUT-pin of the TI BQ25570, the resistor network is modified where R_{OUT2} and R_{OUT1} (see Fig. 6.2) are set to 7.5 MΩ and 5.1 MΩ respectively. The sensor transmits a burst containing the temperature and the humidity information to the main station every 45 seconds ($T_i = 45$ seconds). The burst duration is 823 ms, ($T_p = 823$ ms). The voltage variation on the storage capacitor (CSTOR) is 844 mV (3.844 V to 3.0 V). The energy stored in the capacitor is calculated using Eq. (6.1) and is 2.89 mJ. This results in a 3.5 mW power drawn by the sensor and an average DC output power, using Eq. (6.4), of 62.9μW.

The sensor operated at different RF input power levels. The minimum RF input power level that operates the sensor was -5 dBm[2]. It should be mentioned that the sensor

[2]The system efficiency is 35 % at -5dBm for drawing 55 mW during 10 ms (see Fig. 6.5). The system efficiency is expected to decrease if 3.5 mW are drawn during 823 ms. Since the minimum RF input power level that operated the sensor was -5 dBm (316μW), and the average DC power drawn by the sensor is 62.9μW, this results in a system efficiency of 20 % for powering the Cresta humidity and temperature sensor, which is consistent with our expectations.

is not developed for RF power transport applications, but the sensor was used in this experiment as a proof of concept.

6.3 Conclusion

In this chapter, a complete rectenna system was presented. The system encompasses a matching network, a voltage doubling rectifier, a commercially available power management circuit, a 1000 μF storage capacitor and a dynamic load. The average DC output power and the system's RF to DC conversion efficiency are measured, and compared to those measured for a commercially available rectenna system operated under the same conditions. It has been shown that the commercially available rectenna system fails to operate at low power levels (≤ -6dBm) while the presented system can operate at an RF input power level as low as -13 dBm. This means that for example, 55 mW of DC power can be drawn for 10 ms every 27.5 seconds on a distance of about 10 m from a 2 W ERP source at 868 MHz using a 6.1 dBi receiving antenna.
At an input power level of 0 dBm, the power conversion efficiency of the commercially available system does not exceed 19 %, while the power conversion efficiency of the presented system reaches 40 %, resulting in more than 20 % improved power conversion efficiency.

Chapter seven

A Frequency Selective Surface for RF Energy Harvesting

In this chapter, a novel implementation and application of Frequency Selective Surfaces (FSS) is presented. The novel FSS design can harvest power from arbitrarily polarized incident electromagnetic waves. The design does not involve a matching network, which results in a simple (polarization-independent) power harvester. An equivalent circuit model to predict the transmission and reflection characteristics of a gridded square loop FSS loaded with diodes is employed. The design method is validated for different incident angles, through full-wave analysis and measurements. To that end, the addition of lumped elements (R,L,C) in a metallic conductive grid of a non-harvesting FSS is investigated. Waveguide simulator measurements and full-wave simulations are employed to validate the derived analytical equations. A 3×3 and a 5×5 RF harvesting FSS have been designed, fabricated and measured. An RF to DC conversion efficiency of 25 % for the 3×3 RF harvester and 16% for the 5×5 RF harvester are measured at an incident power density of $3.2\,\mu\mathrm{W/cm^2}$.

7.1 Introduction

In the previous chapters the developed rectennas are designed to harvest linearly polarized waves. In this chapter a practical and efficient way to harvest RF waves that may be polarized in any direction is proposed. The technique can be used to produce RF power harvesting glass, or RF power harvesting wall paper. Figure 7.1 shows a photograph of two RF power harvesting glass prototypes using two different Frequency Selective Surfaces (FSS): the gridded square FSS and the gridded cross FSS. In the final design, transparent conductive film [109, 110] could be implemented on glass for the realization of optically transparent harvesting grids.

Figure 7.1. RF power harvesting glass using frequency selective surfaces.

The main advantages of the suggested RF harvester in comparison to conventional rectenna array configurations, (i.e. wherein each element is connected to a rectifier and wherein the DC-signals are combined) are as follows.

- In a conventional rectenna array configuration, RF combining networks or/and DC combining circuits are needed e.g. [111]. In the FSS-based rectenna, the combining circuits are absent. The DC output voltage is collected using only two DC connections to the structure, which simplifies the design of the RF harvester.
- The matching networks used in conventional rectennas and rectenna arrays are in general narrow-band and therefore enable power harvesting in most cases in a single frequency band only e.g. [112]. In the FSS harvesters presented in this chapter, impedance matching networks are not present. They form an integral part of the FSS structure, which eliminates the losses that would be introduced

by a separate matching network. In addition, the suggested design allows power harvesting from a dual frequency band, more specifically: the FSS transmission and reflection frequency bands.

- To maximize the harvested power, polarization matching between the transmitter and the receiver is crucial. Consequently, dual linearly, or circularly polarized rectennas are designed e.g. [113]. In this chapter, a polarization independent FSS is presented, which allows to harvest power from arbitrary polarized waves by decomposing the polarization of the incident wave into two orthogonal linear polarizations and rectifying them independently.

- Array rectennas (i.e. array antennas connected to a diode) exhibit a relatively high directivity and thus need to be positioned in the direction of the source for an optimal power transfer. The suggested FSS harvester that is a rectenna array (i.e. combination of radiators, each one connected to a rectifier) is less sensitive to angles of incidence and can harvest RF power efficiently at angles away from broadside.

The FSS rectenna discussed in this chapter consists of a metallic grid with inner square loops of conductors disposed in a periodic fashion as shown in Fig. 7.2(a).

The grid is loaded with Schottky diodes for current rectification. After rectification, the DC power is collected at the top-left and bottom-right corners as shown in Fig. 7.2(a). The physical principles of operation were first discussed in [114] and are shown in Figs. 7.2(b) and 7.2(c). For our FSS configuration, the labels U (up), D (down), R (Right) and L (Left) indicate the direction of the induced current in the grid. To start with, a vertically polarized incident wave $\overrightarrow{E_V}$ is considered, see Fig.7.2(b). The induced current will flow from the diodes d_{V1} toward diodes d_{V2} in the U-direction. Diodes d_{H1} and d_{H2} are unbiased, and consequently they will prevent the current from flowing in the R-direction. Similarly, when a horizontally polarized incident wave $\overrightarrow{E_H}$ hits the FSS surface, see Fig.7.2(c), this time diodes d_{H1} and d_{H2} draw the current in the L-direction from d_{H1} toward d_{H2}. Diodes d_{V1} and d_{V2} are unbiased, and consequently they will prevent the current from flowing in the D-direction. When an elliptically polarized wave hits the FSS surface, the vertical and the horizontal components of the electric field will drive the induced current to flow in the U and L-directions. Consequently the induced current can be collected at the top left corner by using the DC collection lines as shown in Fig.7.2(a). With this configuration the grid acts as a half-wave rectifier, making the FSS capable of rectifying the signal from arbitrarily polarized waves.

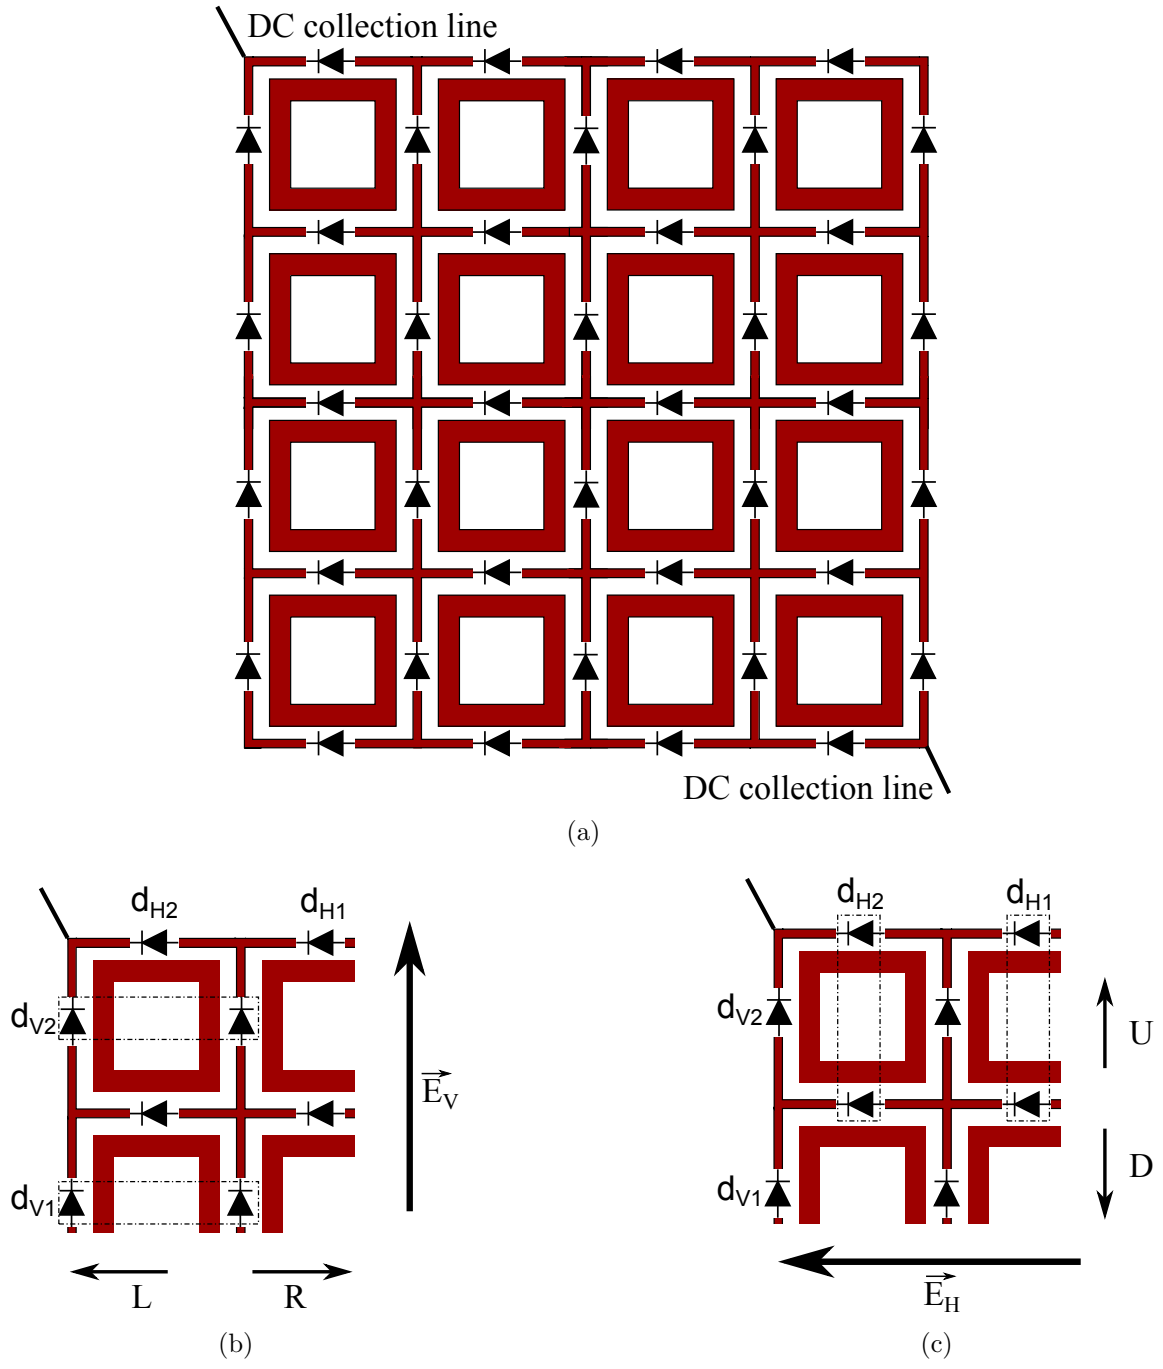

Figure 7.2. Suggested RF FSS harvester (a) and its physical principal of operation for an incident vertical electric Field (E_V), (b) and an incident horizontal electric Field (E_H), (c).

7.2 Square Loop FSS

The square loop FSS has been reported in the literature by several authors [115, 116] and is shown in Fig. 7.3(a).

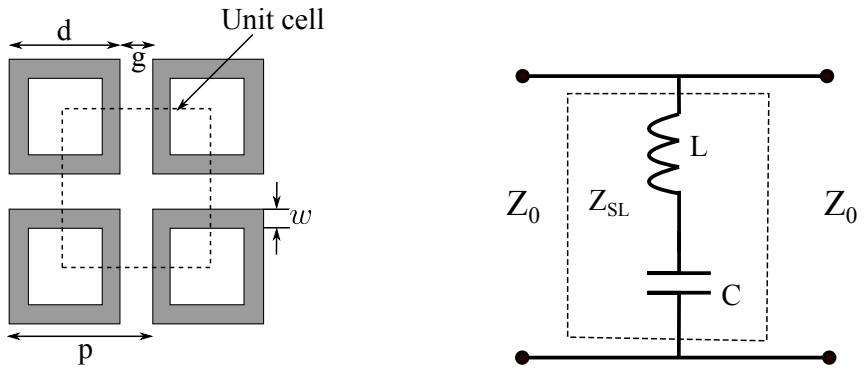

Figure 7.3. Square Loop (SL) frequency selective surface (FSS) configuration (a) and its unit-cell equivalent electric circuit model (b).

It consists of a periodic array of identical conducting strip square loops. g is the gap between neighboring elements, w is the width of the loop strip, d is the length of the square side and $p = (d + g)$ is the periodicity of the unit cell. The unit cell is the structure that is periodically repeated in the two orthogonal planar directions. Several choices can be made, the results are identical. The equivalent circuit model of the unit cell is shown in Fig. 7.3(b) and is a series LC circuit, shunt-positioned in a segment of transmission line carrying a plane incident wave, where L represents the inductance due to the vertical (horizontal) metal conductor and C is the capacitance between the horizontal (vertical) conductors.

The impedance of the unit cell (dashed box in Fig. 7.3(a)), is given by:

$$Z_{fss} = j\left(X_L - \frac{1}{B_C}\right), \tag{7.1}$$

where X_L and B_C are derived as presented in [117]:

$$X_L = Z_0\left(\frac{d}{p}\right) F\left(p,\, 2w,\, \lambda\right), \tag{7.2}$$

$$B_C = \frac{4}{Z_0}\left(\frac{d}{p}\right) F\left(p,\, g,\, \lambda\right). \tag{7.3}$$

Z_0 is the characteristic impedance of free space, $Z_0 = \sqrt{\frac{\mu_0}{\epsilon_0}}$ and λ is the free-space wavelength. The function $F(p, g, \lambda)$ is given in [118] and [119]:

$$F_{TE}(p, w, \lambda) = \Upsilon \left[\ln \csc \left(\frac{\pi w}{2p} \right) + G(p, w, \lambda, \theta) \right], \tag{7.4}$$

$$F_{TM}(p, w, \lambda) = \Phi \left[\ln \csc \left(\frac{\pi w}{2p} \right) + G(p, w, \lambda, \varphi) \right], \tag{7.5}$$

$$F_{TE}(p, g, \lambda) = \Psi \left[\ln \csc \left(\frac{\pi g}{2p} \right) + G(p, g, \lambda, \theta) \right], \tag{7.6}$$

$$F_{TM}(p, g, \lambda) = \Omega \left[\ln \csc \left(\frac{\pi g}{2p} \right) + G(p, g, \lambda, \varphi) \right], \tag{7.7}$$

where $\Upsilon = (p \cos\theta)/\lambda$, $\Phi = (p \sec\varphi)/\lambda$, $\Psi = (p \sec\theta)/\lambda$ and $\Omega = (p \cos\varphi)/\lambda$. Herein, θ and φ are the angles of incidence of a TE and TM polarized wave, respectively. The FSS is supposed to be positioned in the xy-plane of a rectangular xyz coordinate system. G is the first-order correction term for both TE-wave and TM-wave incidence, and has been given in [118] and [120]. The correction factor G is presented in Appendix B.
To account for the influence of the supporting dielectric layer, the results derived in [121] and [122] are used and presented in Sec. 7.2.2. The absolute value in dB of the transmission and reflection coefficients is derived from the normalized impedance of the unit cell [120]:

$$|T|_{dB} = 20 \log_{10} \left[\frac{2Z_{fss}}{1 + 2Z_{fss}} \right], \tag{7.8}$$

$$|R|_{dB} = 20 \log_{10} \left[\frac{-1}{1 + 2Z_{fss}} \right]. \tag{7.9}$$

7.2.1 Model Verification

To demonstrate the accuracy of these Analytical Expressions (AE), the reflection and the transmission coefficients are calculated and compared to the results obtained by

the Finite Integration Technique (FIT) [72] as implemented in CST Microwave Studio. Table 7.1 summarizes the dimensions for different array configurations that are investigated here. t is the substrate thickness and ϵ_r is the substrate permittivity.

Table 7.1. Analyzed Square Loop Array Configurations. Dimensions are explained in Fig. 7.3(a).

Square Loop Array #	**p** (mm)	**d** (mm)	**g** (mm)	**w** (mm)	**t** (mm)	$\epsilon_\mathbf{r}$
1	10.0	8.75	1.25	0.625	0.0	1.0
2	36	31.0	5	3.0	0.25	2.2
3	22.0	21.0	1.0	3.0	see Sec. 7.2.2	2.2
4	32.25	31.0	1.25	3.0	0.25	see Sec. 7.2.2

Figure 7.4 shows the magnitude (a) and the phase (b) of the transmission and the reflection coefficients for FSS #1 in Table 7.1 as a function of frequency calculated by the Analytical Expressions (AE) and by the Finite Integration Technique (FIT) using CST Microwave Studio, demonstrating the validity of the AE.

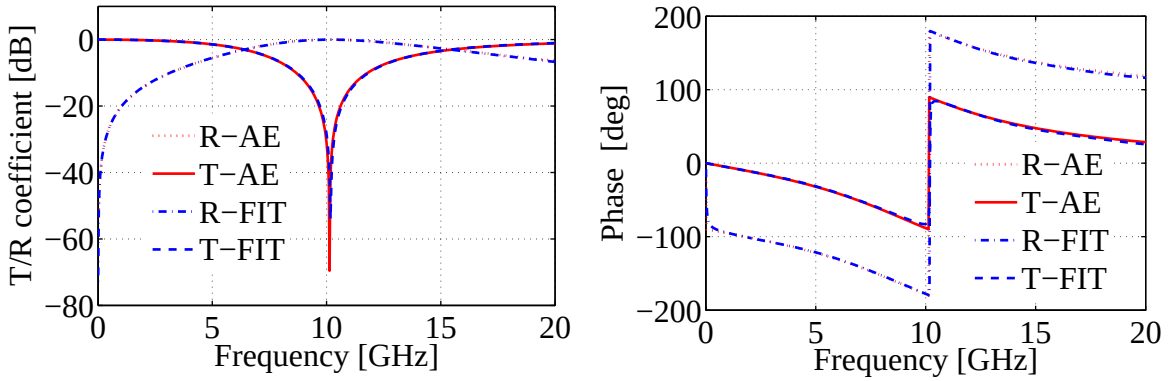

Figure 7.4. Magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #1 of Table 7.1 at normal incidence, $\theta = \varphi = 0°$.

The frequency response of the FSS is affected by the polarization of the incident plane wave (TE, TM) and by its angle of incidence (θ, φ). The main advantage of the presented equivalent circuit model is that it offers the capability of deriving expressions for predicting the behavior of the reflection/transmission coefficients for different polarizations and for an oblique angle of incidence, up to an angle of incidence of 45 degrees [119]. To demonstrate that the equivalent circuit model can accurately predict

the reflection and the transmission coefficients for different angles of incidence and for different polarizations, the square loop array # 2 presented in Table 7.1 is investigated. The frequency response is calculated with the aid of the presented analytical expressions and is compared to the results obtained by CST Mcirowave studio. Figure 7.5 shows the magnitude (a) and phase (b) of the reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #2 of Table 7.1, for a TE incidence with $\theta = 15°$, $\varphi = 0°$. The results for the same FSS are also calculated for a TM wave incidence with $\theta = 0°$, $\varphi = 15°$ and are plotted in Fig. 7.6, again demonstrating the validity of the AE.

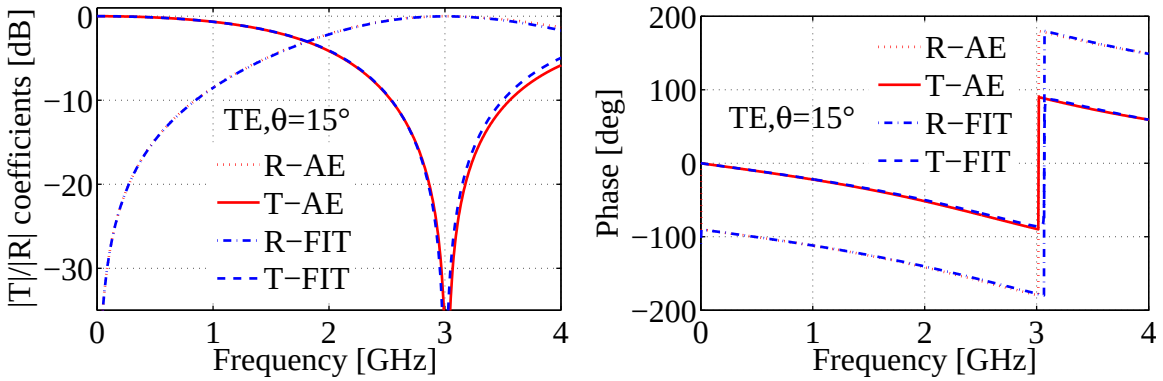

Figure 7.5. Magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #2 of Table 7.1, $\theta = 15°$, $\varphi = 0°$.

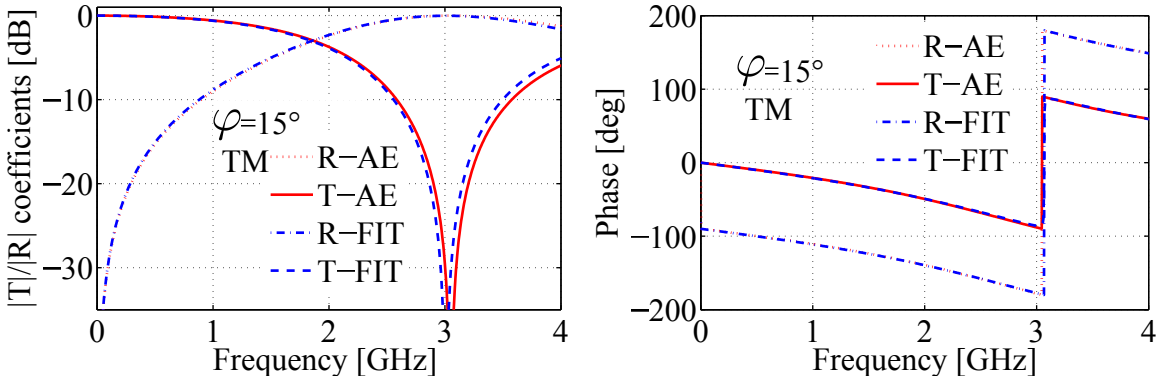

Figure 7.6. Magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #2 of Table 7.1, $\theta = 0°$, $\varphi = 15°$.

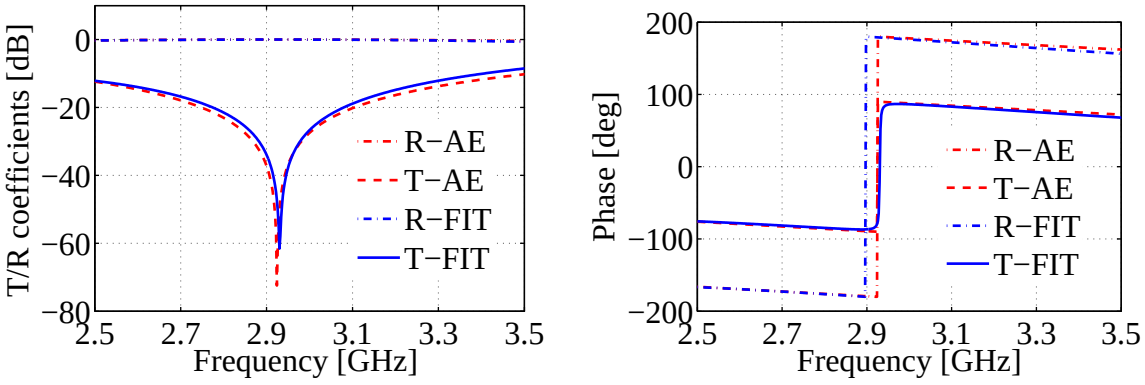
We conclude with a final example, wherein we look at the FSS #2 in Table 7.1 for an

angle of incidence, $\theta = 45°$, and $\varphi = 0°$. The reflection and the transmission coefficients are calculated using the equivalent circuit model and are compared with the results obtained by the FIT with the aid of CST Microwave Studio. Figure 7.7 shows the magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #2 of Table 7.1 at $\theta = 45°$, and $\varphi = 0°$.



(a) (b)

Figure 7.7. Magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for the square loop Array #2 of Table 7.1 at $\theta = 45°$, and $\varphi = 0°$.

It is observed from Figs. 7.4-7.7 that the equivalent circuit model can predict the reflection and the transmission coefficients for a square loop FSS for different polarization and for different angles of incidence, with a frequency shift in the transmission and reflection coefficients less than 5%.

7.2.2 Effect of the Supporting Dielectric Substrate

The effect of the dielectric substrate that is carrying the array elements was discussed in [121–123]. For thin dielectric layers the value of the unit-cell capacitance, see Fig. 7.3(b), varies as a function of dielectric thickness t. A value of the effective permittivity ε_{eff}, which will be used instead of the substrate permittivity ε_r, is calculated via an iterative procedure for thin dielectric substrates in [121]. The expression depends on both ϵ_r and t and the resulting effective permittivity can be included in the equivalent circuit model by multiplying the susceptance B_C (Eq. (7.3)) by this effective permittivity. The expression of the effective permittivity (ε_{eff}) is obtained as:

$$\varepsilon_{eff} = \varepsilon_r + (\varepsilon_r - 1) \cdot \left[\frac{-1}{e^{x \cdot N}}\right], \tag{7.10}$$

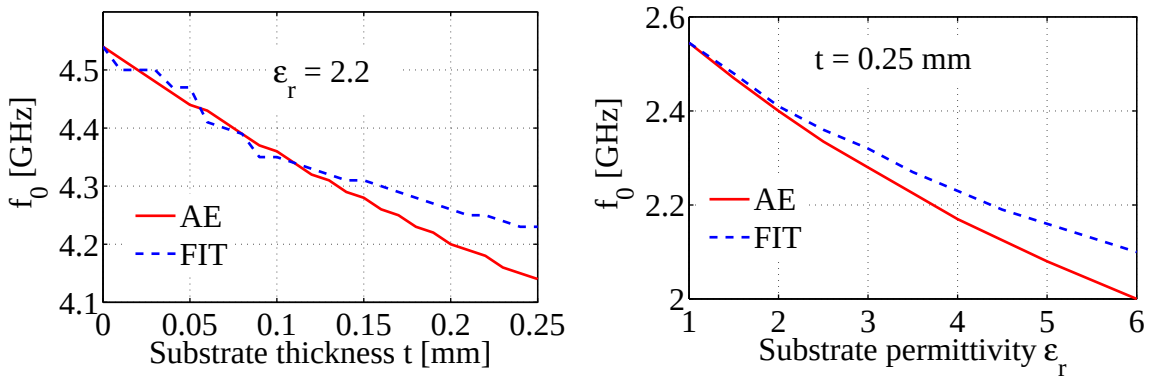
where

$$x = 10 \cdot t/p. \tag{7.11}$$

t is the thickness of the substrate, p is the periodicity and N is an exponential factor that depends on the geometry of the unit cell. For square loop arrays, N is approximately 1.8 [121]. For the square loop FSS the value of the susceptance is, therefore, modified as:

$$B_C = 4 \cdot \varepsilon_{eff} \cdot \frac{1}{Z_0} \left(\frac{d}{p}\right) F\left(p,\, g,\, \lambda\right). \tag{7.12}$$

To investigate the effect of the dielectric substrate, the resonant frequency (f_0), which is the transmission resonance frequency, is calculated by the equivalent circuit model and by FIT. The results are plotted as a function of thickness variation in Fig. 7.8(a) and as a function of substrate permittivity in Fig. 7.8(b).



(a) (b)

Figure 7.8. (a) Transmission resonance frequency as a function of substrate thickness t for the square loop Array #3 of Table 7.1. (b) Transmission resonant frequency as a function of substrate permittivity ε_r for the square loop Array #4 of Table 7.1. Both curves are calculated using the analytical equations (AE) and the Finite Integration Technique (FIT) at normal incidence. $\theta = \varphi = 0°$.

It is shown in the figures that the deviations between the presented analytical expressions and the Finite Integration Technique increases with increasing the substrate thickness (see Fig. 7.8(a)) and with increasing the substrate permittivity (see Fig. 7.8(b)). The relative difference error in the resonant frequency (f_0) between FIT and AE is calculated for a substrate thickness of 0.25 mm and $\varepsilon_r = 2.2$ (see Fig. 7.8(a)) and for a substrate permittivity of $\varepsilon_r = 6$ and a substrate thickness of 0.25 mm (see Fig. 7.8(b)) as are 2.12 % and 4.7 %, respectively.

Since the relative difference in the the resonant frequency (f_0) between FIT and AE less than 5%, then the results of the analytical expressions are considered to be accurate for a substrate thickness less than 0.25 mm and substrate permittivity ε_r between $1 \leq \varepsilon_r \leq 6$.

Since the equivalent circuit model is most accurate for a thin and low permittivity sub-

strate, for the fabricated RF power harvester a substrate thickness of 0.125 mm with a relative permittivity equal to 3.0 is chosen.

Having established the validity of the analytical expressions, we now proceed with the investigation of a gridded square-loop FSS. The addition of the grid to the loops is crucial for RF power harvesting since the diodes will be integrated in the grid.

7.3 Gridded Square Loop FSS

The frequency selective surface that will be used to harvest RF power is the gridded square-loop FSS (see Fig. 7.2(a)). A grid is added to the square-loop FSS introduced in the previous section. The main advantage of this structure is that, when it is loaded with rectifiers, the grid will direct the DC current to the collection point. Moreover, it provides additional physical parameters (width of the grid and grid-loop separation) that can be tuned to control the response of the FSS.

7.3.1 Equivalent Circuit Model

The equivalent circuit model introduced in the previous section is extended for the grid to predict the transmission and the reflection band behaviour for a Gridded Square-Loop (GSL) FSS. The FSS unit cell of the GSL-FSS is shown in Fig. 7.9(a).

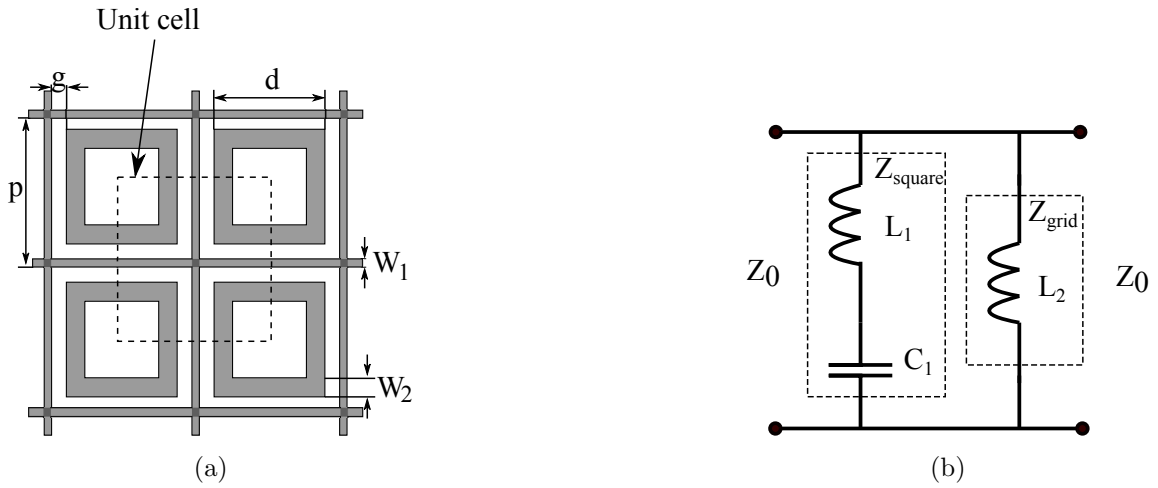


Figure 7.9. Unloaded (i.e. without diodes) gridded square loop configuration (a) and its unit cell equivalent circuit model (b).

In Fig. 7.9(a), p is the periodicity, g is the gap width between the grid and the square loop, W_1 is the strip width of the grid and W_2 and d are the strip width and the

length of the square loop, respectively. The equivalent electric circuit model introduced in [119, 124] is shown in Fig. 7.9(b). Z_{fss} is the equivalent FSS unit cell impedance and is derived by considering two impedances in parallel:

$$Z_{fss} = \frac{Z_{grid}\ Z_{square}}{Z_{grid} + Z_{square}}. \tag{7.13}$$

Z_{square} is the square-loop impedance and is given by:

$$Z_{square} = j\left(X_1 - \frac{1}{B_1}\right), \tag{7.14}$$

Z_{grid} is the grid impedance given by:

$$Z_{grid} = jX_2, \tag{7.15}$$

where [119]

$$X_1 = 2Z_0\left(\frac{X_2X_3}{X_2 + X_3}\right), \tag{7.16}$$

$$X_2 = Z_0F_{TE,TM}\left(p, W_1, \lambda\right), \tag{7.17}$$

$$X_3 = Z_0\frac{d}{p}F_{TE,TM}\left(p, 2W_2, \lambda\right), \tag{7.18}$$

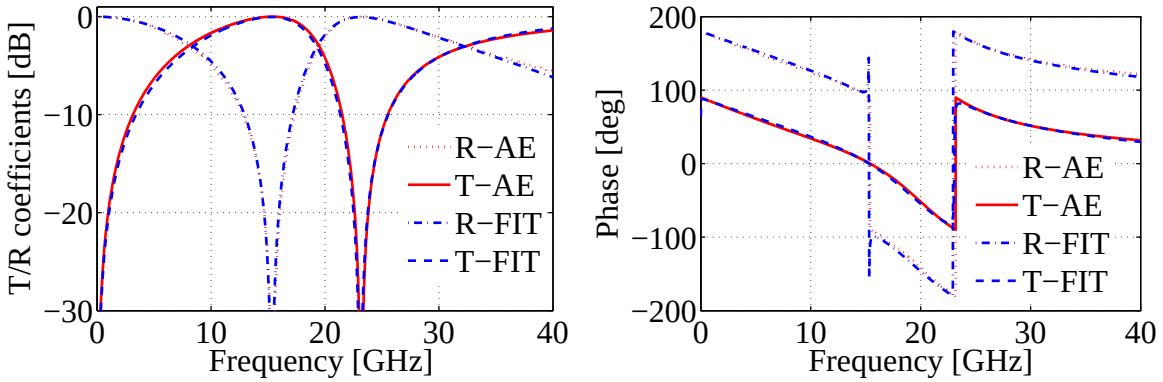
$$B_1 = \frac{2}{Z_0}.\epsilon_{eff}\ .\ \left(\frac{d}{p}\right)F_{TE,TM}\left(p, g, \lambda\right). \tag{7.19}$$

$F_{TE,TM}\left(p, g, \lambda\right)$ is a function of the incident angles θ and φ and depends on whether a TE incidence or TM incidence or if a combination of the two occurs. $F_{TE,TM}\left(p, g, \lambda\right)$ is calculated by using Eq. (7.4) to Eq. (7.7). Again, The FSS is supposed to be positioned in the xy-plane of a rectangular xyz coordinate system.

7.3.2 Model Verification and Waveguide Simulator Measurements

In this section, the equivalent circuit model presented in the previous section is tested by full-wave simulations and by measurements. The reflection and the transmission coefficients of a Gridded Square-Loop (GSL) FSS possessing the following dimensions: $p = 5.05\,\text{mm}$, $d = 3.7\,\text{mm}$, $g = 0.6\,\text{mm}$, $W_1 = 0.15\,\text{mm}$, $W_2 = 0.15\,\text{mm}$, are calculated by using the equivalent circuit model and the Finite Integration Technique. The GSL-FSS is positioned on a 0.027 mm thick substrate ($t = 0.027\,\text{mm}$) having a relative

permittivity of $\epsilon_r = 3.0$. Fig. 7.10 shows the magnitude (a) and the phase (b) of the reflection (R) and transmission (T) coefficients as a function frequency for the gridded square-loop array calculated by the FIT and by the Analytical Expressions (AE) for a TE incidence with $\theta = 0°$, and $\varphi = 0°$.



(a) (b)

Figure 7.10. Magnitude (a) and phase (b) of reflection (R) and transmission (T) coefficients as a function frequency for a gridded square loop array with $p = 5.05\,\text{mm}$, $d = 3.7\,\text{mm}$, $g = 0.6\,\text{mm}$, $W_1 = 0.15\,\text{mm}$, $W_2 = 0.15\,\text{mm}$, $t = 0.027\,\text{mm}$, $\epsilon_r = 3.0$. TE incidence with $\theta = 0°$, and $\varphi = 0°$.

To validate the accuracy of the analytical expressions with measurements, the waveguide-simulator technique is used [125]. The reflection and transmission coefficients versus frequency for a GSL-FSS unit cell with $d = 31\,\text{mm}$, $g = 2\,\text{mm}$, $W_1 = 1\,\text{mm}$, $W_2 = 4\,\text{mm}$ are calculated and compared to waveguide simulator measurements. The chosen dimensions of the FSS unit cell are dictated by the waveguide aperture used for measurements, see Fig. 7.11.

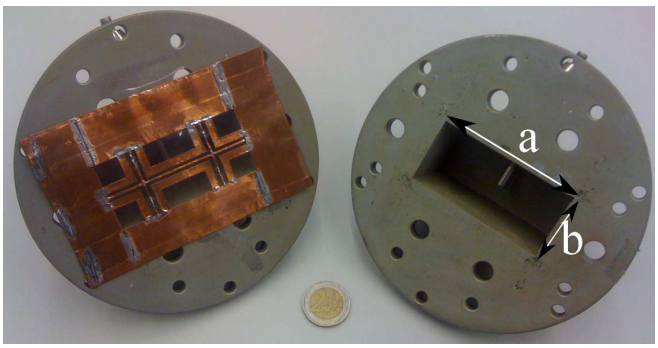


Figure 7.11. Waveguide used for measurements and the fabricated two unit cells matching the waveguide aperture.

The rectangular waveguide (SIVERS-LAB PM 7325 S-04) has side lengths $a = 71.5$ mm and $b = 34$ mm. The waveguide aperture contains two GSL-FSS unit cells. The lower and the higher cut-off frequencies of the waveguide are 2.5 GHz and 3.9 GHz, respectively. The FSS unit cell was designed to create a reflection band around 3.2 GHz.

The waveguide simulator reproduces the behaviour of an infinite array by exploiting the symmetry of a unit cell. The walls of the waveguide act like periodic boundary conditions around the elements [125]. The decomposition of the TE_{10} mode into two plane waves in a rectangular waveguide having the widest dimension a as introduced in [126] is shown in Fig. 7.12.

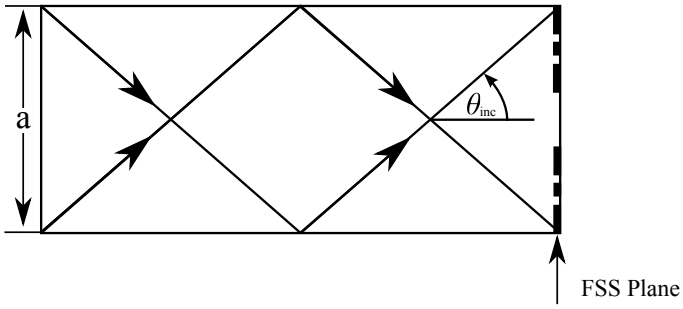

Figure 7.12. Decomposition of the TE_{10} mode into two plane waves in a rectangular waveguide having the widest dimension a as introduced in [126].

The incident angle θ_{inc} on the FSS plane, of the fundamental TE_{10} mode, traveling inside the waveguide, depends on: the operating frequency f, the widest dimension of the rectangular waveguide a, and the free-space speed of light c. The angle of incidence is calculated from the following expression [127]:

$$\theta_{inc}\,[\text{degrees}] = \frac{180}{\pi}\cos^{-1}\left(\frac{\sqrt{\left(\frac{2\pi \mathrm{f}}{\mathrm{c}}\right)^2 - \left(\frac{\pi}{\mathrm{a}}\right)^2}}{\frac{2\pi \mathrm{f}}{\mathrm{c}}}\right). \tag{7.20}$$

From Eq. (7.20), at a frequency of 3.2 GHz, using $a = 71.5$mm, the incident angle on the FSS surface is $\theta_{inc} = 41°$. It should be mentioned that, in order to fit the two fabricated unit cells in the waveguide aperture, a slight asymmetry in the fabricated unit cell is introduced. Fig. 7.13 shows the waveguide simulator setup and specifies this asymmetry.

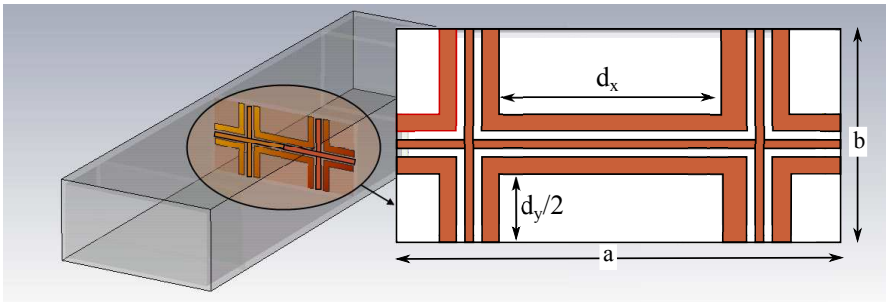

Figure 7.13. Waveguide simulator setup of two unit cells of a GSL-FSS array. $d_x = 31$ mm, $d_y = 30$ mm.

Referring to Fig. 7.13, the dimensions chosen for the fabricated GSL-FSS are $d_y = 30$ mm and $d_x = 31$ mm. With the introduction of the small asymmetry in the unit cell, the elements are now matching the waveguide aperture.

Figure 7.14 shows the simulated and measured magnitudes of the transmission (a) and reflection (b) coefficients as a function of frequency at an angle of incidence of $\theta_{inc} = 41°$.

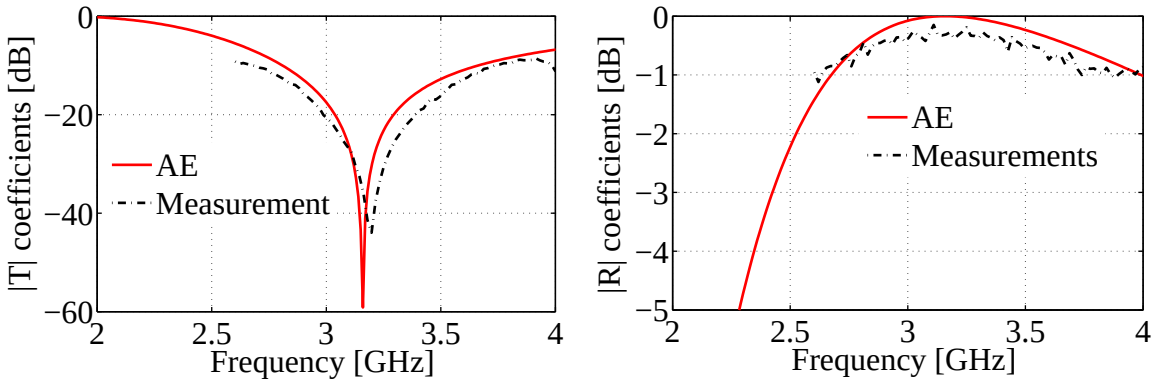

Figure 7.14. Magnitude of the transmission (a) and reflection (b) coefficients versus frequency for a GSL-FSS unit-cell with $d = 31$ mm, $g = 2$ mm, $W_1 = 1$ mm, $W_2 = 4$ mm. TE with $\theta_{inc} = 41°$, as simulated with AE and measured using a waveguide simulator.

As depicted in the figure, a frequency offset exists between the measurement results and the simulated results. This frequency offset is believed to be due to the asymmetry introduced by the fabricated two unit cells in order to match the waveguide aperture. It should be mentioned that the two waveguide adapters (see Fig. 7.11) are tightly fastened to create a good galvanic contact between the unit cell edges and the waveguide walls. Referring to Fig. 7.14(a), the resonance frequency for the measured transmission

coefficient is $F_{T_{measured}} = 3.197$ GHz, while the resonance frequency for the transmission coefficients calculated by the equivalent circuit model is $F_{T_{AE}} = 3.16$ GHz, which results in an offset of 37 MHz. The relative difference frequency offset $\delta\,(\%)$ is calculated as follows:

$$\delta\,(\%) = 100\left(\frac{F_{T_{measured}} - F_{T_{AE}}}{F_{T_{measured}}}\right), \tag{7.21}$$

which is equal to 1.15 %. Since the relative difference frequency offset $\delta\,(\%)$ is less than 5 %, the equivalent circuit model is considered to be accurate and will be extended in the following section for the insertion of lumped elements.

7.4 Loaded Gridded Square-Loop FSS

The basic principle of creating a RF frequency selective surface harvester is to insert diodes in the grid. By resonating the FSS and rectifying the resonating RF currents, DC power is obtained. The harvested DC current is collected at the DC collection lines as shown in Fig. 7.2(a). In this section, the equivalent circuit model introduced in the previous section will be extended to account for the rectifiers (Schottky diodes) that are inserted to the grid.

7.4.1 Equivalent Circuit Model

Figure 7.15(a) shows a loaded unit-cell configuration. The reason for having two rectifiers for each polarization in the unit cell as indicated in the figure will be explained further on.

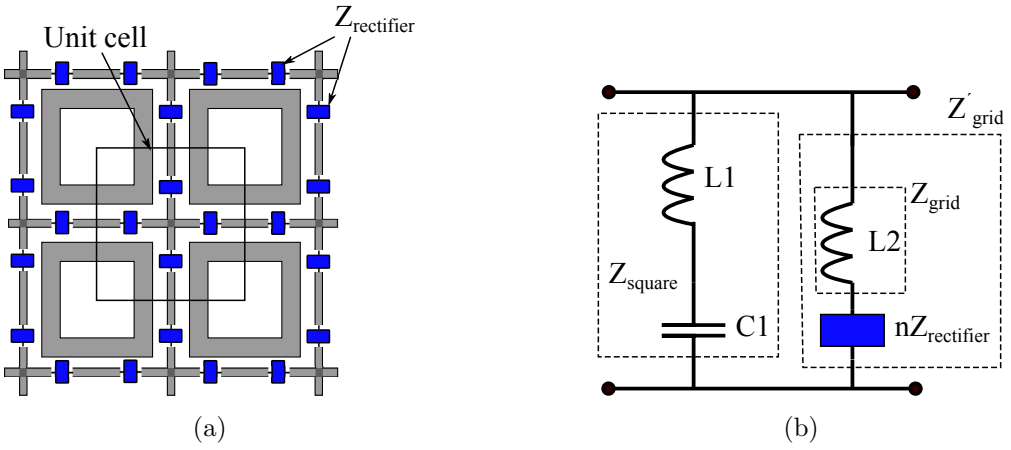

Figure 7.15. Loaded gridded square loop configuration (a) and its unit cell equivalent electric circuit model (b).

Since the rectifiers will be integrated to the grid, the equivalent impedance of the rectifier $Z_{rectifier}$ is placed in series with the grid impedance Z_{grid} in the equivalent unit-cell circuit, see Fig. 7.15(b). Combined, the grid impedance Z_{grid} and the rectifier's impedance $nZ_{rectifier}$ are denoted by Z'_{grid}. n is the number of lumped elements (Schottky diodes) in the unit cell for each polarization. For the unit cell shown in Fig. 7.15(a), two lumped elements for each polarization are shown, consequently n is set to 2. It should be mentioned that in the final design one rectifier per unit cell will be used for each polarization. The reason for having two rectifiers (Schottky diodes) has to do with the practical implementation of measuring a unit cell in a waveguide simulator. The unit-cell as implemented in the waveguide simulator is indicated in Fig. 7.15(a) and is chosen in this way to prevent the creation of a lumped element between the edges of the grid and the waveguide walls. Using a single rectifier would result in needing half a rectifier in the waveguide simulator at the edges of the grid of a unit cell as indicated in Fig. 7.16.

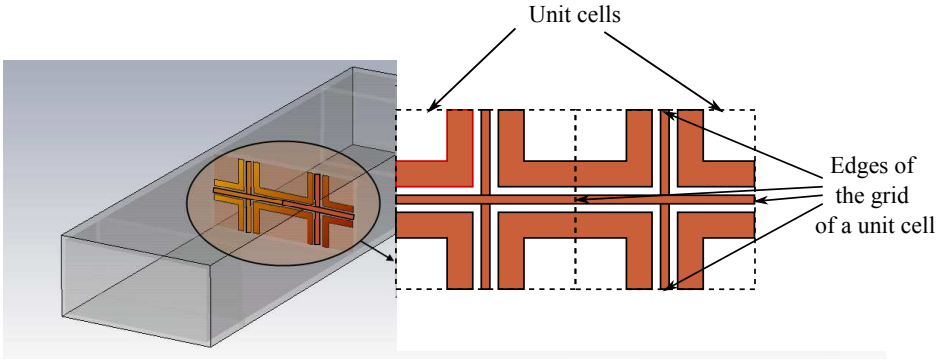

Figure 7.16. Two unit cells fitting the aperture of the waveguide simulator.

It has been demonstrated in Sec. 2.2 that the equivalent impedance of a diode, at an operating frequency below 3 GHz (see Figs. 2.2, 2.3 and 2.8) and at an input power level between -20 dBm and -5 dBm (see Fig. 2.9), may be modeled (linearized) as a series R-C circuit.
For a FSS loaded with an R-C series circuit, the FSS equivalent unit-cell impedance Z_{fss} is calculated from Eq.(7.13), where the grid impedance is extended to

$$Z'_{grid} = jX_2 + nZ_{rectifier} \tag{7.22}$$

$$= n\left[R_{rectifier} + j\left(\frac{X_2}{n} - \frac{1}{B_{rectifier}}\right)\right], \tag{7.23}$$

where $B_{rectifier} = \omega C_{rectifier}$, ω being the angular frequency. With expression 7.23 an FSS having a grid loaded with any combination of R, L and C can be analysed.

7.4.2 FSS Loaded with Capacitors

We start with a unit cell that is loaded with two capacitors in series with the grid inductance L2 (see Fig. 7.15(b)). Figures 7.17 and 7.18 show the transmission and reflection coefficients versus frequency respectively, for the thus loaded FSS for different capacitance values.

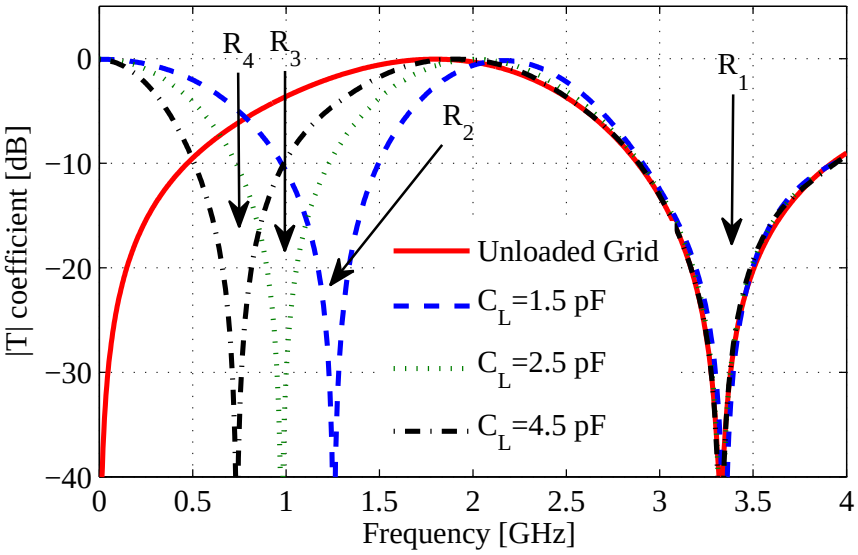

Figure 7.17. Magnitude of the transmission coefficients versus frequency for a gridded-square-loop unit-cell with $d = 31$ mm, $g = 2$ mm, $W1 = 1$mm, $W2 = 4.5$ mm. TE with $\theta_{inc} = 0°$.

In Fig. 7.17, the 'Unloaded Grid' label represents the gridded square loop investigated in Sec. 7.3. It is shown in the figure that for the unloaded grid (solid curve), only one reflection band is observed. The centre of the reflection band is indicated with R_1. This single reflection band is due to the capacitor C_1 placed in series with the inductor L_1 (see Fig. 7.15(b)), which creates a resonance at R_1. However, when the grid is loaded with a capacitor, for instance 1.5 pF (dashed curve) a second reflection band is generated around $R_2 = 1.25$ GHz. Consequently the loaded FSS is characterized by two reflection bands centered around R_1 and R_2. When the capacitance value is increased to 2.5 pF (dotted curve) and to 4.5 pF (dashed-dotted curve) two new reflection bands centered around R_3 and R_4 are created. Increasing the capacitance value thus results in a shifting of the additional reflection band to the lower frequencies. The created second resonance R_2 is due to the capacitor C_2 placed in series with the inductor L_2 (see Fig. 7.15(b)).

From the reflection coefficients shown in Fig. 7.18, it is observed that the unloaded grid (solid curve) resonates around 1.65 GHz (T_1). When a 1.5 pF capacitor is inserted

in the grid, the transmission band is shifted to the right to form a shifted-reflection band T_2. If the capacitance value is further increased to 2.5 pF and to 4.5 pF, the transmission band shifts back to the left toward T_3 (dotted curve) and T_4 (dashed-dotted curve). It is clear from the transmission and reflection bands that, when the capacitance value is further increased to a relatively high value, the loaded FSS will behave like the unloaded one, since high-valued capacitances will behave like a short circuit at the considered frequencies.

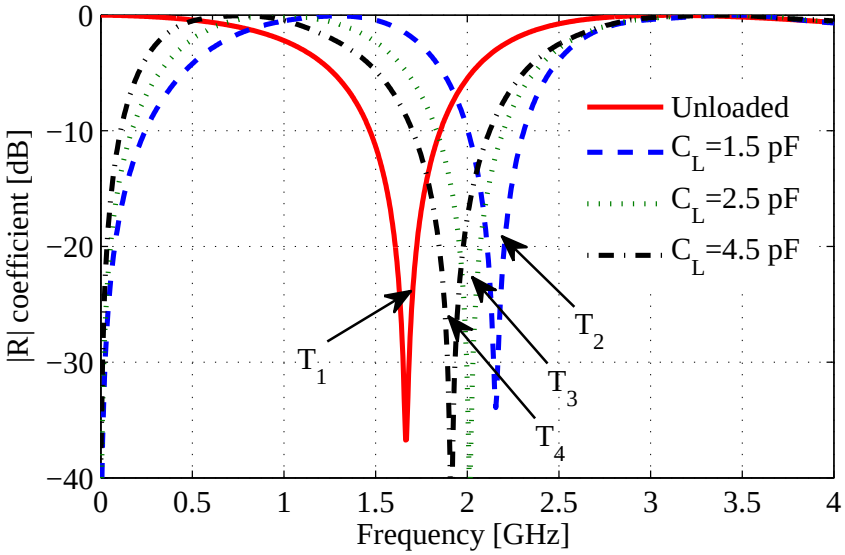

Figure 7.18. Magnitude of the reflection coefficients versus frequency for a gridded-square-loop unit-cell with $d = 31$ mm, $g = 2$ mm, $W1 = 1$mm, $W2 = 4.5$ mm. TE with $\theta_{inc} = 0°$.

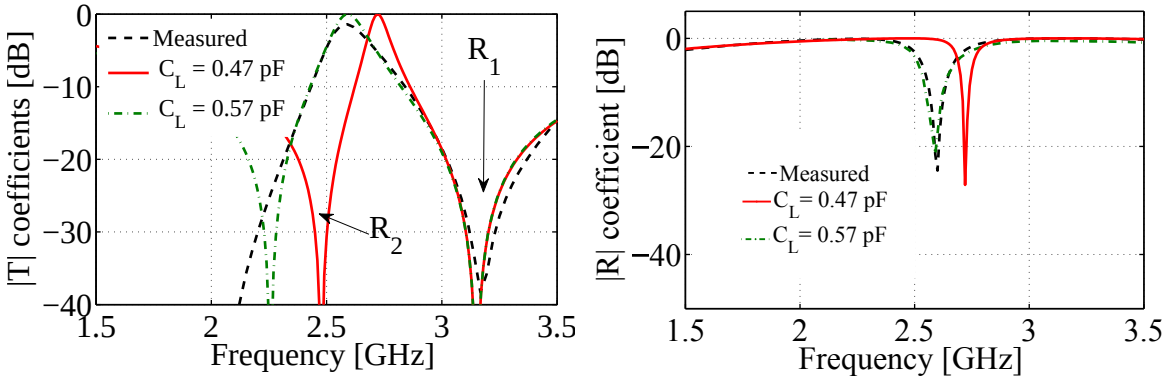
A capacitively loaded GSL-FSS prototype is designed, simulated, manufactured as two slightly asymmetric unit-cells and measured. The gridded square loops are printed on a 0.125 mm thick substrate having a relative permittivity $\epsilon_r = 3.0$ and are loaded with four 0.47 pF capacitors in total positioned in the vertical direction. Fig. 7.19 shows the calculated and the measured transmission (Fig.7.19(a)) and reflection (Fig. 7.19(b)) coefficients as a function of frequency.

It is shown in Fig. 7.19(a) that the first resonance in the transmission coefficients around the centre of the reflection band R_1 is predicted by the analytical expressions. A slight deviation is observed between the results of the analytical expressions and the measured results, which is believed to be due to the asymmetry introduced in the manufactured unit cells to fit the waveguide aperture. However, for the second resonance centered around R_2, which is due to the capacitive load introduced in the grid, a large difference is observed in the centre frequency between the simulated and

the measured results for a capacitive load of 0.47 pF. A similar shift is observed in the transmission resonance shown in Fig. 7.19(b). This difference in the centre frequency of the measured responses is within the tolerance of the capacitor used for measurements (± 0.25pF) [128]. Within the tolerance value of the measured capacitor, it is shown in the same figures that for a capacitive load of 0.57 pF, the results of the analytical expressions match the measured results more closely.



(a) (b)

Figure 7.19. Magnitude of the transmission (a) and reflection (b) coefficients versus frequency for a capacitively loaded GSL-FSS simulated using the presented analytical expressions and measured using the waveguide simulator. $d = 31$ mm, $g = 2$ mm, $W_1 = 1$ mm, $W_2 = 4$ mm. TE with $\theta_{inc} = 41°$, $C_L = 0.47$ pF.

With the design strategy and the analytical expressions considered to be sufficiently validated, we now proceed to the design of a RF power harvesting FSS.

7.5 FSS Power Harvesting - Final Design

For the validation of the new concept, only harvesting power from a vertically polarized wave is considered since this simplifies the measurement setup. Consequently, the Schottky diodes are only placed in the vertical direction. At an operating frequency of 1GHz, the impedance of the diode is calculated for different P_{in} from the analytical expressions presented in Sec. 2.2. This impedance corresponds to an equivalent series circuit of a resistor and a capacitor. For an input power level P_{in} between $-14\,\text{dBm} \leq P_{in} \leq -5\,\text{dBm}$ the real part R of the input impedance and the capacitive part C are shown in Table 7.2.

Table 7.2. Real and capacitive parts of the HSMS-2820 Schottky diode as a function of input power level. The operating frequency is 1 GHz.

P_{in} [dBm]	R [Ω]	C [pF]
-14	5.66	1.17
-11	6.322	1.18
-8	10.85	1.19
-5	39.73	1.21

The rectifier's equivalent impedance is used in the equivalent circuit model introduced in the previous section to predict the reflection and the transmission behavior as a function of frequency. The reflection and the transmission bands will be used as the RF power harvesting bands. The parameters of the GSL-FSS are optimized for the new reflection band introduced by the loading (R_2 see Fig. 7.20(a)) to resonate around 1 GHz. Figure 7.20 shows the magnitude of the transmission (a) and reflection (b) coefficients as a function of frequency for the final GSL-FSS design for different RF input power levels. For every input power level the corresponding rectifier's impedance as stated in Table 7.2 is used. The equivalent circuit model is used for simulations.

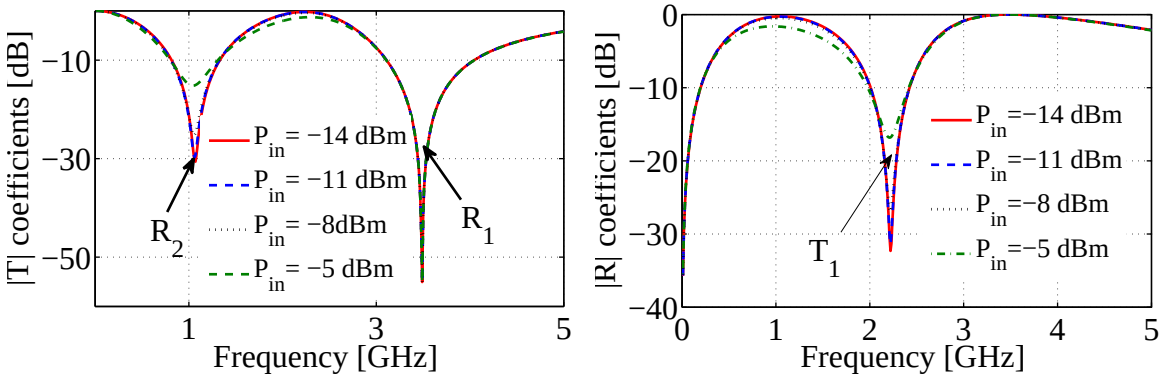


Figure 7.20. Magnitude of the transmission (a) and reflection (b) coefficients versus frequency for different P_{in}, TE incident wave $\theta_{inc} = 0°$. The optimized parameters (see Fig. 7.9(a)) are $d = 31$ mm, $g = 2.5$ mm, $W_1 = 2$ mm, and $W_2 = 5$ mm.

The Figures (Figs. 7.20(a) and 7.20(b)) show that for an input power level increasing from −14 dBm to −5 dBm the amplitudes of the transmission and reflection coefficient at resonances decrease a bit. Up to -8 dBm the values stay more or less constant. This is due to the large increase of the real part of the rectifier's impedance at higher power levels, see Table 7.2. The centre of frequency bands R_1 and R_2, do not shift for both transmission and reflection bands, which makes the system more robust for different power levels. The main reason for choosing the commercially available Schottky diode

HSMS 2820 is its low resistive part of the input impedance at low input power levels. To investigate the effect of the direction of arrival (DoA) of the incident wave, the equivalent circuit model for the loaded GSL-FSS unit cell is used to calculate the reflection and the transmission coefficients for different angles of incidence for a TE polarized wave. The input impedance of the rectifier (see Table 7.2) at an input power level of −5 dBm ($R = 39.73\,\Omega$, $C = 1.21\,\text{pF}$) is used in the simulations. Figures 7.21(a) and 7.21(b) show the reflection and the transmission coefficients as a function of frequency for different angles of arrival.

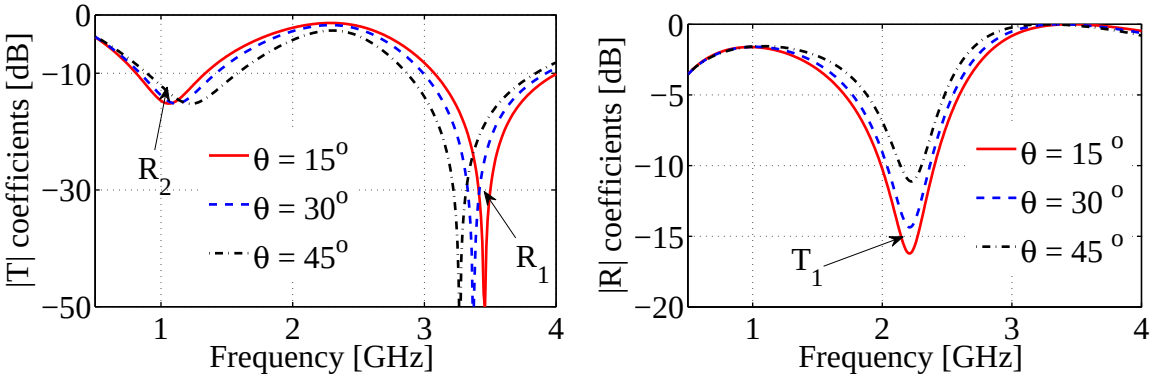

Figure 7.21. Magnitude of the transmission (a) and reflection (b) coefficients versus frequency for different incident angles for $P_{in} = -5$ dBm. The optimized parameters (see Fig. 7.9(a)) are $d = 31$ mm, $g = 2.5$ mm, $W_1 = 2$ mm, and $W_2 = 5$ mm.

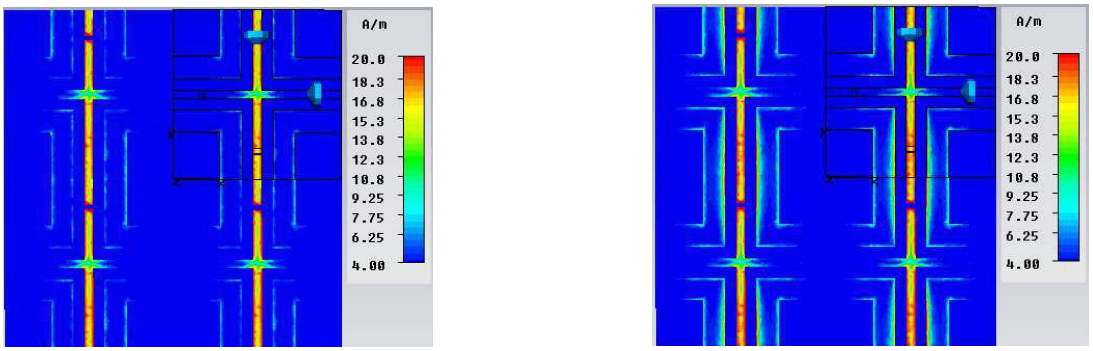
Figure 7.21(a) shows that the centre of first reflection band (R_1) shifts to the left (lower frequencies) when the incident angle increases, while the centre of the second reflection band (R_2) shifts to the right. Fig. 7.21(b) shows that the magnitude of the transmission coefficients increases when the angle of incidence increases. Considering -10 dB as a threshold for the reflection and the transmission coefficients amplitude, one can conclude from the figures that for an incident angle less than 45°, the reflection and the transmission resonance frequencies stay within the required threshold. Thus for the Schottky diode (HSMS-2820), and for an input power level increasing from -15 dBm to -5 dBm, the reflection and the transmission frequency bands are robust (i.e. will not be affected) for different angles of incidence.

7.5.1 FSS Current Density

To visualize the resonance phenomena, Figs.7.22(a) and 7.22(b) show the magnitude of the surface current distribution at the centre of the reflection frequency band (1 GHz) (a) and at the centre of transmission frequency band (2.2 GHz) (b), simulated with CST

Microwave Studio. It is clear that for a normal incident, TE polarized wave ($\theta_{inc} = 0°$), the current density is concentrated in the grid and not in the loops, which is desired for power harvesting since the diodes are integrated in this grid. We will validate the possibility to harvest power at the centre of the reflection band ($R_2 = 1$ GHz).



(a) (b)

Figure 7.22. Magnitude of the surface current distribution at the centre of the reflection band $R_2 = 1$ GHz (a) and at the centre of the transmission band $T_1 = 2.2$ GHz (b). The GSL FSS dimensions are: $d = 31$ mm, $g = 2.5$ mm, $W_1 = 2$ mm and $W_2 = 5$ mm. TE with $\theta_{inc} = 0°$

Since, for the designed GSL-FSS, the maximum surface current density is concentrated in the grid, and the simulations indicate that the GSL-FSS is robust for different input power levels and for different angles of incidence (see Figs. 7.20 and 7.21), two gridded square loop frequency selective surfaces have been manufactured and tested. The first prototype is a 3×3 gridded square-loop FSS. The second prototype is a 5×5 gridded square-loop FSS. Both prototypes are shown in Fig.7.23.

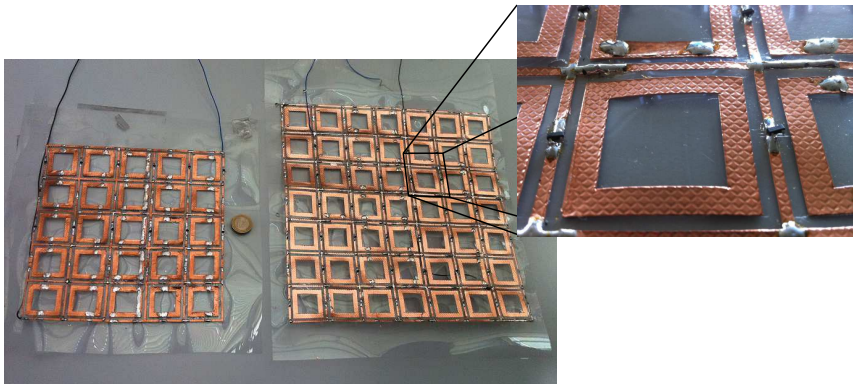


Figure 7.23. Manufactured 3×3 and 5×5 prototypes with $d = 31$ mm, $g = 2.5$ mm, $W_1 = 2$ mm and $W_2 = 5$ mm. Inset showing the soldered diodes in more detail.

As is shown in the figure, both designs are surrounded by a ring of unloaded unit cells to preserve the FSS properties i.e. the coupling between the elements. Both prototypes are printed on a 0.125 mm thick substrate having a relative permittivity equal to 3.0.

7.5.2 RF-Power Transport Measurement Results

The manufactured prototypes are loaded with Schottky diodes, 12 Avago HSMS-2820 [43] diodes for the 3×3 FSS and 30 diodes for the 5×5 FSS. The diodes are placed in the vertical direction to harvest power from TE polarized incident waves. The DC output voltage is measured across an open circuit ($R_L = \infty$) and across a $1\,k\Omega$ resistor ($R_L = 1\,\mathrm{k}\Omega$) connected to the top-left and bottom-right corners with the aid of the DC collection lines as shown in Fig. 7.2(a).

The power density S_{RF} available at a distance R from a transmitter with a transmitted power P_t and antenna transmit gain G_t is:

$$S_{RF} = \frac{P_t G_t}{4\pi R^2} \tag{7.24}$$

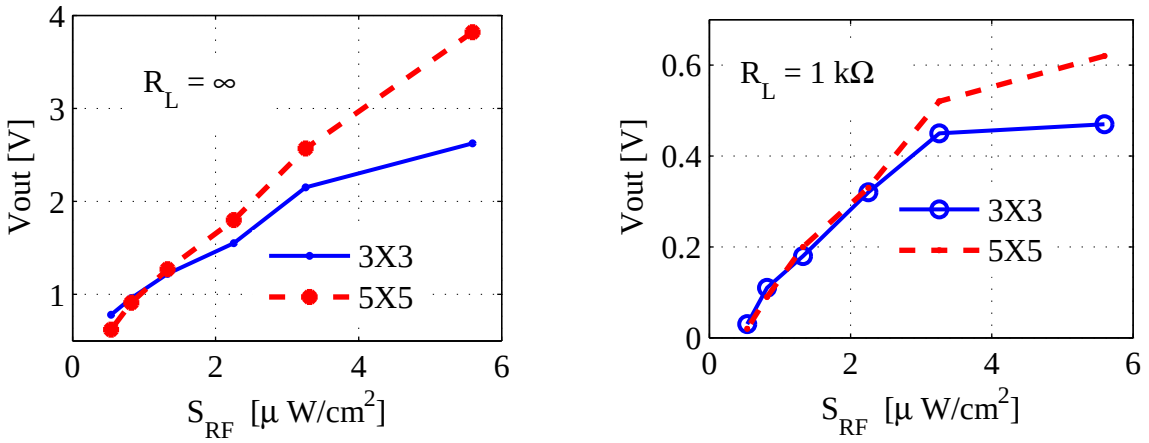
The RF power captured by the FSS surface P_{RF} is assessed using the following equation,

$$P_{RF} = S_{RF} A_{Physiscal}, \tag{7.25}$$

where $A_{Physical}$ is the physical area of the manufactured prototypes. Actually $P_{RF} = S_{RF} A_e$, where A_e is the effective area of the FSS. The physical area will in general be larger than the effective one. By approximating A_e by $A_{Physical}$, we will ensure a conservative assessment of the RF-to-DC power conversion efficiency. The physical area is calculated as follows: $A_{Physical} = ((M+1)p + g + W_1)^2$ (see Fig. 7.9(a)), where M is the number of active cells in the grid. $M = 3$ for the 3×3 FSS and $M = 5$ for the 5×5 FSS.
The RF-to-DC Power Conversion Efficiency (PCE) is then defined as:

$$\eta_{RF/DC} = \frac{V_{out}^2}{R_L} . \frac{1}{P_{RF}}, \tag{7.26}$$

where V_{out} is the measured output voltage across the load resistance R_L. Figure 7.24 shows the open-circuit output voltage (a) and the output voltage across a $1\,\mathrm{k}\Omega$ load (b) as a function of power density available at the FSS surface. It is observed from Fig. 7.24 that both prototypes (3×3 and 5×5) are able to produce an open-circuit output voltage higher than 1V at an available power density larger than $1\mu\,\mathrm{W/cm^2}$.



(a) (b)

Figure 7.24. Measured open circuit output voltage (a), and output voltage across 1 kΩ load (b) as a function of the power density S_{RF}.

Figure 7.25 finally shows the calculated RF-to-DC power conversion efficiency as a function of the input power density. It is shown in the figure that the 3×3 fabricated FSS prototype is more efficient than the 5×5 fabricated FSS prototype. The maximum RF-to-DC conversion efficiency for both prototypes is found at an available power density of 3.2 μ W/cm^2, and is equal to 25 % for the 3×3 prototype and to 16 % for the 5×5 prototype. This is believed to be due to the larger losses and due to the diode cascading saturation effect as previously noticed is Chapter 2 (see Fig. 2.15).

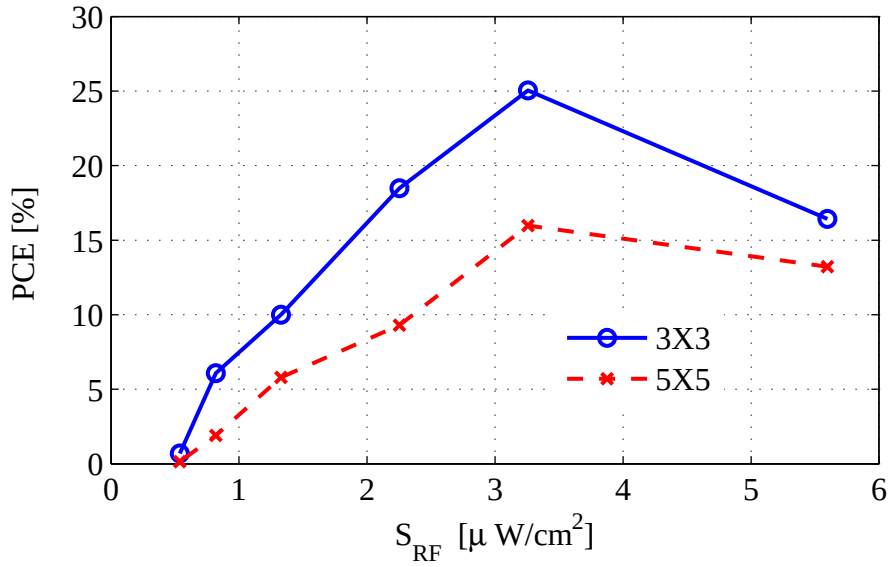


Figure 7.25. RF-to-DC Power Conversion Efficiency (PCE) versus the available power density (S_{RF}).

7.6 Conclusions

The concept, modeling, design, realization and measurement of frequency selective surfaces to harvest RF power is demonstrated in this chapter. The resulting harvester can potentially capture arbitrarily polarized waves, at two different frequency bands, namely the transmission and the reflection bands. A simple and easy-to-implement equivalent circuit model, extended for the insertion of linear lumped components, is investigated, validated and employed for the design. A maximum RF-to-DC power conversion efficiency of 25% at $3.2\mu\,\mathrm{W/cm^2}$ available power density is measured for a 3×3 elements harvester. When the size of the FSS is increased to 5×5 elements, the maximum RF-to-DC power conversion efficiency at the same power density decreases to 16 %, the reason for the decrease in the power conversion efficiency is currently under investigation. This effect is assumed to be due to the the diode cascading saturation effect. The main potential of the novel RF harvester is that it can be implemented for large area RF power harvesting applications. The novel application is suitable for an energy-harvesting glass that can be used in buildings. It could also be implemented in wall papers.

Chapter eight

Conclusions and Recommendations

This thesis addresses the analysis and design of far-field RF power harvesting devices. The potential application of this technology is envisaged in powering wireless sensors that are used in smart buildings. The 'smartness' is found in measuring parameters like e.g. light, temperature and presence of people and acting upon the gathered information (switching off light, turning down heating) thus saving energy consumption. Powering these sensors wirelessly is a challenge due to the restricted transmit power levels allowed. Therefore a highly efficient rectenna design is crucial. It is then important to develop accurate and easy to implement design models for rectenna subsystems, including the rectifier and the antenna. In addition, it is essential to develop a design strategy that copes with the low power density constraint.

A new design strategy has been developed. It is found that we need to optimize a rectenna for a low input power level (-10 dBm), conjugate match the antenna to the rectifier and design the rectifier circuit for a minimum real part and maximum imaginary part $|X_{rec}| \gg |R_{rec}|$. In implementing this design strategy, it has been found that the antenna can be miniaturized up to a level that the radiation resistance still dominates the loss resistance. Consequently, a compact and highly efficient rectenna system that is matched for a broad input power band can be designed.

An analytical model to determine the input impedance and the output voltage of a high-frequency, rectifying Schottky diode is discussed. Based on this model, the influence of the contact resistance and the saturation current on the DC output voltage is analyzed. It has been shown that a higher saturation current and/or a lower contact resistance will result in a higher output voltage. Based on these observations, the commercially available Schottky diode HSMS-2852 has been selected for the rectenna design.

8.1 Conclusions

The first rectenna system presented in this thesis is a 50 Ω rectenna system, where a modified 50 Ω Yagi-Uda antenna is introduced to realize a reasonable gain (4 dBi) over a frequency bandwidth covering the Digital Television broadcasting frequency bands (475 MHz - 794 MHz). The modified Yagi-Uda antenna is implemented in the rectenna design, using a lumped-element matching network to match the antenna impedance to the complex input impedance of a voltage doubling rectifier. The suggested 50 Ω rectenna system shows an increased power conversion efficiency compared to state-of-the-art results reported in the open literature, see Table 8.1.

Table 8.1. Comparison of the 50 Ω rectenna system with results published in the open literature that are based on commercially available discrete diodes.

Ref.	Pin [dBm]	Frequency [MHz]	Resistive Load kΩ	Discrete rectifier	PCE (%)
[66]	-10	866.5	3	HSMS285C	24%
[19]	-10 -20	1800	2.4	HSMS2850	38% 15%

This work (50Ω rectenna)	-10 -20	868	10	HSMS2852	49.7% 31.6%

The second rectenna system presented in this thesis deals with antenna structures intended for a direct conjugate matching to the rectifier, thus omitting an impedance matching network, that will lead to a higher power conversion efficiency (less loss) and a more compact design (fewer lumped elements). For this reason, different antenna structures are investigated that are capable of being tuned to the required complex impedance by changing some geometrical features. The validity range (length and width) of the expression for the impedance of a strip dipole antenna has been extended by deriving new fitting equations. Next, the accuracy of an existing strip-folded dipole antenna has been improved by using the improved strip-dipole antenna model. Evolving from this latter antenna, a new, electrically small antenna type has been invented that allows for tuning the complex input impedance and the radiation efficiency independently.

The new modified loop antenna is used for a rectenna design, and is co-designed with a commercially available Schottky diode based rectifier and with an integrated custom-made rectifier. Both realized rectennas demonstrate characteristics better than the state

of the art as reported in the open literature, see Tables 8.2 and 8.3.

Table 8.2 gives a short overview of the state-of-the-art results for rectennas as reported in the literature that use commercially available diodes for RF-to-DC power conversion.

As a proof of principle, a complete rectenna system is presented where a commercially available power management circuit is used to power a temperature and humidity sensor. The average DC output power and the system's RF to DC conversion efficiency are measured, and compared to those measured for a commercially available rectenna

system operated under the same conditions. It is shown that the commercially available rectenna system fails to operate at low power levels (≤ -6dBm) while the presented system can operate at an RF input power level as low as -13 dBm. At an input power level of 0 dBm, the power conversion efficiency of the commercially available system does not exceed 19 %, while the power conversion efficiency of the presented system reaches 40 %, resulting in more than 20 % improved power conversion efficiency.

Finally, for large-area RF power harvesting applications, the concept, modeling, design, realization and measurement of frequency selective surfaces equipped with Schottky diodes to harvest RF power is demonstrated. A simple and easy-to-implement equivalent circuit model, extended for the insertion of linear lumped components, is investigated, validated and employed for the design. A 3×3 and a 5×5 RF harvesting FSS have been designed, fabricated and measured. An RF to DC conversion efficiency of 25 % for the 3×3 RF harvester and 16% for the 5×5 RF harvester are measured at an incident power density of $3.2\,\mu\mathrm{W/cm^2}$. The novel application is suitable for an energy-harvesting glass that can be used in buildings. It could also be implemented in wall papers.

8.2 Recommendations

In this thesis different rectenna topologies and different methods to match the impedance of the rectifier to that of the antenna have been reported. In addition, harvesting RF power for large areas using frequency selective surfaces was introduced. Possible directions for future research include:

- **Power and data transfer**: The introduced rectenna topologies collect the RF power and convert it into DC power. From a system perspective, a second antenna is needed for communication purposes, i.e. transfer of data. A dual port antenna [129] can be used for data and power transfer, one port can be used for communication purposes and the second port can be used for RF power harvesting. Also the rectifier can be used as a matching element for the communication port [130].

- **Environment independent rectennas**: The developed antennas in this thesis are characterized for a free-space environment. However, when the antenna is brought close to a metallic ground plane, its input impedance will deteriorate due to the coupling with the antenna image. Consequently, the matching between the antenna and the rectifier will deteriorate and the power conversion efficiency will decrease. To overcome this negative effect, Metamaterial (MTM) structures can be employed to design environment independent rectennas. Adding an MTM layer between the existing antenna and the metal object may maintain the antenna matching, and enhance the radiation characteristics. The properties of the

electromagnetic band gap (EBG) will make it possible to keep the dimensions of this layer small [131].

- **RF power harvesting using Frequency Selective surfaces**: We have experimentally verified in Chapter 7 that the use of Frequency Selective Surfaces to harvest RF power is feasible. We do need to investigate the relation between size and power conversion efficiency. Further, for the RF power harvesting glass application, optical transparency is needed. An optically transparent conductive film manufactured with a silver grid layer (AgGL) is used in [109] where an antenna with a radiation efficiency better than 85% is designed and measured. The reported optical transparency is 81.3%. The same technology could be used to develop the transparent RF power harvesting glass. Ideally, printed diodes should be available to fully exploit these advantages.

Appendix A

King-Middleton Second Order Method Investigation

A.1 King-Middleton Second-Order Method

The King-Middleton method is an approximate solution procedure for the second order Hallen's integral equation [70]. This method introduces two empirically found fitting expressions to calculate the input impedance of a cylindrical dipole antenna. The input resistance and the input reactance are calculated using Eq. (A.1) and Eq. (A.2), respectively.

$$R(kL, \frac{a}{\lambda}) = \sum_{m=0}^{4} \sum_{n=0}^{4} a_{mn} \left(kL\right)^m \left(\frac{a}{\lambda}\right)^{-n}, \tag{A.1}$$

$$X(kL, \frac{a}{\lambda}) = \sum_{m=0}^{4} \sum_{n=0}^{4} b_{mn} \left(kL\right)^m \left(\frac{a}{\lambda}\right)^{-n}, \tag{A.2}$$

where a_{mn} and b_{mn} are the coefficients shown respectively in Tables A.1 and A.2 corrected as indicated in [132]. These equations are valid for:

- $1.3 \leq kL \leq 1.7$, where k is the wave number and L is the half-length of the dipole.
- $0.0016 \leq \frac{a}{\lambda} \leq 0.01$, where a is the dipole radius and λ is the wavelength.

Table A.1. a_{mn} coefficients to be used in Eq. (A.1) to calculate the input resistance of a cylindrical dipole antenna.

A.1.1 Verification of the King-Middleton Equations by the Finite Integrating Technique

To verify the accuracy of the King-Middleton equations, CST Microwave Studio is used to calculate the impedance of a cylindrical dipole of half-length $= L = 0.2\lambda$ and for different cylindrical radii. The results are compared with the results of the King-Middleton expressions. Fig. A.1 shows the input impedance of the cylindrical dipole antenna for a radius of 2 mm $\left(\frac{a}{\lambda} = 0.002,\ \lambda = 1m\right)$.

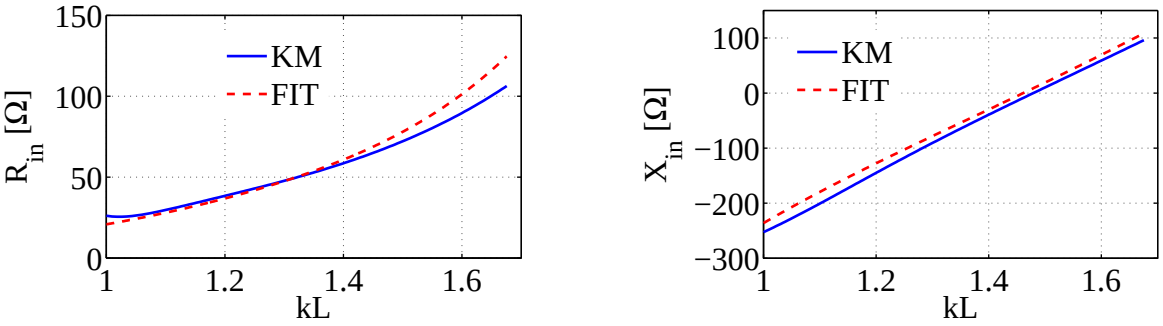

Figure A.1. Real (a) and imaginary (b) parts of the input impedance of a cylindrical dipole antenna calculated by the King-Middleton (KM) second order equations and by the Finite Integration Technique (FIT). Cylindrical radius = 0.002 m, $\left(\frac{a}{\lambda} = 0.002,\ \lambda = 1m\right)$.

It is clearly indicated in the figure that the King-Middleton equations can accurately predict the impedance of a thin cylindrical dipole with less than 10 % difference between the results calculated using the presented expressions and the results calculated using the FIT.

The radius of the cylindrical dipole in increased to 6 mm $\left(\frac{a}{\lambda} = 0.006\right)$ and 10 mm $\left(\frac{a}{\lambda} = 0.01\right)$ and the input impedance is calculated using the King-Middleton equations and the Finite Integration technique. The results are plotted in Fig. A.2 for the radius of 6 mm and in Fig. A.3 for the radius of 10 mm. It is clear from the figures that when the radius of the cylindrical dipole increases, the deviations between the results of the FIT and the results of the KM expressions increase, which validates that the King-Middleton equations are most accurate for thin cylindrical dipoles $\left(\frac{a}{\lambda} < 0.005\right)$.

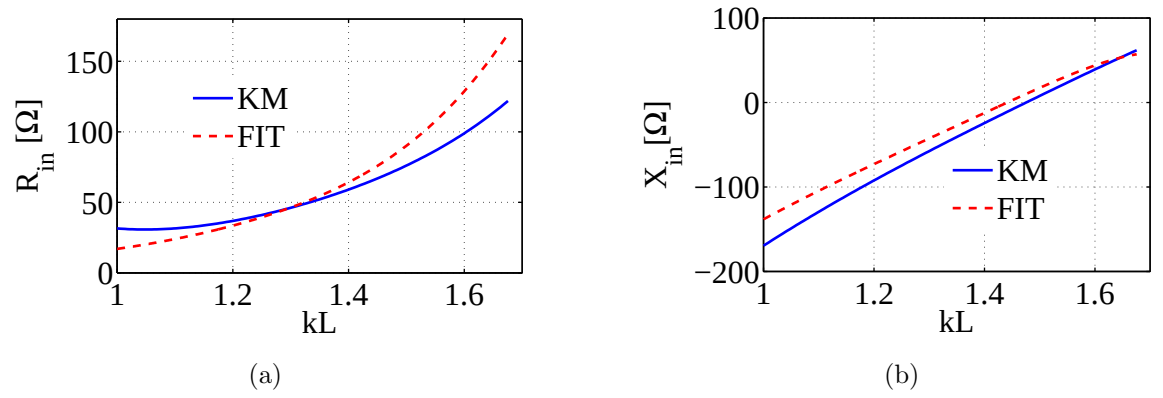

Figure A.2. Real (a) and imaginary (b) parts of the input impedance of a cylindrical dipole antenna calculated by the King-Middleton (KM) second order equations and by the Finite Integration Technique (FIT). Cylindrical radius = 0.006, λ = 1m.

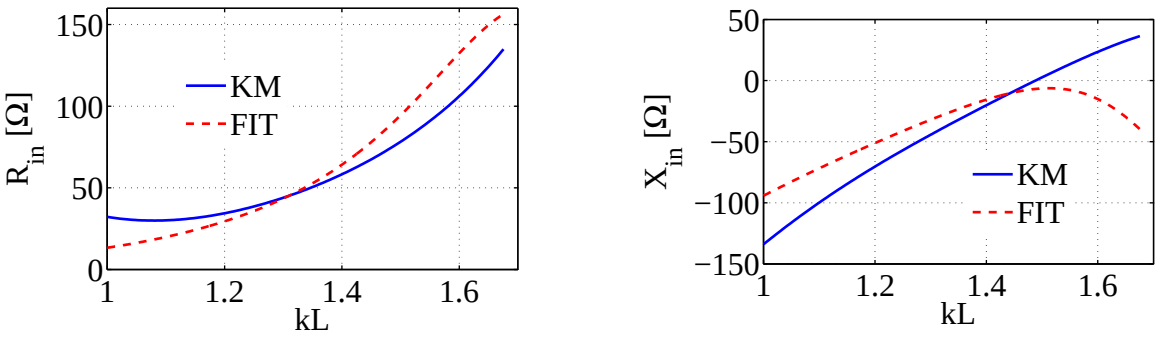

Figure A.3. Real (a) and imaginary (b) parts of the input impedance of a cylindrical dipole antenna calculated by the King-Middleton (KM) second order equations and by the Finite Integration Technique (FIT). Cylindrical radius = 0.01, $\lambda = 1$m.

A.2 Modified King-Middleton Equations

To accurately calculate the impedance of a cylindrical dipole correction factors are introduced into the King-Middleton equations. One for both the real part and one for the imaginary part of the input impedance. The corrections are based on fitting FIT results for an antenna of different radius and length at a frequency of 300 MHz.

A.2.1 Modified King-Middleton Equations - Real Part

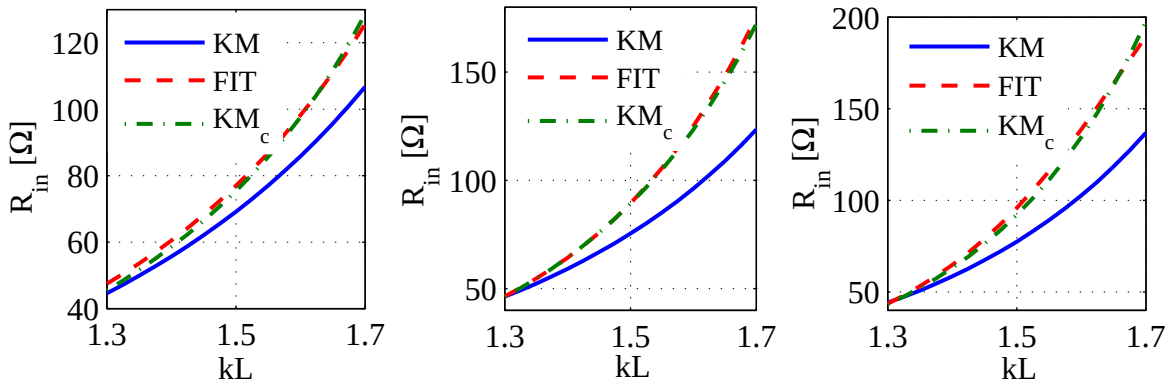
The correction factor of the real part of the input impedance of a cylindrical dipole is expressed by:

$$RC(kL, \frac{a}{\lambda}) = \begin{cases} \alpha e^{\beta\left(\frac{a}{\lambda}\right)} \left(\sum_{m=0}^{4} \sum_{n=0}^{4} a_{mn} (kL)^m \left(\frac{a}{\lambda}\right)^{-n}\right) & \text{for } a < 0.008\lambda \\ \\ \frac{1}{\gamma e^{\delta(kl)}} \left(\sum_{m=0}^{4} \sum_{n=0}^{4} a_{mn} (kL)^m \left(\frac{a}{\lambda}\right)^{-n}\right) & \text{for } a \geq 0.008\lambda \end{cases} \tag{A.3}$$

$$\text{where} \begin{cases} \alpha & = 0.9204 e^{(0.08023(kL))} + 2.565.10^{-7} e^{(7.498(kL))}, \\ \beta & = 35.16 \sin\left(3.393\,(kL) + 8.036\right), \\ \gamma & = 3.657 \sin\left(168.7\left(\frac{a}{\lambda}\right) + 0.02044\right), \\ \delta & = 1.004 \sin\left(189.8\left(\frac{a}{\lambda}\right) + 3.063\right). \end{cases}$$

The coefficients a_{mn} are shown in Table A.1. These modified equations have the same validity ranges as the King-Middleton equations. Fig. A.4 shows the real part of the input impedance as a function of the electrical half-length kL, for a cylindrical dipole

of half-length 0.237 m ($L = 0.237\lambda$) for different dipole radii. The resistive part of the input impedance is calculated using the King-Middleton (KM) equations (solid curve), the corrected King-Middleton (KM_c) equations (dashed-dotted curve) and the Finite Integration Technique (FIT) (dashed curve). It is clearly indicated in the figures that the results of the KM equations deviate from the result of the FIT especially when the electrical length of the cylindrical dipole increases. Moreover, it is shown that when the correction factor is introduced to the the KM equations, the results of the corrected KM (KM_c) equations match the results of the FIT.



(a) $a = 0.0016\ m$ (b) $a = 0.006\ m$ (c) $a = 0.01\ m$

Figure A.4. Real part of the input impedance of a cylindrical dipole of length 0.237 m for different dipole radii calculated using the King-Middleton (KM) Method, the Finite Integration Method (FIT) and the corrected King-Middleton (KM_c).

A.2.2 Modified King-Middleton Equations - Imaginary Part

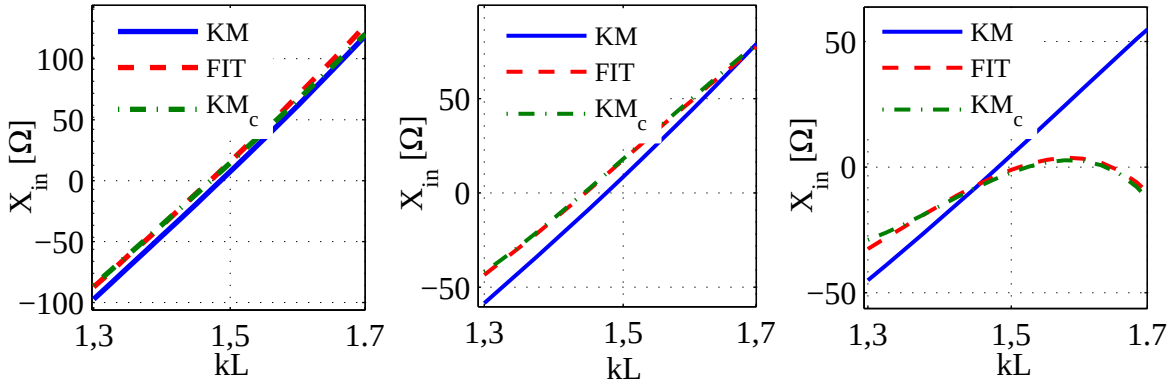
The modified imaginary part of the King-Middleton equation is represented in Eq. (A.4).

$$XC(kL, \frac{a}{\lambda}) = \left(\sum_{m=0}^{4} \sum_{n=0}^{4} b_{mn} (kL)^m (\frac{a}{\lambda})^{-n} \right) + p_0 + p_1 \left(\frac{a}{\lambda} \right) + p_2 \left(\frac{a}{\lambda} \right)^2 \tag{A.4}$$

$$\text{where} \begin{cases} p_0 &= -0.01716 e^{(4.445(kL))} + 9.986 e^{(0.2436(kL))}, \\ p_1 &= 9.107.10^{+9} e^{(-12.47(kL))} + 0.6792 e^{(5.894(kL))}. \\ p_2 &= -27.13 e^{(6.616(kL))}. \end{cases}$$

The coefficients b_{mn} are shown in Table A.2. The imaginary parts of the input impedance of the same cylindrical dipole investigated in the previous section, for different dipole radii as a function of electrical length, are shown in Fig. A.5.
It is shown in the figure that the results of the corrected KM_c expressions overlap the results of the Finite Integration Technique, while the results of the KM expressions

clearly deviate from the results of the FIT especially for large radius cylindrical dipole. To quantify the deviations between the FIT and the KM equation in terms of power wave reflection coefficients, the Figure of Merit introduced in Sec. 1.6 will be used in the following section.

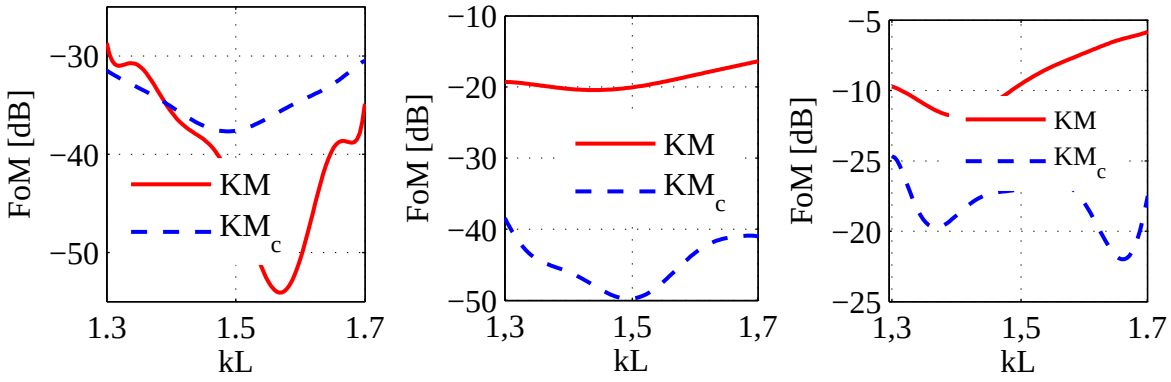


(a) $a = 0.0016\ m$ (b) $a = 0.006\ m$ (c) $a = 0.01\ m$

Figure A.5. Imaginary part of the input impedance of the dipole antenna for different dipole radii using the King-Middleton (KM) Method, Finite Integration Method (FIT) and the corrected King-Middleton (KM_c) .

A.2.3 Comparison Between KM and Corrected KM

From Eq. (1.2), the power wave reflection coefficients due to the deviation between KM equations and FIT is calculated. Using the same equation, the deviations between the corrected KM_c and the FIT are also calculated for the results shown in Fig. A.4 and Fig. A.5. The Figure of Merit (FoM) results are shown in Fig. A.6.



(a) $a = 0.0016\ m$ (b) $a = 0.006\ m$ (c) $a = 0.01\ m$

Figure A.6. Figure of Merit (FoM) to calculate the deviations between KM and FIT and between (KM_c) and FIT as a function of the electrical length for different dipole radii.

It is shown in the figures that the results of the KM_c expressions when compared to the results of the FIT are at least 10 dB more accurate than the KM expressions when compared to the same results (FIT) for larger dipole radii (a = 0.006 m and a = 0.01 m). To validate the modified King-Middleton (KM_c) expressions for different half-lengths, three different cylindrical dipoles are investigated where the input impedance is calculated using the KM expressions, the (KM_c), and the FIT. Fig. A.7 shows the real and imaginary parts of the input impedance of a cylindrical dipole of half-length of 0.119 m and a radius of 2.5 mm. It is shown in the figure that the results of the (KM_c) match the results of the FIT. The same behaviour is shown in Fig. A.8 and in Fig. A.9. In Fig. A.8, the half-length is set to 8 cm, and the cylindrical radius is set to 2.5 mm. The half-length and the radius of the cylindrical dipole are decreased to 5.5 cm and 1 mm and the results of the input impedance are plotted in Fig. A.9. It is shown in the figures that the modified KM (KM_c) expressions can accurately predict the impedance of a cylindrical dipole.

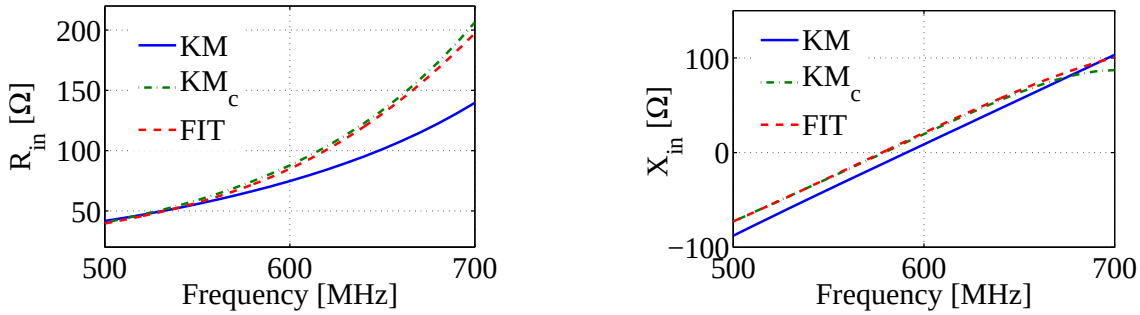


Figure A.7. Real and Imaginary parts of the input impedance, using King-Middleton (KM), corrected King-Middleton (KM_c) and the Finite Integration Technique (FIT). Cylindrical length = 11.9 cm, cylindrical radius = 2.5 mm.

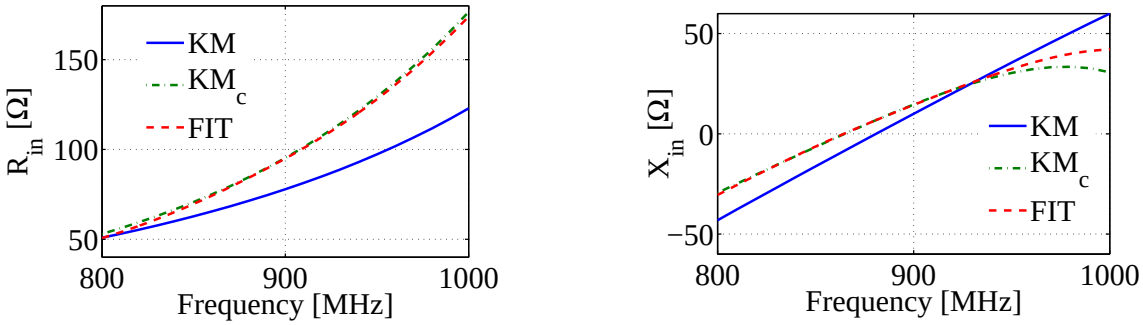

Figure A.8. Real and imaginary parts of the input impedance, using King-Middleton (KM), corrected King-Middleton (KM_c) and the Finite Integration Technique (FIT). Cylindrical length = 8 cm, cylindrical radius = 2.5 mm.

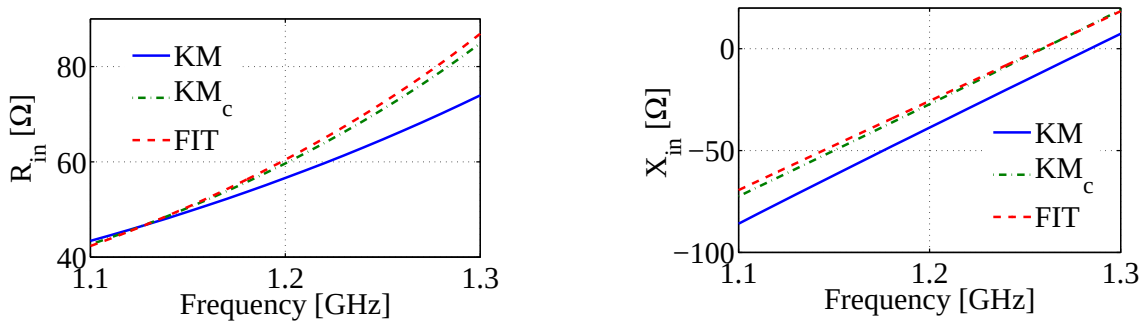

Figure A.9. Real and imaginary parts of the input impedance, using King-Middleton (KM), corrected King-Middleton (KM_c) and the Finite Integration Technique (FIT. Cylindrical length = 5.5 cm, cylindrical radius = 2.5 mm.

A.3 Strip Folded-Dipole Antenna

In this section, the accuracy of the analytical expressions for the strip folded dipole antenna is discussed. Two simulation examples implementing the analytical expressions introduced in Sec. 4.3 at 300 MHz and at 1.5 GHz are presented. Fig. A.10 shows the input impedance (real and imaginary parts) of a strip folded-dipole antenna possessing the following dimensions, $W_1 = 0.04\,\text{m}$, $W_2 = 0.03\,\text{m}$, $d = 0.0125\,\text{m}$, $L = 0.25\,\text{m}$, calculated with and without the correction factor (see Eq. (4.9)) for the inter-element spacing d.
In the same figure FIT-results are shown.

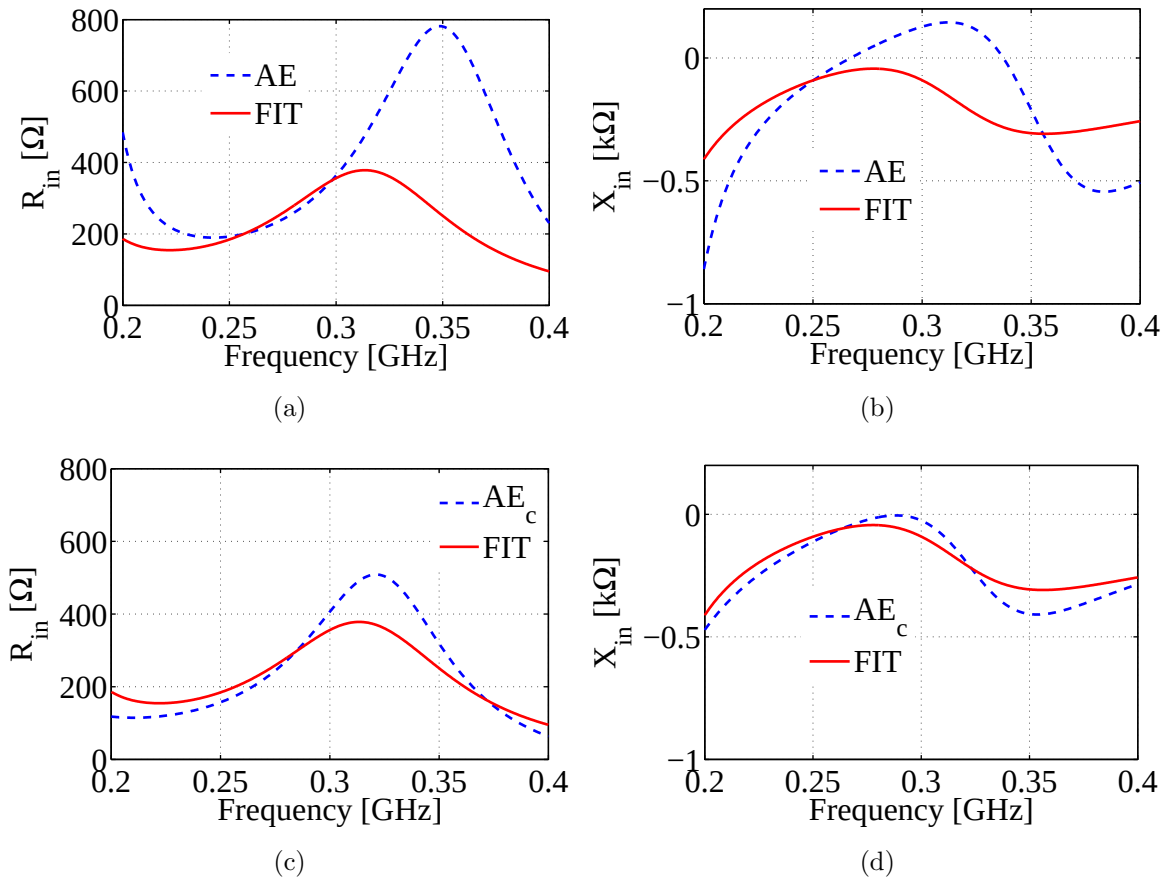

Figure A.10. Real (a) and imaginary (b) parts of the input impedance vs. frequency. And the corrected real (c) and imaginary (d) parts of the input impedance versus frequency. $W_1 = 0.04\,\text{m}$, $W_2 = 0.03\,\text{m}$, $d = 0.0125\,\text{m}$, $L = 0.25\,\text{m}$.

To quantify the improvement of the correction factor in terms of a single Figure of Merit, Eq.(1.2) is used to transform the deviations into power reflection coefficients. Fig. A.11 shows the resulting FoM as a function of frequency with (dashed curve) and without (solid curve) implementing the correction factor in the analytical expressions. Both results are compared to the results of the Finite Integration Technique (FIT). It is clear from the figure that when the correction factor is implemented, the validity range (0.2 GHz - 0.4 GHz) is extended 1.5 times compared to the validity range without implementing the correction factor (0.22 GHz - 0.3 GHz).

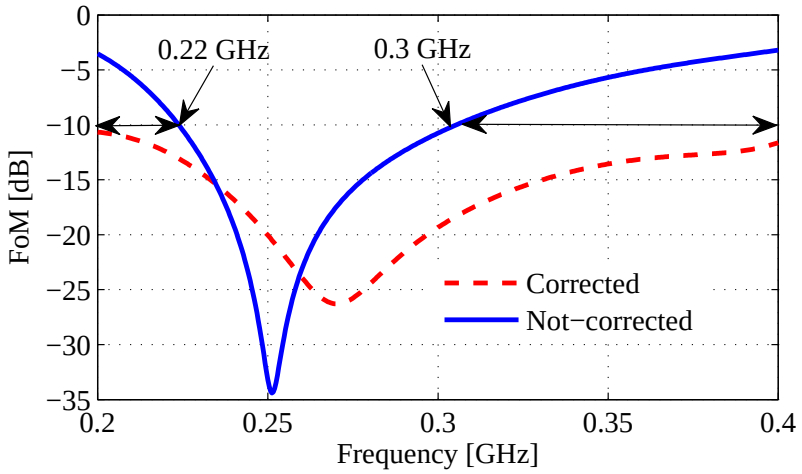

Figure A.11. FoM as a function of frequency due to the mismatch between AE and FIT.

Fig. A.12 shows the input impedance (real and imaginary parts) of a strip folded-dipole antenna possessing the following dimensions, $W_1 = 0.004\,\text{m}$, $W_2 = 0.002\,\text{m}$, $d = 0.004\,\text{m}$, $L = 0.0475\,\text{m}$, calculated with and without the correction factor (see Eq. (4.9)) for the inter-element spacing d. Figs. A.12(a) and A.12(b) show the real and imaginary parts, consecutively, of the input impedance calculated using the analytical expressions presented in Sec. 4.3 without implementing the correction factor for the inter-element distance d. In addition, the Figures show the real and imaginary parts of the input impedance calculated by the FIT using CST Microwave Studio.
The results after using the correction factor are plotted in Figs. A.12(c) and A.12(d). It is indicated in the figures that when the correction factor is implemented, the deviations between the results of the FIT and the results of the analytical expressions decreases. To quantify the improvement when the correction factor is implemented, the FoM is used to transform the deviations into reflection coefficients. Fig. A.13 shows the resulting FoM as a function of frequency with (solid curve) and without (dashed curve) implementing the correction factor in the analytical expressions. It is clear from the figure that when the correction factor is implemented, the validity range (1.22 GHz - 1.88 GHz) is extended more than 50 % compared to the validity range without implementing the correction factor (1.22 GHz - 1.64 GHz).

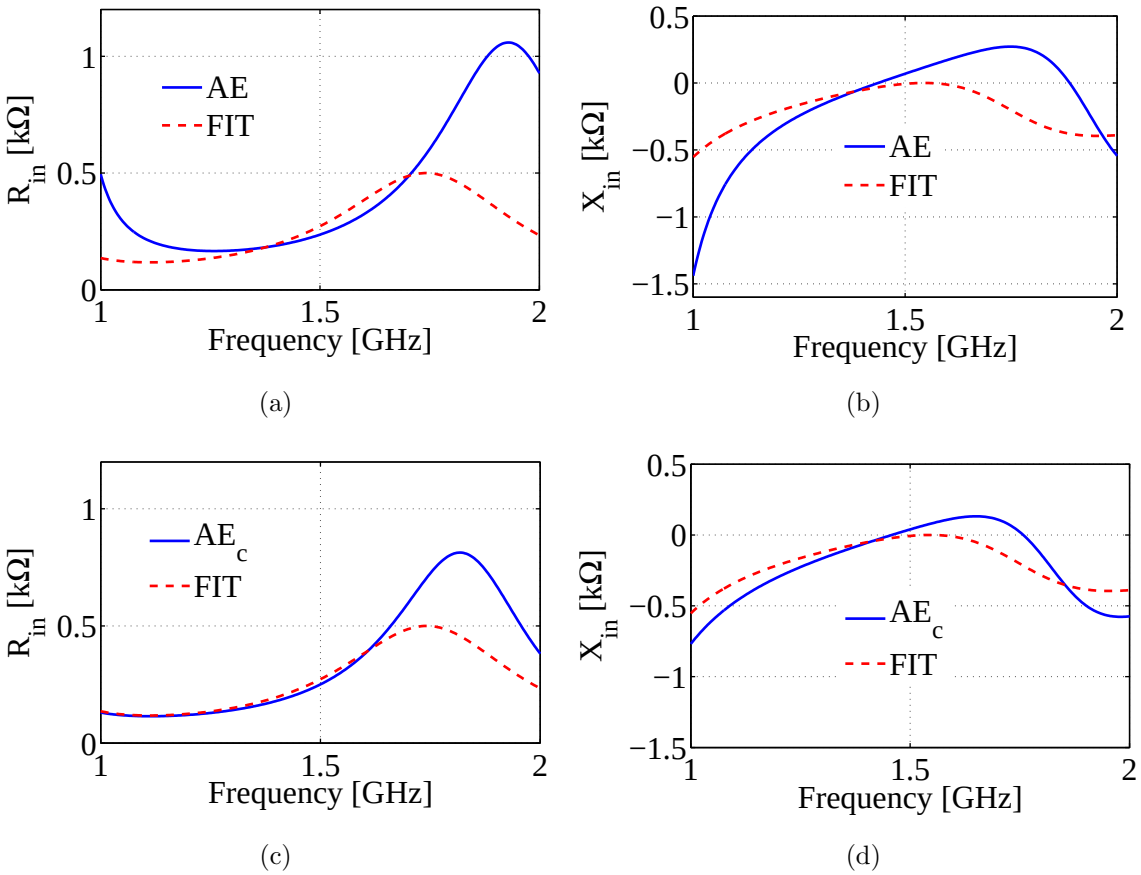

Figure A.12. Real (a) and imaginary (b) parts of the input impedance versus frequency. And the corrected real (c) and imaginary (d) parts of the input impedance versus frequency. $W_1 = 0.004$m, $W_2 = 0.002$m, $d = 0.004$m, L = 0.0475 m.

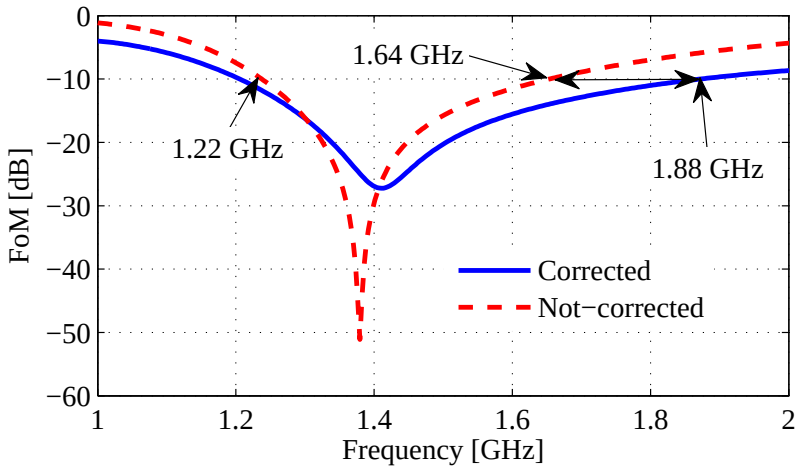

Figure A.13. FoM as a function of frequency due to the mismatch between AE and FIT.

Appendix B

Frequency Selective Surfaces Equivalent Circuit Model

B.1 Correction Factor G

In [119] the first order correction term G, at oblique angle of incidence is obtained as:

$$G(p, d, \lambda, \theta, \varphi) = \frac{A}{B}, \tag{B.1.1}$$

where:

$$A = \frac{1}{2}(1-\beta^2)^2 \left[\left(1 - \frac{\beta^2}{4}\right)(C_{+1} + C_{-1}) + 4\beta^2 C_{+1} C_{-1} \right], \tag{B.1.2}$$

$$B = \left(1 - \frac{\beta^2}{4}\right) + \beta^2 \left(1 + \frac{\beta^2}{2} - \frac{\beta^2}{8}\right)(C_{+1} + C_{-1}) + 2\beta^6 C_{+1} C_{-1}. \tag{B.1.3}$$

In the above:

$$\beta = \sin\left(\frac{\pi w}{2p}\right). \tag{B.1.4}$$

The coefficients $C_{\pm 1}$ are obtained from:

$$C_n = \frac{1}{tS_n} - \frac{1}{|n|}, \qquad n = \pm 1, \pm 2, ... \tag{B.1.5}$$

For a TE polarized incident plane wave:

$$t = j\frac{p\cos(\theta)}{\lambda}, \tag{B.1.6}$$

$$S_n = \frac{\gamma_n}{\gamma_0}. \tag{B.1.7}$$

The propagation constant γ_n is given by:

$$\gamma_n = -j\sqrt{\left(\sin(\theta) + \frac{n\lambda}{p}\right)^2 - 1}, \tag{B.1.8}$$

from which follows that $\gamma_0 = \cos(\theta)$. From B.1.12 and B.1.7:

$$S_n t = -j\sqrt{\left(\frac{p\sin(\theta)}{\lambda} \pm n\right)^2 - \frac{p^2}{\lambda^2}}, \tag{B.1.9}$$

and from B.1.5:

$$C_n{}^{TE} = \frac{1}{\sqrt{\left(\frac{p\sin(\theta)}{\lambda} + n\right)^2 - \frac{p^2}{\lambda^2}}} - \frac{1}{|n|}. \tag{B.1.10}$$

Therefore:

$$C_{\pm 1}{}^{TE} = \frac{1}{\sqrt{\left(\frac{p\sin(\theta)}{\lambda} \pm 1\right)^2 - \frac{p^2}{\lambda^2}}} - 1. \tag{B.1.11}$$

For the dual case of a TM polarized incident plane wave:

$$t = j\frac{p\sec(\varphi)}{\lambda}, \tag{B.1.12}$$

$$S_n t = \gamma_n \gamma_0, \tag{B.1.13}$$

where:

$$\gamma_n = -j\sqrt{\left(\sin(\varphi) + \frac{n\lambda}{p}\right)^2 - 1}, \tag{B.1.14}$$

from which $\gamma_0 = \cos(\varphi)$ is obtained. Therefore:

$$S_n t = \sqrt{\left(\frac{p\sin(\varphi)}{\lambda}\right)^2 + n^2 - \frac{p^2}{\lambda^2}}, \tag{B.1.15}$$

and from B.1.5:

$$C_n{}^{TM} = \frac{1}{\sqrt{\left(\frac{p\sin(\varphi)}{\lambda}\right)^2 + n^2 - \frac{p^2}{\lambda^2}}} - \frac{1}{|n|}, \tag{B.1.16}$$

from which follows that

$$C_{\pm 1}{}^{TM} = \frac{1}{\sqrt{1 - \left(\frac{p\cos(\varphi)}{\lambda}\right)^2}} - 1. \tag{B.1.17}$$

Acknowledgements

It is my pleasure to thank many people who in different ways have contributed to the completion of this thesis.

First and foremost, I would like to thank my promoter Hubregt Visser. Without your constant motivation, support and guidance, I would have never been able to grow and become an independent researcher. Without your help, especially during the writing phase, this thesis would have never been completed on time. I greatly appreciate the high degree of freedom and the trust you gave me.

Additionally, I am thankful to my second promotor Anton Tijhuis. You were always there when I really needed your help. You have always encouraged and guided me. Thank you for your critical questions, remarks and comments concerning this thesis that improved greatly thanks to your feedback. You have always encouraged and taught me to think beyond the antenna-rectifier research more into the 'Helicopter view' system level.

I am grateful to Gianluca Perotto, together we shared the same office for almost one year. Thank you for the pleasant atmosphere. I was really lucky to co-supervise your internship and your Master's thesis project. Your work contributed to Chapter 7 of this thesis.

Many thanks also to all the members of my Ph.D. committee for their comments that improved the consistency of the thesis. I would especially like to thank, Prof.dr. E.A. Lomonova, Prof.dr.ir. P.G.M. Baltus and Prof.dr.ir. G.A.E Vandenbosh. Thank you for your time and your comments. I wish to thank Prof.dr. Cristian Vollaire for all the discussions and comments and also for the warm welcome during my three months exchange period in Lyon. Thank you for taking care about my accommodation in Lyon and providing all the necessary components and equipment needed for the project.

I would like to thank all my colleagues and friends at the EM group, special thanks to Mojtaba Zamanifekri. We have started our Ph.D together and we have shared almost everything, I enjoyed the conferences that we have attended together and also the coffee

breaks during several years. Also I would like to thank Satoru Sakai for proof-reading different parts of this thesis. Furthermore, I would like to thank Ulf Johansen and Rob Mestrom for providing me with their LaTex template. I am really grateful to Suzanne Kuijlaars. Thank you for taking care about all the administrative stuff especially by fixing my defence date. I especially would like to mention Ad Reniers for his time and assistance during most of the measurements presented in this thesis, especially for the radiation efficiency measurements. I would also like to thank Rainier van Dommele for taking care about all the software licenses. I express my gratitude to Martijn van Beurden, especially during the writing phase of my thesis. Your exceptional organization skills are inspiring all the EM group members. Thank you for helping me structuring my thesis, also thank you for answering different questions regarding the rectifier's impedance modeling and antenna feed modeling. I would also like to thank Bas de Hon for providing time and answering different questions during the last three years.

It has been a great pleasure to work with all the colleagues at the Holst Centre. I am thankful to Hans Pflug, who contributed directly to the completion of this thesis by building the measurement setup and providing all the measurement results of Chapter 6. Thank you Hans for answering all my questions. A special thanks goes to Ruud Vullers and Rob van Schaijk. Thank you both for your support and motivation especially during the initial phase of my Ph.D. I would like also to thank Nauman Kiyani for his advices, especially during the writing phase of the thesis. A special thank goes to Mark Stoopman for designing the CMOS rectifier and the control loop that allowed us to considerably decrease the size of the rectenna. It has been a pleasure working together on the same project.

I am indebted to my brother Fakher El-Dine Keyrouz. You have encouraged and helped me to come to Germany and continue my Master studies. Thank you for your support on all different levels. I am deeply thankful to my parents for their unconditional support and sacrifices.

Last but certainly not least, I want to thank my life-companion Rosy. Thank you for all your sacrifices, all the weekends you spent with me in the office while writing this thesis. Without your love, I probably would have lost a great deal of my discipline, endurance, and eagerness.

Curriculum Vitae

Shady Keyrouz was born on January 21st, 1984, in Bsharri, Lebanon. He enrolled in electrical engineering at the Notre Dame University (NDU) in Beirut, Lebanon, in 2003 and obtained his BE degree in 2008. He received his M.Sc. degree in Communication Technology from Ulm University, Germany, in 2010. In the same year he started as a Ph.D.-student at the Electromagnetics group (EM) of the Faculty of Electrical Engineering of Eindhoven University of Technology (TU/e), Eindhoven, The Netherlands. In 2010 he joined Holst Centre/imec as a Ph.D. researcher. His research interests include antenna modeling, rectenna design, wireless power transmission and reflect-array antennas.

Rectenna materials improving low scale RF power harvesting for embedded miniature sensors

Samir Mekid

Mechanical Engineering Department, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia

Abstract

The paper reviews suitable innovative materials used to improve harvesting power through ambient Radio Frequency (RF) needed for standalone embedded sensors. The Rectenna (a combination of a rectifier and antenna) material is one of the main three key elements constituting the scavenging system including the resonator based on the material, the number of multiplier stages and the low pass filter. The system uses electromagnetic waves travelling in ambient air captured through an antenna to an electronic unit and will excite a subsystem to harvest energy. This subsystem is the heart of the concept of power scavenging and is material based concept in most of the cases treated in this paper.

Keywords: Power harvesting, RF, resonator, rectenna, batteryless

1. Introduction

Permanent energy supply is highly needed for battery-less standalone electronic devices. The daily and continuous use of these devices exhibit a real issue with batteries and their fast recharging. Methods for extracting or harvesting energy from the surrounding environment are of great importance because it reduces the maintenance scheduling, transportation, weight and cost of energy needed by the standalone devices. The energy sources of interest are the largely untapped sources of ambient energy resulting from human activity and environmental energy flows in the form of waste heat, movement and vibration.

It is important to remind that power transmission dates back in early work of Hertz who has shown the propagation of electromagnetic waves in air. Tesla followed by transmitting power from one side to another wireless in 1899.

A couple of innovative techniques have already shown a possibility of improvement of scavenged power through RF waves in ambient air. The known three parameters governing the power scavenging are the resonator, the number of multiplier stages and the low pass filter. The resonator or the rectenna shows better performance if specific promising micro-scale energy harvesting standard materials are used e.g. ceramics, single crystals, polymers and composites, and also new engineered materials currently being developed. Resonator can provide increased voltage level with single stage voltage multiplier. Further improvement with this scheme can be obtained by multiple stages. It is also demonstrated that the use of LPF provides the output voltage with little amount of harmonics. Since RF to DC conversion efficiency has emerged as challenging issue, so band pass filter can be used to complete this objective by removing the second and third harmonic at antenna [1].

Our current interest is material. The energy sources of interest to this paper is in the Low power requirements (μW to mW) – for example heat and movement lost from portable electronics and mobile communications. The aim is not to generate large-scale power, but to capture small amounts of ‘energy’ that is ‘wasted’ during industrial and everyday processes. There is currently a great commercial potential for energy harvesting technologies, hence many projects are supported by European companies, from

automotive to electronics manufacturers as well as European framework 7 programmer [2], [3]. It important to note the amount of harvested power has very low density power ranging from 0.1 μW/cm3 to 0.001 mW/cm3. Fig. 1 shows measured GSM-900 power density levels.

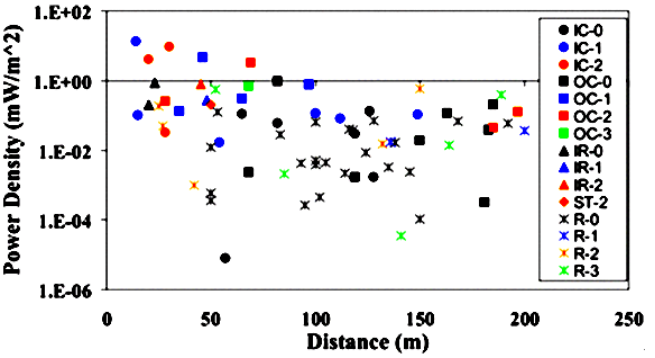

Fig. 1. Measured GSM-900 peak power density levels as a function of distance to the nearest base station. 2. Types Materials Used in RF-Based Energy Harvesting

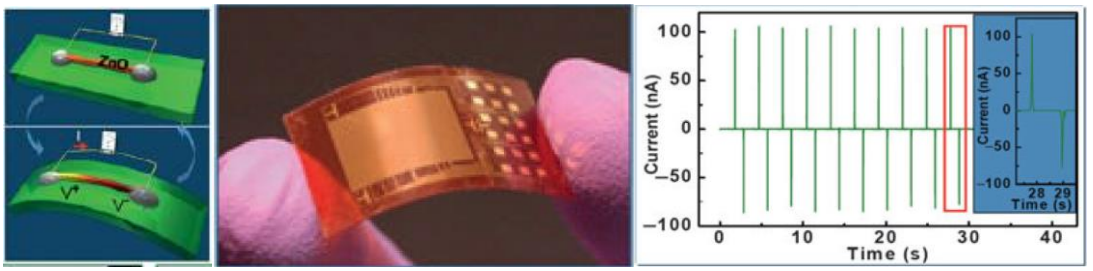
Several promising micro-scale energy harvesting standard materials are used e.g. ceramics, single crystals, polymers and composites, and also new engineered materials currently being developed. Micro- and nano-scale Metal Insulator-Metal (MIM) tunnel diodes are being developed [5] to provide half-wave rectification as part of a "rectenna" energy harvesting system, which includes a radiation-collecting antenna, a rectifying MIM tunnel diode, and a storage capacitor. High-frequency MIM tunnel diodes for power rectification were designed, fabricated and characterized. Planar $Pt/TiO_2/Ti$ stacks are being fabricated to create a diode with highly asymmetric I-V characteristics that has a very low threshold voltage. A MIM tunnel diode is composed of two conductive metal layers separated by a very thin dielectric, and operates on the principles of thermionic emission and quantum tunneling Preliminary results exhibit asymmetric I-V characteristics with threshold voltages of less than 700 mV. Initially this MIM was a poor resistive element because of fabrication issues.

Single and multi-walled carbon nanotube-based technology for radio frequency [6] switch working in the range of 40–60 GHz and fulfilling the specifications were exploited. The first processed component had an operating voltage of 14 V for an ohmic contact in a Nano-Electro Mechanical System (NEMS) tweezer design. High Frequency Simulation Software (HFSS) RF-simulation on an innovative NEMS geometry shows encouraging results with transmission ratios between "on" state and "off" state up to 34% for ohmic-contact switch and 25% for a capacitive-contact switch.



a) b) c)

Fig. 2. a) principle of ZnO with two metal electrode in equilibrium and stretched, b) high output nanogenerator using integration of millions of nanowires transferred to polymer substrate. c) output of 2V and 100 nA are obtained.

Piezoelectric cantilever [7], [8] is used to induce strain via RF signal propagation. Hence, when a piezoelectric cantilever is subjected to RF propagation field, an alternating current is induced in the piezoelectric cantilever causing mechanical movement. Hence, maximum effect is achieved when RF frequency matches the resonant frequency of the cantilever. When a voltage signal of 10 Vpp propagates in the line it sets an alternating current in the actuator electrodes. The effect of piezoelectric material was also exploited in ZnO nanowires laterally bonded on a flexible substrate (Fig. 2). One of the unique advantages of ZnO is that all of the nanowires grow along the *c* -axis (i.e., in the polar direction) and are uni-axially aligned. Once the wires are strained, a macroscopic piezo-potential is created, which can drive a flow of electrons, thus converting mechanical energy into electricity.

On another application [9], RF waves are received from a mobile phone and rectified to generate a DC voltage by a rectenna (a rectifying circuit with an antenna). The layered rectenna is photo-etched from copper-clad FR4 material [10], which allowed for a fast realization of the product. To model the dc output voltage, the incident power received by the patch antenna is measured for a fixed transmit-receive setup. This data is used in the model to predict the dc output voltage of the rectenna. The dc output voltage is predicted and measured in Fig. 3. The system was fabricated with 0.6 _m-CMOS technology, and can supply well-regulated 4.0 V/1mA DC power to the load for 10 ms periodically.

a) b) c)

Fig. 4. a) Nanorods grown on, b) current received from 2x2 cm^2 based on concept in c).

ZnO is also used to generated power as follows [11]. An optimal Radio Frequency (RF) sputtering process (sputtering power, sputtering time, and target type) to grow a ZnO seed layer on an Indium Tin Oxide (ITO) glass followed by the hydrothermal growth of a well-aligned perpendicular ZnO nanorod array for the fabrication of a piezoelectric nanogenerator Fig. 3. The change in nanorod morphology, crystallinity, orientation, growth rate, diameter, length, and number density of ZnO nanorods were controlled by modifying various processing parameters. A prior seeding of ZnO nanoparticle with good wurtzite structure and with preferred orientation along the (002) direction of the crystal is critical for the

subsequent growth of well-aligned vertically oriented ZnO nanorods on ITO substrates. A large area (2_2cm^2) of the piezoelectric nanogenerator bimaterial sheet was fabricated by combining the vertically grown ZnO nanorod array electrode with an Au-coated polyurethane (PU) film as the other electrode. By rubbing the two electrodes together, the nanodevice generates an optimal output current density of about $1\mu A/cm^2$ in Fig. 4c).

3. Conclusion

A couple of innovative techniques have already shown a possibility of improvement of scavenged power. The known three parameters governing the power are the resonator, the number of multiplier stages and the low pass filter. The resonator or the rectenna has shown better performance if specific promising micro-scale energy harvesting standard materials are used e.g. ceramics, single crystals, polymers, composites, and new-engineered materials currently under development.
Piezoelectric nanogenerators have been developed that can serve as self-sufficient power sources formicro-/nanosystems. For wurtzite structures that have non-central symmetry, such as ZnO, GaN, and InN, a piezoelectric potential (piezopotential) is created by applying a strain.

***Abstract*—This paper introduces a novel compact ultra-lightweight multiband RF energy harvester fabricated on a paper substrate. The proposed rectenna is designed to operate in all recently released LTE bands (range $0.79-0.96$ GHz; $1.71-2.17$ GHz; $2.5-2.69$ GHz). High compactness and ease of integration between antenna and rectifier are achieved by using a topology of nested annular slots. The proposed rectifier features an RF-to-dc conversion efficiency in the range of $5-16\,\%$ for an available input power of -20 dBm in all bands of interest, which increases up to $11-30\,\%$ at -15 dBm. The rectenna has been finally tested both in laboratory and in realistic scenarios featuring a superior performance to other state-of-the-art RF harvesters on flexible substrates.**

I. Introduction

In THE near future, an explosion of the number of devices connected to the Internet is foreseen, which will impose tremendous challenges both in terms of spectrum and power supply [1]- [4]. On the one hand, new communication protocols and wider bandwidths will be released to manage this huge number of heterogeneous users (both humans and machines), with different levels of intelligence and needs [5]. On the other hand, according to the emerging Internet of Things (IoT) paradigm, electronic apparatuses will be deployed almost everywhere. The next generation of sensors and circuits will be literally embedded in the items, so their maintenance will be hindered by the fact that they will be difficult to reach or even to localize. This means that the battery replacement will be difficult or even impractical, so in most of the cases batteryless devices will be the only option. Additionally, these devices have to be conformal to the hosting objects both in terms of shape and cost, while the environmental impact of these distributed and ubiquitous electronics should be minimized in order not to increase the pollution risks and cause a worsening of the quality of human life.

For these reasons, it is important to avoid the traditional battery and to find new efficient and reliable ways to power the circuits from ambient RF sources, both exploiting already available resources through wireless energy harvesting and enabling the intentional wireless power transferring, so as to make them robust and autonomous.

To this end, research is focusing on both the development of low-power sensors and energy harvesting to produce autonomous wirelessly interconnected smart nodes [6]. State-of-the-art dc/dc converters are able to operate for input voltages as low as 70 mV [7], thus thoroughly reducing the amount of energy required for electronics. Thanks to this trend, ambient RF energy harvesting is becoming ever more appealing among the different forms of energy harvesting (e.g., solar, mechanical, and thermal). So far, the scarcity of the available power density has been its main drawback, but both the development of lower power and lower voltage circuits and the increasing number of wireless applications, which in the future will lead to a dramatic increase of the ambient RF energy, are concurrently bridging the gap.

In this scenario, broadband rectennas are the most suitable solutions to realize reliable power supply [8], since they are able to harness a larger part of the available spectrum; plus, the harvester should be easily mounted on commonly used objects, so it is necessary that they are lightweight and conformal.

Recently, numerous high-performing broadband and multi-band rectennas have been proposed (see [9]- [15]), which are able to take advantage of the simultaneous presence of RF power at different frequencies. An in-depth analysis of the rectifier architectures and operating principles was conducted as well, aiming at improving specific properties of the harvesting circuits, such as their bandwidth [16], sensitivity [14] and operating power range [17]. However, further improvements are needed in terms of compactness and conformability to achieve truly practical and scalable solutions.

This paper is a substantial expansion [18] and [19]. In the

previous works, a single band rectenna was designed and demonstrated. Here, both the antenna and the rectifier have been enhanced in order to allow for multiband operation. Furthermore, a compact printed module integrating the proposed new antenna is demonstrated. In the end, a novel ultracompact multiband rectenna is presented, able to harvest power from all released LTE bands.

This paper is organized as follows. Section II presents the system-level design of the multiband rectenna. Section III describes the low-cost fabrication technology utilized for the rectenna prototype. Sections IV and V describe the design procedure of the proposed harvester for the antenna and the rectifier, respectively. Results discussing the performance of the rectenna in various representative harvesting scenarios are given in Section VI. The conclusions are drawn in Section VII.

II. System Level Design

The proposed rectenna is aimed at harvesting energy from all new bands released by the Third Generation Partnership Project (3GPP) [20] , [21], both in uplink and in downlink. A list of the bands adopted in Europe is reported in Table I. It has been noticed that all these bands can be divided into two groups well separated in frequency: the bands 8 and 20 on the one hand, which occupy the range from 790 to 960 MHz, and all others on the other hand, which extend from 1710 to 2690 MHz.

Therefore, an approach based on two antennas has been developed instead of a single broadband rectenna. The rectenna block diagram is reported in Fig. 1. The idea is to use a relatively narrowband antenna tuned around 900 MHz and a broadband one which is able to gather energy from frequencies between 1.71 and 2.69 GHz. Both antennas are connected to two separate rectifiers and then their outputs are summed with a dc combining technique. Finally, an RC low-pass filter isolates the dc component, which can be utilized by practical loads (a low-power sensor, a dc/dc converter, and so on).

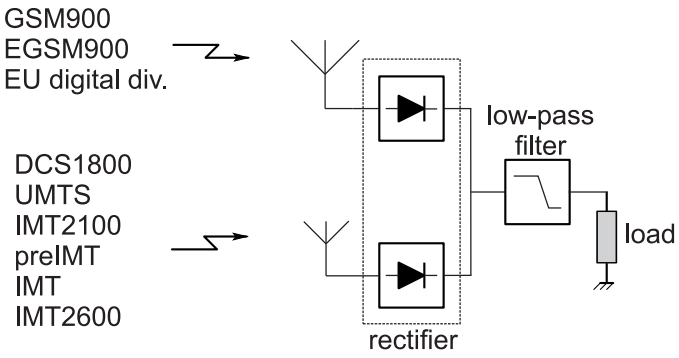

Fig. 1. Architecture of the proposed multiband rectenna.

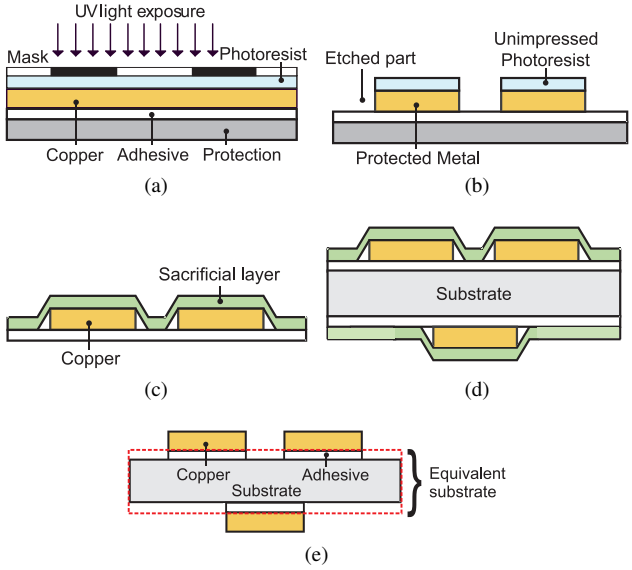

Fig. 2. Adhesive copper laminate technology: fabrication steps. (a) Deposition and selective exposure of photoresist to UV light through a mask. (b) Wet etching of copper. (c) Introduction of a sacrificial layer on the copper side and removal of the protection of the adhesive layer. (d) Transferring of the etched traces to both sides of the substrate. (e) Removal of the sacrificial layer.

Thanks to this approach, the bandwidth requirements for both the antenna and the rectifier are less demanding, thus allowing for a reduction in the complexity of each circuit block. On the other hand, the number of blocks is increased. So, in order not to end up with an increased rectenna area, it is essential to choose the most suitable technology and guarantee a compact arrangement of the utilized components.

III. Adhesive Copper Laminate Technology

The whole circuit has been manufactured on a paper substrate using the adhesive copper laminate technology described in detail in [22]. The main steps of this technology are reported in Fig. 2. It relies on a copper adhesive tape shaped by a photolithographic process [see Fig. 2(a) and (b)] and then transferred to the paper substrate by means of a sacrificial layer [Fig. 2(c)]. Since in the present work a double layer structure is needed, the two layers are processed separately by using two different pieces of copper tape that are then attached to the two sides of the substrate [Fig. 2(d) and (e)] and manually aligned by means of alignment marks. The latter process is estimated to

feature a misalignment tolerance of about 1 mm, which can be considered acceptable in the low-GHz range. In the case of a simple microstrip structure, a slab of copper tape is attached to the bottom side of the substrate so as to obtain a ground plane.

The advantages of the adopted technique with respect to other emerging ones, such as ink-jet printing [23], are higher metal conductivity ($\sigma = 5.8 \times 10^7$ S/m), the possibility to solder surface mount components by means of conventional eutectic alloy while eliminating curing steps, and compatibility with Printed Circuit Board fabrication equipment. The price to pay for this is the presence of a photolithographic step that makes this technique not fully additive.

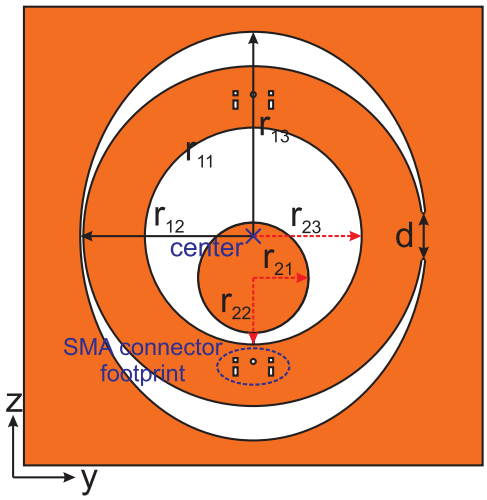
In this context the paper substrate has been chosen for its unique properties of being lightweight, flexible, biodegradable, and intrinsically inexpensive [24], as well as for being an example of unconventional material in full compliance with the IoT paradigm that requires electronic technologies to be as compliant as possible with materials in common objects. The electrical parameters of the adopted substrate, which is a photo-paper from Mitsubishi Electric (model CK-D715), are quoted in [25]. The equivalent composite substrate, including both the paper substrate and the glue layers interposed between each layer of copper and paper, features a permittivity of 2.55, a loss tangent equal to 0.05, and a thickness of 0.37 mm. Despite the fact that the high losses of the substrate represent a substantial limitation to the circuit performance, especially for the rectifier (see Section V), this paper introduces an ultra low-cost solution and can be considered as a proof-of-concept demonstration of the feasibility of autonomous wireless sensor nodes on almost every kind of material.

IV. Antenna Design

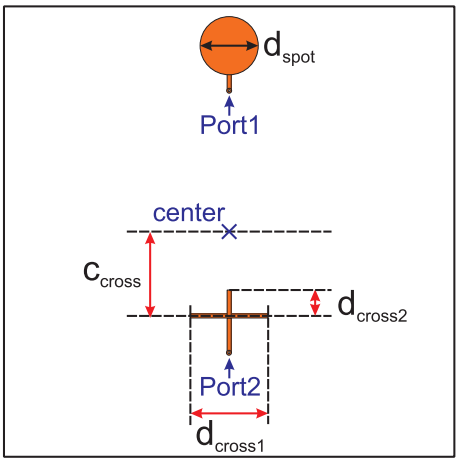
The proposed antenna consists of two annular slots nested one inside the other, according to a technique already demonstrated in [26]. The antenna layout is shown in Fig. 3 and its design was carried out by means of Computer Simulation Technology Studio suite. The antenna input ports are marked with "Port1" and "Port2".

Since the antennas are substantially etched out from the ground plane, they do not add weight to the structure and are compatible with substrates as thin as a sheet of paper. Moreover, slot antennas feature a relatively wide impedance bandwidth due to their low quality factor (see [27]) and, thanks to the exponential decrease of the current density at the borders of the slots, the metal, which surrounds the slots, can be exploited as the ground plane for the circuitry placed on the other side, thus allowing an easy integration between the antenna and the rectifier.

The outer antenna is the tapered annular slot used and analyzed in [18]. The slot, tuned to the band $790 - 960$ MHz, is the result of the intersection of an ellipse and a circle and features a maximum and minimum width of 8.25 and 0.75 mm, respectively. The antenna is fed by means of a proximity coupled microstrip line terminating on a circular stub introduced to match the antenna to a $50 - \Omega$ iimpedance, as shown in Fig. 3(b) (Port1). Since the annular slot features



(a)

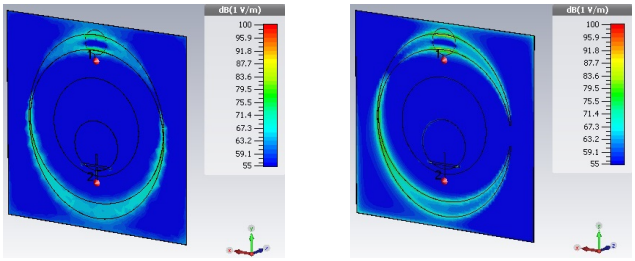


(b)

Fig. 3. Layout of the antenna prototype. (a) Top side. (b) Bottom side. Active area: 11×11 cm^2. The main parameters of the antenna topology are: $r_{11} = 40.75$ mm, $r_{12} = 41.5$ mm, $r_{13} = 49$ mm, $d = 11$ mm, $d_{spot} = 14.2$ mm for the first antenna, $r_{21} = 13.24$ mm, $r_{22} = 15.99$ mm, $r_{23} = 26$ mm, $d_{cross1} = 19$ mm, $d_{cross2} = 6$ mm, $c_{cross} = 21$ mm for the second antenna.

a length equal to λ_g, i.e., the guided wavelength in slot technology at the central frequency, the magnitude of the electric field across the slot features a maximum at the feeding point and at its symmetric point (where the slot width is maximum as well), whereas it is ideally null at the antisymmetric points (approximately where the slot width is minimum). As a consequence, the latter two points can be viewed as virtual grounds and it is possible to replace one of them by means of a real short (marked with "d" in Fig. 3) at the expense of an increased cross-polar component [28]. Fig. 4 reports the very minor change in the distribution of the electric field across the slot due to the physical short-circuited connection to the right large ground. On the other hand, this short allows a microstrip line to be placed in a cross configuration below this slot using the metal sheet as ground plane, thus making it possible to arrange circuit components both on the interior and the exterior metal surface of the outer slot.

The inner antenna is a broadband annular slot with a cross-



(a) (b)

Fig. 4. Electric field distribution at 900 MHz for the outer slot (a) without and (b) with a short-circuit connection to the right large ground.

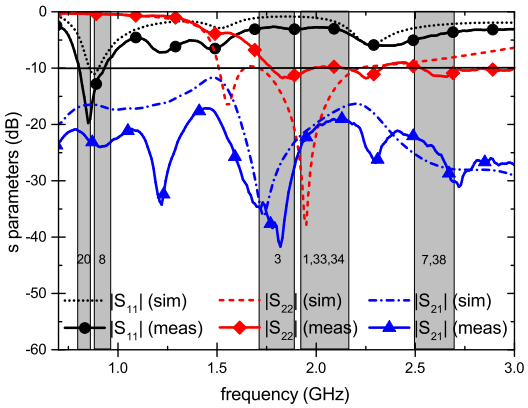


Fig. 5. Scattering parameters of the proposed antenna topology: simulations (solid) and measurements (dashed line). The bands of interest are marked with gray stripes and their number is reported at the bottom of each stripe.

shaped feed line [29]. It consists of a circular slot, a circular patch radiator, which is offset with respect to the slot center, and a proximity-coupled cross-shaped feed line, which also in this case is optimized to obtain a good impedance matching to $50-\Omega$ throughout the whole band of interest ($1.71-2.69$ GHz). All relevant parameters of the antenna are reported in Fig. 3.

Fig. 5 shows a comparison between the simulated and measured scattering parameters of the proposed antenna topology. Number "1" refers to the outer slot, while number "2" is linked to the inner slot, according to the port numeration reported in Fig. 3. The bands involved in the design are marked with gray rectangles. A good matching can be noticed in all bands with the exception of the frequency range on the right part of band 8 and on the left part of band 3. The slight mismatch is on the order of 1-2 dB. Slight discrepancies between simulations and measurements are due to fabrication tolerances. Moreover, the mutual coupling is below -19 dB in all frequencies of interest.

Finally, an estimation of the maximum realized gain of both antennas (linear polarization), which occurs in broadside direction, has been reported (see Fig. 6). The first antenna features a gain of 1.3 dBi at 900 MHz and its maximum gain around 2.3 dBi is achieved at 940 MHz, whereas the second antenna features a gain varying between 4 and 6 dBi in the band of interest. Antenna #1 features a half-power beamwidth (HPBW) of around 108° in the xy plane and 81° in the xz plane at 900 MHz, whereas antenna #2 shows HPBW of 78° and 78.5° in the xy plane, and 71° and 63° in the xz plane at 1.8 and 2.6 GHz, respectively.

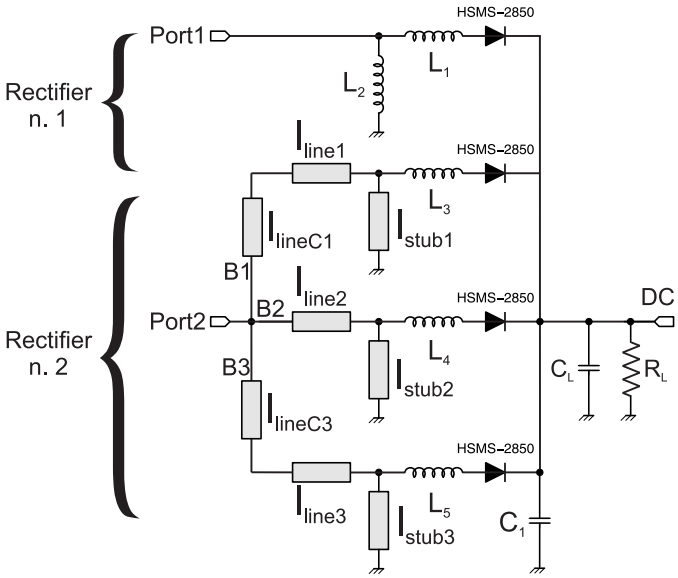

Fig. 7. Schematic of the multiband rectifier. The main circuit parameters are: $L_1 = 47$ nH, $L_2 = 27$ nH, $L_3 = 10$ nH, $L_4 = 8.7$ nH, $L_5 = 4.7$ nH, $l_{stub1} = 9.1$ mm, $l_{stub2} = 6.9$ mm, $l_{stub3} = 5.9$ mm, $w_{stub} = 0.4$ mm, $l_{lineC1} = 6.5$ mm, $l_{line1} = 11$ mm, $l_{line2} = 13$ mm, $l_{lineC3} = 4.25$ mm, $l_{line3} = 11$ mm, $w_{line} = 1$ mm, $C_1 = 100$ pF, $C_L = 100$ pF and $R_L = 3\,\text{k}\Omega$.

V. Rectifier Design

The design of the rectifier has been carried out with the aim of achieving a good balance among circuit complexity, number of utilized surface mount components, and low-power performance, to be consistent with the inexpensive nature of the adopted substrate.

The schematic of the proposed rectifier is shown in Fig. 7. The circuit parameters have been optimized to achieve the maximum RF-to-dc conversion efficiency for available input power levels ranged between -20 and -15 dBm. The design has been carried out by means of the Advance Design System suite.

As anticipated in Fig. 1, each antenna is connected to its own rectifier. each antenna is connected to its own rectifier. Due to its relatively small bandwidth (19.3 % around 880 MHz) the first rectifier ("rectifier #1" in Fig. 1) was realized with a simple envelope detector. On the other hand, this configuration was impractical for the second rectifier ("rectifier #2"). In fact, because of the frequencydependent input impedance of the diode and the limited bandwidth of common compact matching networks, it was very hard to achieve a reasonable large-signal input matching all over the band (45 % around 2.2 GHz), which is essential to guarantee the maximum power transfer to the load. Examples of multiband single-branch rectifiers have been provided in the literature (see [14], [17], [30], [31]), but such approaches are not able to guarantee the coverage over the intended broad frequency band, while allowing for low-power operation. So, in order to achieve a high RF-to-dc conversion efficiency of the rectifier throughout the band, it has been chosen to connect three envelope detectors in parallel, in such a way that each of them operates in a narrower band, according to the approach reported in [12], effectively synthesizing the aggregate band. Each branch, labeled with "B1", "B2" and "B3" in Fig. 7, has been tuned around 1.8, 2.05 and 2.6 GHz, respectively. By optimizing each branch of the rectifier, it is possible to finetune its conversion efficiency so as to achieve a local maximum in each subband of interest. To make the optimization process as accurate as possible, the S-parameter files provided for the lumped inductors by the manufacturer were introduced in the Advanced Design System schematic (the selected inductors belong to the Coilcraft 0603HP series).

Each utilized envelope detector is based on a seriesconnected HSMS2850 low-barrier Schottky diode from Avago, which is suitable for operation in the μW range [32]. Each diode is connected to an input matching network, consisting of an L-type impedance transformer, aimed at converting the input impedance of the antenna (around 50 Ω) to the conjugate of the large-signal input impedance of the diode (see [33]). Unlike in [19], here, some transmission line sections have been replaced by lumped (Coilcraft) components. In fact, it has been observed that the utilized rectifier topology is particularly sensitive to the losses of the line which connects the diode to the stub, since in this section, there is a higher voltage drop (this is actually the aim of the transformer). It was observed that the Coilcraft lumped components are less lossy for the inductance levels of interest in the circuit, as shown in Fig. 8. Simulations were conducted, considering both the S-parameter files of the inductors provided by Coilcraft and the high-impedance microstrip lines connected to ground. The technological pitch of 0.2 mm was chosen for the linewidth. The simulations were performed for both the smallest and the highest inductance values utilized in the rectifier, and in both cases the superiority of the Coilcraft components is noticeable, although this effect is more prominent for the 47-nH inductance. In the first rectifier, the stub has been replaced as well by an inductance due to its low frequency of operation, to reduce the circuit size.

In addition to "lineC1" and "lineC3", introduced for the sake of feasibility, three transmission line sections ("line1", "line2" and "line3" in Fig. 7) have been added to the three branches of the second rectifier in order to rotate the input impedance of each branch, so that the frequencies outside the operating subband feature a high impedance. On the contrary, the operating center frequency of each branch is only marginally affected by its respective line section, since the circuit is designed in such a way that the input impedance at this frequency is approximately located at the center of the Smith chart.

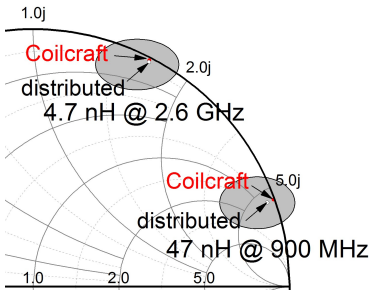

Fig. 8. Inductance implementation: study of the losses related to lumped (Coilcraft) and distributed inductors on paper substrate.

The main idea is to allow each frequency to enter predominantly the branch which is optimized to convert it, thus reducing the consequent loss of power. Fig. 9 reports the input reflection coefficient of each branch of the second rectifier with and without the respective input transmission line sections ("line1", "line2" and "line3" are mentioned as "input line" in Fig. 9), whereas Fig. 10 shows the transmission coefficient between Port2 and each branch of the second rectifier. All reported results were calculated for the design power level of 15 dBm. The addition of these lines was shown to improve the transmission coefficient by up to 4 dB for each branch of the rectifier and for all frequencies of interest. This approach is analogous to that applied to frequency division multiplexers and, although suboptimal for branches B1 and B3 (only one external band can be rotated to open), it eliminates the need to implement high-order bandpass filters [12].

Finally, all branches were connected to a single RC filter, with the exception of the last branch that was tuned to 2.6 GHz, where an additional capacitor was introduced in order to minimize interferences among detectors. The load, equal to 3 kΩ, was a parameter of the rectifier optimization (see Fig. 17).

In the end, the whole multiband on-paper rectifier was realized with four diodes, five inductors, two capacitors, and the load.

A photograph of the rectifier prototype is shown in Fig. 11.

After a fine-tuning of the value of the lumped components, which has been conducted in order to compensate for additional parasitics not included in the simulations (such as the soldering effects on the paper and the glue of the copper tape, the connectors impact, and so on), the performance of the rectifier under a single tone sweep has been evaluated for different power levels, and the results are reported in Figs. 12-19.

Fig. 12 shows the adequate large signal input reflection coefficient at both ports of the rectifier for a -15-dBm avail-

able input power. An $|S_{11}|$ of less that -6 dB was achieved throughout all bands of interest.

In Fig. 13 the rectifier performance in terms of output dc voltage is demonstrated, whereas Fig. 14 shows the resulting

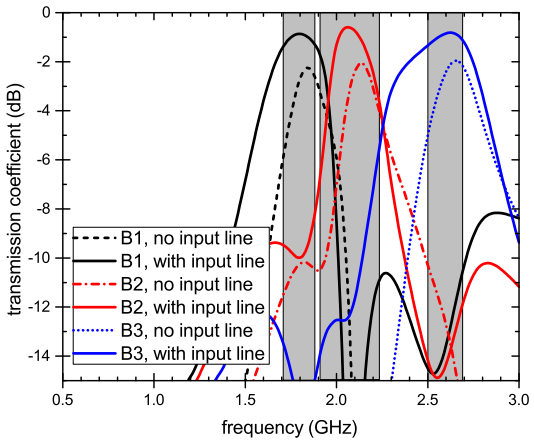

Fig. 10. Transmission coefficient for each branch of rectifier n.2 with and without transmission line sections. The simulation results are reported for an available input power of -15 dBm.

power delivered to the load, and P_{avs} is the available RF power at the source. The measurement has been separately carried out for Port1 [reported in Fig. 14(a)] and for Port2 [in Fig. 14(b)].

The first rectifier, which features the best performance, shows an output dc voltage in the operating band ranging from 50 to 70 mV and from 140 to 170 mV for the available input power levels of 20 and 15 dBm, respectively, corresponding to peak efficiencies of $16\,\%$ and $30\,\%$. Moreover, its peak efficiency grows up to the $52\,\%$ at 0 dBm.

On the other hand, the second rectifier presents an output dc voltage in the range of 36-57 mV and 101-142 mV at -20 and -15 dBm, with the respective peak efficiencies of $10.2\,\%$ and $21.3\,\%$, which are achieved in the first band (band 3 of Table I). In the other two bands, the respective peak efficiencies of $11\,\%$ and $6\,\%$ are obtained for -20 dBm and of $20.5\,\%$ and $14.3\,\%$ for -15 dBm. This performance deterioration is mainly due to the diode losses, which increase with frequency [32], and to the input interaction and interference among the three branches, which is missing, instead, in the first rectifier.

However, it is worth noticing that the circuit performance varies quite smoothly in all bands for all power levels under test, thus achieving the goal to ensure energy harvesting from all bands of interest.

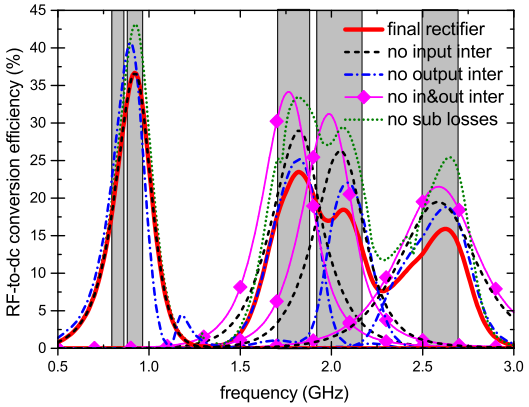

Fig. 15. Multiband rectifier: simulation study of the impact of substrate losses, input and output interactions.

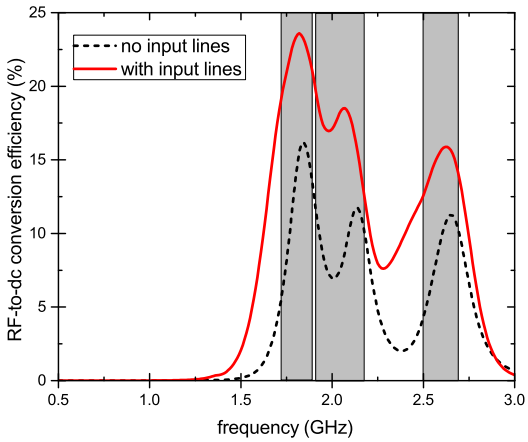

Fig. 16. Simulated RF-to-dc conversion efficiency of rectifier #2 with and without input transmission line sections for an available input power of -15 dBm.

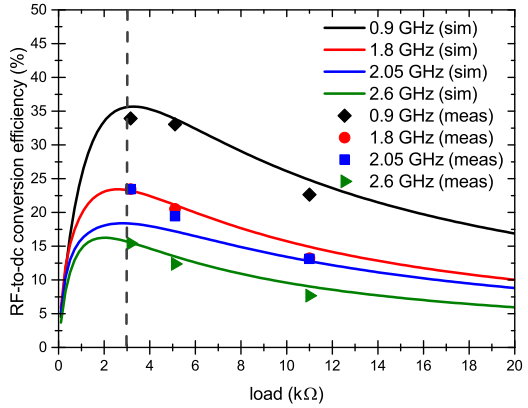

Fig. 17. Multiband rectifier: RF-to-dc conversion efficiency versus load (P_{avs}=-15 dBm).

In Fig. 15, an analysis of the losses associated with both the substrate and the chosen architecture is reported. Four simulations regarding four different scenarios are considered. In the first one, all branches are separated at the input, and the source is connected to one branch at a time, while the others are connected to a $50-\Omega$ impedance, thus removing the effect of input coupling; in the second one, all rectifier branches are connected to a different output RC filter, thus removing their output interaction; then, the performance of each branch of the rectifier is separately evaluated, i.e., each branch is connected to a different source and load (no input and output interactions); finally, in the fourth one, the substrate losses have been removed without changing the final circuit topology. As a case study, the RF-to-dc conversion efficiency for an available input power of 15 dBm is considered. It is apparent that the major limitation to the rectifier efficiency is represented by the substrate losses, which causes an efficiency reduction around $10\,\%$ at all center bands. The aggregate losses related to the circuit topology with both input and output coupling are on the whole comparable with the dielectric ones, with the input and output interactions having an impact on average around $7\,\%$ and $3\,\%$, respectively. Nevertheless, the maximum efficiency achieved in [19] around 2.4 GHz is intermediate between the ones of the rectifiers operating around 2.05 and 2.6 GHz without any input and output interactions. It is worth noticing that the branch centered around 900 MHz is only affected by an output interaction, thus experiencing a lower efficiency degradation. Additionally, Fig. 16 highlights the beneficial impact of the input transmission line sections on the conversion efficiency of the second rectifier due to the more selective bandpass characteristic experienced by the input signal in each branch. The simulations were carried out for the 15-dBm available input power and show an improvement of the peak performance in each subband around $7\,\%$.

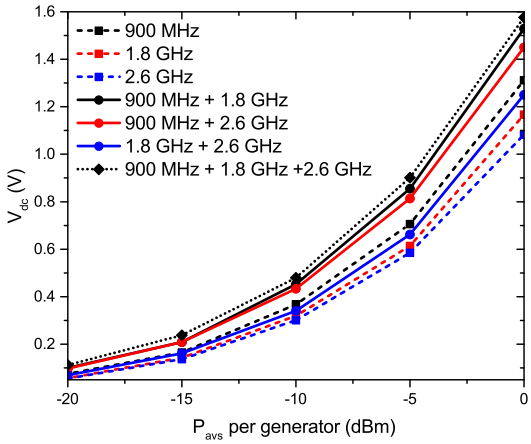

Fig. 18. Multitone test: measured output dc voltage versus an available input power (P_{avs}) per source for one, two and three tones.

Fig. 17 reports the RF-to-dc conversion efficiency with respect to the load resistance at the design power of 15 dBm. The optimum load is different for the four branches of the rectifier, and the value of $3\,\mathrm{k}\Omega$ is chosen as a result of a tradeoff aimed at maximizing the output dc power under the assumption that an equal amount of power enters each branch of the rectifier at its respective central frequency. This is equivalent to maximizing the sum of the efficiencies calculated at the four central frequencies, as reported in

$$\begin{aligned} P_{dc} &= P_{dc,0.9} + P_{dc,1.8} + P_{dc,2.05} + P_{dc,2.6} = \\ &= \eta_{0.9} P_{avs} + \eta_{1.8} P_{avs} + \eta_{2.05} P_{avs} + \eta_{2.6} P_{avs} = \\ &= P_{avs}(\eta_{0.9} + \eta_{1.8} + \eta_{2.05} + \eta_{2.6}), \end{aligned} \quad (2)$$

where P_{dc} is the total output dc power, $P_{dc,x}$ is the output dc power corresponding to an RF input power P_{avs} at a frequency of x GHz, and η_x is the RF-to-dc conversion efficiency associated with the P_{avs} input power and calculated at a frequency of x GHz. Therefore, this approach penalizes the rectifier efficiency at 2.6 GHz, which features a maximum efficiency for a load equal to $2\,\mathrm{k}\Omega$.

Finally, the circuit performance under multitone input signals has been tested. The rectifier has been connected to

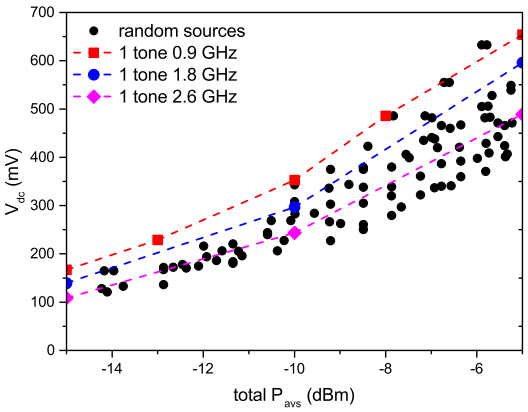

Fig. 19. Multione test: measured output dc voltage for an available RF input power randomly distributed over three tones.

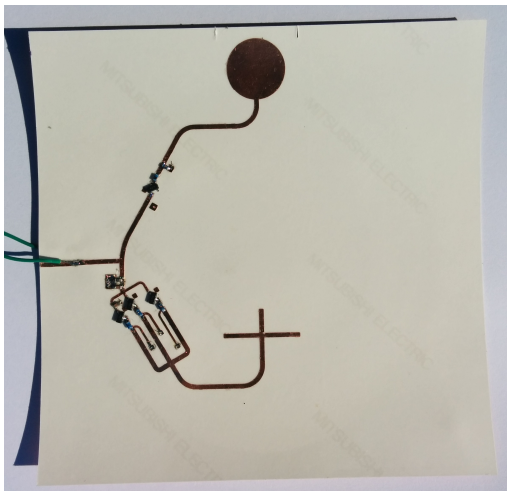
(a)



(b)

Fig. 20. Layout of the rectenna prototype. (a) Top side. (b) Bottom side.

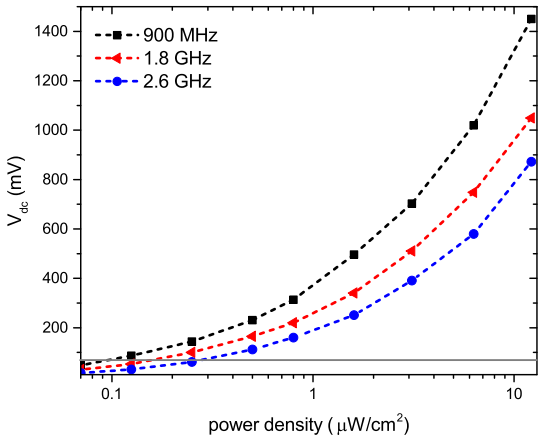
three different power generators, each of them transmitting a single tone tuned to 900 MHz, 1.8 GHz, and 2.6 GHz, respectively. The output dc voltage is recorded as a function of the available input power per source for one, two, and three tones. In this way, the rectifier capability to take advantage of the simultaneous presence of multiple tones has been verified. As a second experiment, the power associated with each tone has been randomly varied in such a way that their sum takes values within the range [15, 5] dBm. This operation has been repeated for 100 times, and the output dc voltage has been recorded with results shown in Fig. 19. It is worth noticing that the data variance is mainly due to the different conversion efficiencies experienced in each band and that, as expected, the best performance is obtained for the lower band. A few points are above the 900-MHz one-tone performance due to the fact that the phases of the three independent generators are randomly combined to achieve an optimized waveform [34].

Fig. 21. Test of the rectenna in laboratory: experimental setup.

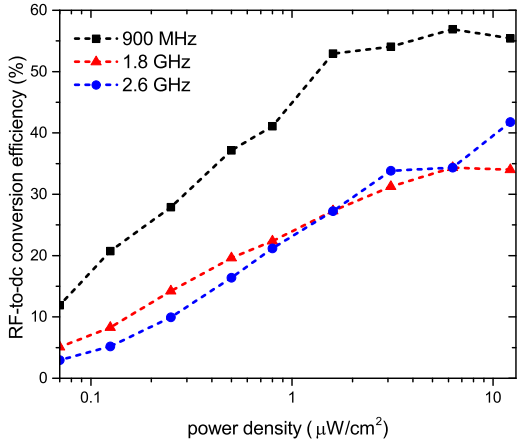
VI. RF Harvester Measurements

In order to validate the proposed architecture, the whole rectenna topology was fabricated on a paper substrate, by using the materials and techniques described in Section III, and tested (see Fig. 20 where both sides of the circuit are shown). The rectenna maximum thickness is equal to 1.2 mm, including both the thickness of the substrate and the lumped components. The two rectifiers were arranged so as to take advantage of the ground plane between the two antennas. This guarantees that the rectifiers are placed near the antenna feed, thus reducing the presence of losses. Moreover, thanks to this arrangement, the rectenna area corresponds to the bare area of the outer antenna, confirming the compactness of the proposed solution, whereas the cut in the outer slot allows for the usage of the outer metal surface to host other circuit components. The proposed rectenna prototype features a weight of only 6 g, while it is conformal and suitable for a broad range of low-cost applications. For instance, it can be used together with a suitable energy storage unit and a circuit with very low duty cycle operation ensuring a large energy autonomy and batteryless operation. Such a system can also be used as a trickle charge for batteries in order to compensate for their self-discharging.

The rectenna performance was first measured in a controlled environment, as reported in Section VI-A-A, and finally tested in real scenarios, both in normal (flat) and in bent conditions.



(a)



(b)

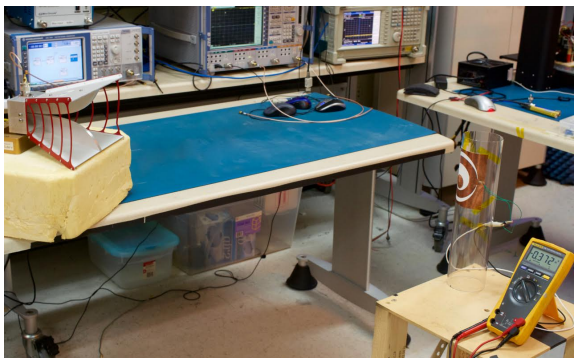

Fig. 23. Rectenna testing under bending conditions: experimental setup.

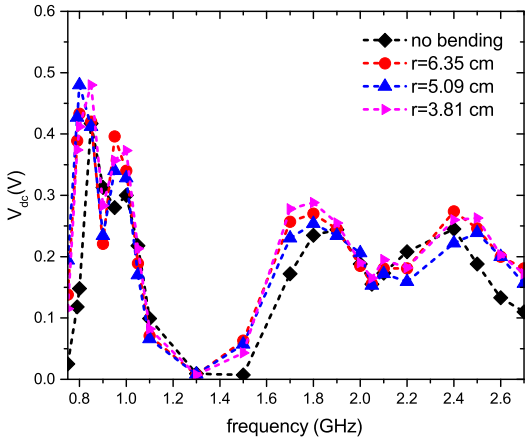

Fig. 24. Rectenna performance under different bending conditions: output dc voltage for different radii of curvature.

A. Rectenna characterization in a controlled environment

A controlled experiment was performed in a laboratory room using the setup shown in Fig. 21. A power source was connected to a double-ridged waveguide horn antenna (3115 model from ETS-LINDGREN). The rectenna was aligned with the antenna and placed at a distance of 1.6 m, which is outside the Fraunhofer region, delimited by the well-known equation (3), for both the transmitting and the receiving antenna

$$R = \frac{2\,D^2}{\lambda_0}, \tag{3}$$

where R is the distance between the phase center of the antennas, D is the largest dimension of the power-source antenna (equal to 25 cm for the horn), and λ_0 is the free-space wavelength associated with the operating frequency.

The rectenna was connected to a multimeter, and the power source was set to three different frequencies (900 MHz, 1.8 GHz, and 2.6 GHz), while for each tone the transmitted power was varied from 5 to 29 dBm. Fig. 2222(a) and (b) shows the measured output dc voltage and RF-to-dc conversion efficiency as a function of the power density at the antenna of the harvester. To calculate the latter quantity, the "standalone" antenna topology on paper was placed in the same position as the rectenna under test, and it was connected to a power meter. The measured RF input power was divided by the effective area of the respective slot antenna, estimated with the well-known equation as

$$A_{eff} = G_i \frac{{\lambda_0}^2}{4\,\pi}, \tag{4}$$

where G_i is the measured gain for the respective-to-the-band slot antenna. In particular, the power density was calculated for the three frequencies of interest for each power level, and the results were averaged in order to compensate for uncertainties stemming from the experimental setup.

According to the obtained results, a power density in the order of 0.1-1 μW/cm^2 is sufficient to activate emerging ultralow voltage electronics, while 10 μW/cm^2 is required for standard electronics ("switch ON" voltage around and above 1 V).

B. Rectenna testing in real scenarios

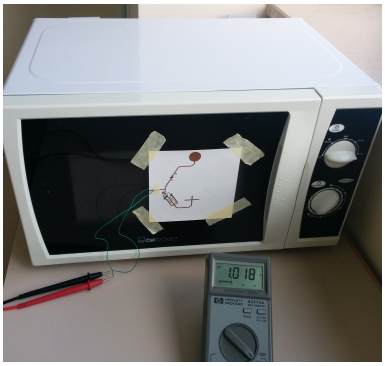
The performance of the presented flexible rectenna was tested under different bending conditions (see Fig. 23). The rectenna was placed at a distance of 90 cm and aligned with the transmitting antenna. The latter was connected to a signal generator set to a fixed transmitting power of 15 dBm. The recorded output dc voltages versus frequency were collected for three radii of curvature, as shown in Fig. 24. The impact of bending seems to be neglectable, and the rectenna performance remains nearly unchanged for a radius of curvature as small as 3.81 cm.

The proposed rectenna was proved to be suitable for utilization in a broad range of realistic scenarios, with numerous ambient devices using microwaves for different purposes, thus effectively increasing the local RF power density. For instance, the rectenna was mounted on the door of a microwave oven, which operates at the ISM S-band [Fig. 25(a)]. Despite the power shielding, an output dc voltage around 1 V was measured across the 3-kΩ load during the whole cooking time. In the second example, the rectenna was placed under a smartphone. During an incoming call (GSM900 band), an output dc voltage around 300400 mV was observed.

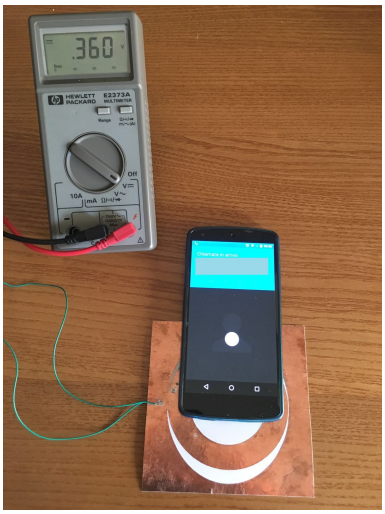
C. Performance Comparison

In Table II, a comparison of the presented rectenna with other state-of-the-art rectennas fabricated on flexible and/or unconventional substrates is reported. Reference [19] has already been presented in the introduction, and consists of a single annular slot and an envelope detector. A dual-band rectifier and a single wideband monopole were used in [35], while [36] was based on a class-F rectifier and a direct matching between the antenna and the diode. In [37] a half-wave double monopole antenna and a two diode rectifier were employed, and finally, multilayer wearable rectennas were proposed both in [38] and [39]. Reference [38] relies on a rectangular patch antenna, while [39] is based on a slot-loaded annular ring antenna; both solutions utilize a single-stage full-wave rectifier. As it can be easily observed, the majority of these papers focus on single-band or even single-frequency harvesters.

The presented rectenna features a very good performance in terms of occupied area and maximum efficiency with respect to incident power density, while it guarantees operation over a broader frequency range over multiple bands.



(a)



(b)

Fig. 25. Photograph of possible practical scenarios for the proposed rectenna: ambient RF energy harvesting from (a) operating microwave oven and (b) cell phone during an incoming call.

VII. CONCLUSION

A novel compact multiband rectenna on paper for ambient RF energy harvesting has been introduced in this effort. Both the design procedure and the measurement results have been thoroughly discussed. The rectenna is able to harvest power in all LTE frequency bands at the available input power levels as low as 20 dBm in a variety of practical and conformal scenarios, thus setting the foundation of truly autonomous IoT and smart node configurations.

Future improvements are also possible: the rectifier can be

optimized for multitone operation, for instance, by means of the adoption of higher order bandpass filters in each branch of the second rectifier [12]; the applicability of the system can be freed from orientation constraints by developing compact broadband circularly polarized antennas, achievable through the introduction of ad hoc shorts in specific positions of the slot antennas [28].

Valentina Palazzi (S'15) received the B.Sc. and M.Sc. degrees (*magna cum laude*) from the University of Perugia, Perugia, Italy, in 2012 and 2014, respectively, where she is currently pursuing the Ph.D. degree in industrial and information engineering at the High Frequency Electronics Laboratory.

In 2015, she was a Visiting Ph.D. Student with the Tyndall National Institute, Cork, Ireland. In 2016, she spent three weeks with the Centre Tecnolgic de Telecomunicacions de Catalunya, Barcelona, Spain, sponsored by the COST action IC1301 Wireless Power Transmission for Sustainable Electronics. In 2016, she joined the Agile Technologies for High- Performance Electromagnetic Novel Applications Research Group, School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA, USA, for five months, where she is currently involved in additive manufacturing technologies and flexible electronics. Her current research interests include the design of passive transponders with sensing capabilities, radar front ends, wireless power transfer technologies, additive manufacturing processes, and conformal electronics.

Ms. Palazzi is a member of IEEE MTT-S TC-24 RFID Technologies. She was a recipient of the First Place Award of the IEEE MTT-S Student Design Competition on Wireless Energy Harvesting held at the International Microwave Symposium 2016. She was also a recipient of the IEEE MTT-S Graduate Fellowship in 2017.

Jimmy Hester (S'14) received the degree in fundamental chemistry, math, and physics, the degree and M.S. degree in electrical and signal processing engineering (with a major in radio frequency electronics) from ENSEEIHT, INP Toulouse, Toulouse, France, in 2012 and 2014, respectively, and the M.S. degree in electrical and computer engineering from the Georgia Institute of Technology, Atlanta, GA, USA, in 2014, where he is currently pursuing the Ph.D. degree in electrical and computer engineering.

He is currently a Research Assistant with the Agile Technologies for High-Performance Electromagnetic Novel Applications Research Group, Georgia Institute of Technology. He has been developing solutions for the use of carbon nanomaterials and optimized RF structures toward the implementation of inkjet-printed flexible low-cost ubiquitous gas sensors for Internet of Things and smart skin applications. His work covers the entire development process, from the development of inkjet inks, improvement of fabrication methods, sensor component design, high-frequency characterization, and environmental testing to the design, simulation, and fabrication of the RF system embedding the sensor. His current research interests include the interface between radio frequency engineering and material science in the form of flexible electronics technologies and nanotechnologies.

Jo Bito (S'13) received the B.S. degree in electrical and electronic engineering from Okayama University, Okayama, Japan, in 2013, and the M.S. degree in electrical and computer engineering from the Georgia Institute of Technology, Atlanta, GA, USA, in 2016, where he is currently pursuing the Ph.D. degree.

From 2010 to 2011, he was with the University of Illinois UrbanaChampaign, Champaign, IL, USA, where he joined the international programs in engineering (IPENG). He is currently a Research Assistant with the Agile Technologies for High-Performance Electromagnetic Novel Applications (ATHENA) Research Group, Georgia Institute of Technology. His current research interests include the application of inkjet printing technology for flexible and wearable electronics, RF energy harvesting, and wireless power transfer systems.

Mr. Bito was a recipient of the Japan Student Services Organization Long Term Scholarship beginning in 2013.

Federico Alimenti (S'91-A'97-M'06-SM'09) received the Laurea and Ph.D. degrees in electronic engineering from the University of Perugia, Perugia, Italy, in 1993 and 1997, respectively.

In 1996, he was a Visiting Scientist with the Technical University of Munich, Munich, Germany. From 2011 to 2014, he was a Scientific Coordinator of the ENIAC ARTEMOS Project. In 2014, he was a Visiting Professor with the cole Polytechnique Fdrale de Lausanne, Lausanne, Switzerland. Since 2001, he has been with the Department of Engineering, University of Perugia, where he teaches the class Microwave Electronics. He holds 2 patents and has co-authored over 200 papers in journals and conferences. His current research interests include microwaveintegrated circuit design and electronics on cellulose.

Dr. Alimenti was a recipient of the URSI Young Scientist Award in 1996 and the IET Premium (Best Paper) Award in 2013. He was the TPC Chair of the IEEE Wireless Power Transfer Conference in 2013. He has an h-index of 18 in Google Scholar.

Christos Kalialakis (S'94-M'00-SM'09) received the B.Sc. degree in physics and the M.Sc. degree in telecommunications from the Aristotle University of Thessaloniki, Thessaloniki, Greece, in 1993 and 1995, respectively, the Ph.D. degree in electronic and electrical engineering from the University of Birmingham, Birmingham, U.K., in 1999, and the M.B.A. degree from Hellenic Open University, Patras, Greece, in 2016.

He has industry experience in U.K. as an Antenna Designer and then in Greece and USA as an RF Hardware Engineer. Since 2002, he has been with the National Regulatory Authority of Greece for ICT as an Expert on Wireless Communications. He joined the Centre Tecnolgic de Telecomunicacions de Catalunya, Barcelona, Spain, in 2015, as a Senior Researcher.

Ana Collado (M'08-SM'12) received the M.Sc. and Ph.D. degrees in telecommunications engineering from the University of Cantabria, Santander, Spain, in 2002 and 2007, respectively.

From 2007 to 2016, she was a Senior Research Associate and the Project Management Coordinator with the Centre Tecnolgic de Telecomunicacions de Catalunya, Barcelona, Spain. Since 2016, she has been an Assistant Professor with the Microwaves and Antennas Research Group, School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, U.K. She has participated in national and international research projects. Among her activities, she has collaborated in the organization of several international workshops in different countries of the European Union and also a Training School for Ph.D. students. She has co-authored over 90 papers in journals and conferences. Her current research interests include active antennas, substrate-integrated waveguide structures, nonlinear circuit design, and energy harvesting and wireless power transmission solutions for self-sustainable and energy-efficient systems.

Dr. Collado is a member of IEEE MTT-26 Wireless Energy Transfer and Conversion and MTT-24 RFID Technologies. She serves on the Editorial Board of the Radioengineering Journal. She is an Associate Editor of IEEE Microwave Magazine, an Associate Editor of the IET Microwaves, Antennas and Propagation Journal, and a member of the Editorial Board of the Cambridge Wireless Power Transfer Journal.

Paolo Mezzanotte (M'12) was born in Perugia, Italy, in 1965. He received the Ph.D. degree from the University of Perugia, Perugia, in 1997.

Since 2007, he has been an Associate Professor with the University of Perugia, where he has been involved in teaching the class Radiofrequency Engineering. His current research interests include numerical methods and CAD techniques for passive microwave structures, the analysis and design of microwave and millimeter-wave circuits, and the study of advanced technologies, such as LTCC, RF-MEMS, and microwave circuits printed on green substrates. These research activities are testified by over 100 publications in the most important specialized journals and at the main conferences of the microwave scientific community. His present h-index (ISI journals) is equal to 13.

Apostolos Georgiadis (S'94-M'02-SM'08) was born in Thessaloniki, Greece. He received the B.S. degree in physics and M.S. degree in telecommunications from the Aristotle University of Thessaloniki, Thessaloniki, in 1993 and 1996, respectively, and the Ph.D. degree in electrical engineering from the University of Massachusetts at Amherst, Amherst, MA, USA, in 2002.

In 2006, he was a Consultant with Bitwave Semiconductor, Lowell, MA, USA. In addition, he collaborated with ACORDE S.A., Santander, Spain, where he was involved in the design of integrated CMOS VCOs for ultrawideband applications. From 2013 to 2016, he was a Group Leader with the Microwave Systems and Nanotechnology Department, Centre Tecnolgic de Telecomunicacions de Catalunya (CTTC), Barcelona, Spain. In 2002, he joined Global Communications Devices, North Andover, MA, USA, as a Systems Engineer, where he is involved in CMOS transceivers for wireless network applications. In 2003, he joined Bermai, Inc., Minnetonka, MN, USA, as an RF/Analog Systems Architect. In 2005, he joined the University of Cantabria, Santander, as a Juan de la Cierva Fellow Researcher. In 2007, he joined CTTC as a Senior Researcher in communications subsystems. In 2016, he joined Heriot-Watt University, Edinburgh, U.K., as an Associate Professor. He has authored over 170 papers in peer-reviewed journals and international conferences. His current research interests include energy harvesting and wireless power transmission, RFID technology, active antennas and phased array antennas, inkjet and 3-D printed electronics, and millimeter wave systems.

Dr. Georgiadis is an EU Marie Curie Global Fellow. He is a member of the IEEE MTT-S TC-24 RFID Technologies (past Chair) and a member of the IEEE MTT-S TC-26 Wireless Energy Transfer and Conversion. In 1996, he was the recipient of the Fulbright Scholarship for graduate studies at the University of Massachusetts at Amherst. In 2016, his proposal for Inkjet/3D printed millimeter-wave systems received the Bell Labs Prize, Third Place among more than 250 proposals recognizing ideas that change the game in the field of information and communications technologies. He was the General Chair of the 2011 IEEE RFID-TA Conference and a General Co-Chair of the 2011 IEEE MTT-S IMWS on Millimeter Wave Integration Technologies. He is a Vice Chair of URSI Commission D, Electronics and Photonics and an AdCom member of the IEEE Council on RFID serving as a Vice President of conferences. He is a Distinguished Lecturer of the IEEE Council on RFID. He was an Associate Editor of the IET Microwaves Antennas and Propagation Journal, IEEE MICROWAVE AND WIRELESS COMPONENTS LETTERS, and the IEEE RFID VIRTUAL JOURNAL. He serves as an Associate Editor of the IEEE JOURNAL ON RFID. He is the Founder and an Editor-in-Chief of the Wireless Power Transfer Journal (Cambridge Univ. Press).

Luca Roselli (M'92-SM'01) joined the University of Perugia, Perugia, Italy, in 1991. In 2000, he founded the spin-off WiS Srl. He was involved in electronic technologies for Internet of Things for six years. He is currently a Qualified Full Professor with the University of Perugia, where he teaches applied electronics and coordinates the High Frequency Electronics Laboratory. He has authored over 280 papers (H-i 23, i10 51, over 2200 citations-Scholar) and Green RFID System (Cambridge Univ. Press, 2014). His current research interests include HF electronic systems with a special attention to RFID, new materials, and wireless power transfer.

Dr. Roselli was a member of the Board of Directors of ART Srl, Urbino, Italy, from 2008 to 2012. He is a member of the list of experts of the Italian Ministry of Research, the past Chair of the IEEE Technical Committees MTT-24-RFID, the Vice Chair of 25-RF Nanotechnologies, 26-Wireless Power Transfer, the ERC Panel PE7, and the Advisory Committee of the IEEE-WPTC, and the Chairman of the SC-32 of IMS. He is the Co-Chair of the IEEE Wireless Sensor Network Conference. He organized the VII Computational Electromagnetic Time Domain in 2007 and the first IEEE Wireless Power Transfer Conference in 2013. He is an Associate Editor of IEEE Microwave Magazine. He is involved on the boards of several international conferences. He is a Reviewer for many international reviews, including the PROCEEDINGS OF THE IEEE, the IEEE TRANSACTIONS ON MICROWAVE THEORY AND TECHNIQUES, and IEEE MICROWAVE AND WIRELESS COMPONENTS LETTERS.

Manos M. Tentzeris (S'94-M'98-SM'03-F'10) received the Diploma (magna cum laude) degree in electrical and computer engineering from the National Technical University of Athens, Athens, Greece, and the M.S. and Ph.D. degrees in electrical engineering and computer science from the University of Michigan, Ann Arbor, MI, USA.

He was a Visiting Professor with the Technical University of Munich, Munich, Germany, in 2002, he was a Visiting Professor with GTRI-Ireland, Athlone, Ireland, in 2009, and a Visiting Professor with LAAS-CNRS, Toulouse, France, in 2010. He has given over 100 invited talks to various universities and companies all over the world. He has helped develop academic programs in 3-D/inkjet-printed RF electronics and modules, flexible electronics, origami and morphing electromagnetics, highly integrated/multilayer packaging for RF and wireless applications using ceramic and organic flexible materials, paper-based RFIDs and sensors, wireless sensors and biosensors, wearable electronics, green electronics, energy harvesting and wireless power transfer, nanotechnology applications in RF, microwave MEMS, and SOP-integrated (ultra-wideband, multiband, mmW, and conformal) antennas, and heads the Agile Technologies for High- Performance Electromagnetic Novel Applications Research Group, Georgia Institute of Technology, Atlanta, GA, USA (20 researchers). He has served as the Head of the GT-ECE Electromagnetics Technical Interest Group, the Georgia Electronic Design Center Associate Director of the RFID/Sensors Research, the Georgia Tech NSF-Packaging Research Center Associate Director of the RF Research, and the RF Alliance Leader. He is currently a Ken Byers Professor in flexible electronics with the School of Electrical and Computer Engineering, Georgia Institute of Technology. He has authored over 650 papers in refereed journals and conference proceedings, 5 books, and 25 book chapters. He holds 14 patents.

Dr. Tentzeris is a member of the URSI-Commission D, the MTT-15 Committee, and the Technical Chamber of Greece, an Associate Member of EuMA, and a Fellow of the Electromagnetic Academy. He was a recipient/ co-recipient of the 2017 Georgia Tech Outstanding Achievement in Research Program Development Award, the 2017 Archimedes IP Salon Gold Medal, the 2016 Bell Labs Award Competition 3rd Prize, the 2015 IET Microwaves, Antennas and Propagation Premium Award, the 2014 Georgia Tech ECE Distinguished Faculty Achievement Award, the 2014 IEEE RFID-TA Best Student Paper Award, the 2013 IET Microwaves, Antennas and Propagation Premium Award, the 2012 FiDiPro Award in Finland, the iCMG Architecture Award of Excellence, the 2010 IEEE Antennas and Propagation Society Piergiorgio L. E. Uslenghi Letters Prize Paper Award, the 2011 International Workshop on Structural Health Monitoring Best Student Paper Award, the 2010 Georgia Tech Senior Faculty Outstanding Undergraduate Research Mentor Award, the 2009 IEEE TRANSACTIONS ON COMPONENTS AND PACKAGING TECHNOLOGIES Best Paper Award, the 2009 E. T. S. Walton Award from the Irish Science Foundation, the 2007 IEEE APS Symposium Best Student Paper Award, the 2007 IEEE IMS Third Best Student Paper Award, the 2007 ISAP 2007 Poster Presentation Award, the 2006 IEEE MTT Outstanding Young Engineer Award, the 2006 AsianPacific Microwave Conference Award, the 2004 IEEE TRANSACTIONS ON ADVANCED PACKAGING Commendable Paper Award, the 2003 NASA Godfrey Art Anzic Collaborative Distinguished Publication Award, the 2003 IBC International Educator of the Year Award, the 2003 IEEE CPMT Outstanding Young Engineer Award, the 2002 International Conference on Microwave and Millimeter- Wave Technology Best Paper Award (Beijing, China), the 2002 Georgia Tech-ECE Outstanding Junior Faculty Award, the 2001 ACES Conference Best Paper Award, and the 2000 NSF CAREER Award and the 1997 Best Paper Award from the International Hybrid Microelectronics and Packaging Society. He was the TPC Chair of the IEEE MTT-S IMS 2008 Symposium and the Chair of the 2005 IEEE CEM-TD Workshop. He is the Vice Chair of the RF Technical Committee (TC16) of the IEEE CPMT Society. He is the Founder and the Chair of the RFID Technical Committee (TC24) of the IEEE MTT-S and the Secretary/Treasurer of the IEEE C-RFID. He served as the IEEE MTT-S Distinguished Microwave Lecturer from 2010 to 2012 and the IEEE CRFID Distinguished Lecturer. He is an Associate Editor of the IEEE TRANSACTIONS ON MICROWAVE THEORY AND TECHNIQUES, the IEEE TRANSACTIONS ON ADVANCED PACKAGING, and the International Journal on Antennas and Propagation.

Antennas and Metamaterials for Electromagnetic Energy Harvesting

by

Thamer Almoneef

A thesis
presented to the University of Waterloo
in fulfillment of the
thesis requirement for the degree of
Master of Applied Science
in
Electrical and Computer Engineering

Waterloo, Ontario, Canada, 2012

I hereby declare that I am the sole author of this thesis. This is a true copy of the thesis, including any required final revisions, as accepted by my examiners.

I understand that my thesis may be made electronically available to the public.

Abstract

The emergence of microwave energy harvesting systems, commonly referred to as rectenna or Wireless Power Transfer (WPT) systems, has enabled numerous applications in many areas since their primary goal is to recycle the ambient microwave energy. In such systems, microstrip antennas are used as the main source for collecting the electromagnetic energy.

In this work, a novel collector based on metamaterial particles, in what is known as a Split Ring Resonator (SRR), to harvest electromagnetic energy is presented. Such collectors are much smaller in size and more efficient than existing collectors (antennas). A feasibility study of SRRs to harvest electromagnetic energy is conducted using a full wave simulator (HFSS). To prove the concept, a 5.8 GHz SRR is designed and fabricated and then tested using a power source, an Infiniium oscilloscope and a commercially available patch antenna array. When excited by a plane wave with an H-field normal to the structure, a voltage build up of 611 mV is measured across a surface mount resistive load inserted in the gap of a single loop SRR. In addition, a new efficiency concept is introduced, taking into account the microwave-to-AC conversion efficiency which is missing from earlier work. Finally, a 9X9 SRR array is compared with a 2X2 patch antenna array, both placed in a fixed footprint. The simulation results show that the array of SRRs can harvest electromagnetic energy more efficiently and over a wider bandwidth range.

Acknowledgements

In the name of allah the most gracious, the most merciful:

First of all, I would like to thank God Almighty for providing me with the strength, health, patience and the tools to accomplish this thesis work.

Second, I would like to express my sincere gratitude to my supervisor, Prof. Omar Ramahi. I cannot thank him enough for his guidance and friendly assistance that helped me improve my technical skills and academic knowledge. Prof. Ramahi has been my inspiration as I hurdle all the difficulties and obstacles in the completion of this research work. I believe that having discussions with him is a peerless privilege.

I owe a debt of gratitude to my committee members Dr. Bo Cui and Dr. Karim Karim for serving in my examination committee and for their invaluable feedback. I greatly appreciate the time they devoted and their sincere advices. In addition, I would like to thank Dr. Dayan Ban for attending and participating in my seminar presentation and for his valuable feedback.

I would like to extend my utmost gratitude to my dear parents for their support, love and patience. Many thanks to my brothers and sisters for their advice, support and faithful love. I really apologize to all my family members for being away for a long period.

I am very lucky to be a member of an active and friendly research group. I would like to thank all my colleagues in the microwave and electromagnetics research group at the University of Waterloo: Dr. Muhammed Boybay, Dr. Babak Alavikia, Zhao Ren, Mohammed Alshareef, Ali Albishi, Ahmed Ashoor, Abdulaziz alqahtani, Abdulbaset Ali, Miguel Ruphuy, Ferhat Aydinoglu and special thanks to Dr. Mohammed M. Bait-Suwailam for his valuable support in regards to the fabrication process. Their hot discussions always sparked novel ideas.

This research was supported by the Saudi Arabian Ministry of Higher Education.

Dedication

To my parents

Chapter 1

Introduction

1.1 Thesis Objective

The work presented in this thesis is aimed at harvesting electromagnetic energy. In the literature, this topic is presented as rectenna systems or Wireless Power Transfer (WPT) systems. Therefore, both systems should be reviewed and the differences between the two systems should be understood in order to contribute to this topic. Hence, there are three main objectives of this thesis:

- Review the history of microwave energy harvesting through the work presented in the literature under rectenna and WPT systems. *(Chapter 2)*
- Analyze the challenges, limitations and working mechanism of rectenna systems through simulation and fabrication. *(Chapter 3)*
- Propose new and novel structures (metamaterial particles) for collecting electromagnetic energy, which are smaller in size and more efficient than existing collectors (antennas). *(Chapter 4)*

1.2 Thesis Contribution

The research work presented in this thesis provides three main contributions: a novel collector based on metamaterial particles for harvesting electromagnetic energy is introduced. A proof of concept through simulation and measurement is provided. In addition, a new method for calculating the efficiency of collectors is proposed to account for the microwave-to-AC conversion efficiency which is missing from earlier work presented in the literature. Finally, a simulation study is conducted which compares an array of patch antennas and an array of metamaterial particles in terms of microwave-to-AC conversion efficiency, with arrays both occupying the same footprint.

1.3 Thesis Outline

The reminder of the thesis is organized as follows:

Chapter 2 reviews the history and development of Wireless Power Transfer (WPT) and rectenna systems. In addition, the working mechanism of WPT and rectenna systems are provided. This chapter also reviews the compromises and challenges one can face when designing a full rectenna system. Finally, the most common applications of rectenna systems and their working mechanisms are covered.

Chapter 3 provides detailed procedures for designing a full rectenna system operating at 2.45 GHz. The steps taken during the fabrication process are also listed. A microstrip-line fed patch antenna is then fabricated and its results were compared to the once obtained by simulation. A strong agreement is observed in the return loss plot. Finally, the rectifier circuit is fabricated and tested.

Chapter 4 proposes a novel and new energy collector based on metamaterials in what is known as a Split Ring Resonator (SRR). A brief overview of metamaterials and some of their applications is presented. Two validity tests are conducted through simulation to study the feasibility of using one type of SRRs to harvest electromagnetic energy. Then an experiment is conducted though testing and measurements; it yielded results that prove the concept of using SRRs as collectors. Finally, the efficiency of an array of 9 X 9 SRRs

is compared to that of an array of 2 X 2 patch antennas placed over an identical footprint. The SRR array resulted in at least 25% more efficiency and a wider bandwidth ,over which the energy is collected, than that of the antenna array.

Chapter 5 finally, reviews the main milestones presented in this thesis. In addition, some concluding remarks and suggestions for future work are provided.

Chapter 2

Background

2.1 Introduction

This chapter provides a comprehensive overview of the most important milestones in the history and development of WPT systems, from the work and experiments of Hertz up to the date of this thesis. In addition, the working mechanism of WPT and rectenna systems, and some existing design challenges are discussed. Finally, a number of promising applications of rectenna systems along with a brief description of their operating mechanism are presented.

2.2 Historical Milestones

2.2.1 Early History

The notion of Wireless Power Transfer (WPT) was sparked in 1888 when Heinrich Hertz demonstrated electromagnetic wave propagation in free space [13]. Hertz used half wavelength dipoles operating at 500 MHz along with parabolic reflectors for transmitting and receiving electromagnetic energy. The high frequency power was generated by charging the opposite halves of the dipoles with high voltage in order to develop an arc across the gap.

As a result energy is stored in the gap, forming oscillations, and then the half wavelength dipoles radiate some of the oscillating energy as microwaves [52]. Hertz's experimental work constitutes crucial validation of Maxwell's hypothesis in regards to electromagnetic propagation in free space.

At the turn of the 20th century, further experiments on the concept of wireless power transfer were conducted by Nickola Tesla. A grant of $30,000, offered by Colonel John Jacob Astor, was used to build a gigantic coil resonating at 150 kHz, which was then placed in a large building in Colorado Springs, Colorado. Over the coil, was raised a 60 m pole topped by a 1 m diameter copper ball. The coil was then excited with low frequency power of 300 kW obtained from the Colorado Springs' electric power company. Consequently, a large RF potential was produced on the sphere, reaching 100 MV. After all his hard work at the Colorado Springs laboratory, Tesla was able to light 200 light bulbs placed 42 km away from the base station [18]. Tesla's work intrigued many researchers in Japan [57] and the US [1];however, technological limitations prevented them from progressing in this area.

It was not until the 1950s that the WPT became a useful technology, with the development of high power microwave tubes by the Raytheon Company. These tubes were considered essential for transmitting efficient high power at GHz frequencies. In 1963, William C. Brown, a pioneer in the concept and development of WPT, and his colleagues, demonstrated the first complete and efficient WPT system to a group of United States Air Force officials who funded the high power microwave tubes. In the demonstration, DC power was first converted to microwaves at 2.45 GHz and a power level of 400 W. A horn antenna was used to transmit the generated microwave energy, illuminating a reflector, which then bounced back the energy to its focal point. At the focal point, a diagonal horn antenna was placed to collect the microwave energy, which was converted back to DC by means of thermionic diodes. Conversion efficiencies of only 50% were realized [52].

Due to the low AC to DC conversion efficiency, which is attributed mainly to the diode, researchers have since focused on developing new and more efficient diodes. As a result, Hewlett-Packard Associates offered their new silicon Schottky-barrier diodes to C. Brown's group [12]. This type, the 2900 diodes, has the following advantages: much greater efficiency, much smaller size, and better capability of handling power than any of the previous diodes.

Both the development of high power microwave tubes and of the silicon Schottky-barrier diodes represent a paradigm shift in the history and development of the WPT technology.

In 1975, another key experiment was conducted in the Mojave Desert at the Jet Propulsion Laboratory's (JPL) Goldstone Facility to show the feasibility of transferring microwave power over a long distance. In this experiment, a new record was reached in terms of the amount of power received and the total distance over which the power was transmitted. The setup of the experiment consisted of a high powered klystron, which created microwave energy at 2.388 GHz and then fed it to a 26-m transmitting parabolic antenna as shown in Figure 2.1 [52]. This antenna excited a 26 m^2 rectenna (rectifying antenna) array located 1.54 km away. The rectenna array contained 4590 rectenna elements arranged in 17 panels, each panel consisting of 270 rectennas. Each rectenna element utilized a dipole antenna 0.47λ in length for capturing the microwave energy. Every two adjacent dipole antennas were separated by 0.6λ to maximize the collected microwave energy [19]. A set of lights were used as loads, each rectenna panel devoted to powering two lights. The total DC power collected by the rectenna array was over 30 kW, representing a total conversion efficiency of 84%. Overall, the developed WPT system in the Goldstone experiment was deemed successful for its ability to transmit power over a long distance, to demonstrate high conversion efficiency and to survive various weather conditions.

It is of interest to note that in parallel to the work accomplished by the Americans in regards to WPT, Canadian and Japanese researchers have developed their own programs, which contributed significantly to the advancement of WPT. An example of such a program developed by Canadian researchers is the Stationary High Altitude Relay Program (SHARP) and for those conducted by the Japanese are the Microwave Ionosphere Nonlinear Interaction Experiment (MINIX) and the Microwave Lifted Airplane Experiment (MILAX). For brevity, those programs are only mentioned ; however, details of each program can be found in [46, 33, 24] respectively.

Since the total efficiency of the WPT system depends significantly on the receiving system, commonly referred to as the rectenna system, research on this subject has focused on developing various rectenna systems that yield higher conversion efficiencies. In 1977, W. C. Brown at Raytheon developed a 2.45 GHz rectenna system that reached a conversion efficiency of 90.6% [11]. Both the dipole antenna and the transmission lines used in this

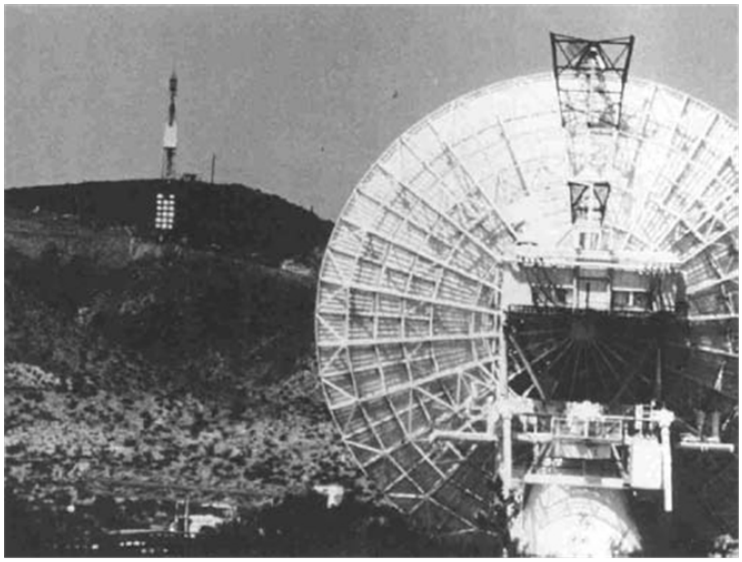

Figure 2.1: A picture showing the experiment conducted at the JPL Goldstone facility in the Mojave Desert.

system were made out of aluminum bars, and the microwave power collected by the antenna was converted to DC using a GaAs-Pt Schottky barrier diode. The conversion efficiency of this rectenna system is recognized as one of the greatest efficiencies ever recorded [34].

In 1985, Brown and Triner developed a revolutionary rectenna system using printed thin film technology. The rectenna system was designed to operate at 2.45 GHz and was able to achieve 85% conversion efficiency [14]. The main advantage of using such technology is its light weight, being 10 times lighter than previously developed rectennas. Since then, most rectenna systems have been made using photolithographic etching techniques for their ease of fabrication, low cost and light weight [52].

2.2.2 Recent Development

In most of the aforementioned experiments, rectenna systems have been designed to operate at around 2.45 GHz due to the limitations of the microwave energy sources available then. However, in 1991 a 35 GHz rectenna was developed by ARCO Power Technologies, with a

total conversion efficiency of 72% [30]. A low atmospheric absorption is the main advantage of operating in the vicinity of this frequency but doing so requires the use of more expensive and inefficient components [34].

In 1992, to compromise among efficiency, component cost and size, the first C band rectenna array was designed, operating at 5.87 GHz. The rectenna array was comprised of 1000 dipole antennas, which fed rectifier circuits with a silicon quad-bridge Schottky diode having a high reverse voltage. This new diode has the advantage of higher power-handling capabilities than those of the previously used GaAs diodes [10]. Conversion efficiencies exceeding 80% were obtained.

Up to that time, the main tools used to analyze and design rectennas were Libra [60], Touchstone [2], and Transmission Line Models [10]. It was not until 1997 that a full wave simulator was used by K. Chang's group at Texas A&M University to design a complete rectenna system. They have used I3ED by Zeland to iteratively design the length and width of the microstrip-lines of a dipole antenna, a low pass filter and the transmission lines linking them. A total RF-to-DC conversion efficiency of 82% was achieved with input power levels of 50 mW at 5.8 GHz [35]. After this point, most of the designs of rectenna systems have incorporated highly efficient full wave simulators such as HFSS, ADS, I3ED and CST. Using such advanced programs allows the designer to simulate both the antenna and the passive components simultaneously.

For the last decade, researchers have focused on improving different aspects of rectenna systems to suit the targeted applications. Such aspects include, but are not limited to:

- Antenna polarization (*i.e.,* linear/circular)
- Antenna type (*i.e.,* rectangular patch, bowtie, dipole, etc.)
- Operating frequency (*i.e.,* single/dual)
- Total size of the rectenna system
- Type of filter (*i.e.,* low-pass/band-pass)
- Impedance bandwidth

- Type of diode
- Rectifier circuit (*i.e.,* half-wave, full-wave, voltage doubler, etc.)
- Substrate material
- Feeding mechanism (*i.e.,* probe, micro-strip, aperture, etc.)

There is no absolute freedom in optimizing each aspect independently as a change in one aspect will alter one or more other aspects undesirably. Therefore, there is always a trade off when one or more aspects are optimized. Depending on the targeted application, one can balance those aspects to arrive at the desired rectenna performance.

Most of the recent microwave rectenna systems have been designed to operate in the range of frequencies between 1-35 GHz. Total conversion efficiencies of 50-80% are reachable when operating at frequencies in the C-band (*i.e.,* 5.8 GHz) as in [16, 50, 38]. However, the conversion efficiency degrades as the operating frequency increases, as in the case of rectennas working in the X-band [37] and the Ka-band [43], where efficiencies of only 21% and 35% are realized, respectively. Even though operating at higher frequencies exhibits a noticeable degradation in the total conversion efficiency, it has the advantage of miniaturizing the total size of the rectenna system, which is crucial for applications where portability is the primary concern. Hence, there is a trade off between efficiency and size when rectennas are designed at various frequencies.

Since the power availability is not always guaranteed when working at a narrow band of frequencies, operating at dual frequencies increases the reliability of rectenna systems. In such designs, rectennas utilize dual antennas that ,when designed properly, can receive the microwave energy at two ranges of frequencies (*i.e.,* 2.45 and 5.8 GHz) as in [42, 53, 27]. However, using dual-frequency rectennas increases the total size of the system due to the use of an additional antenna. A decrease in the total conversion efficiency is also noticeable since the matching network, the output load, and the diode input impedance must be optimized to maximize the power at both frequencies and, therefore, a compromise is always present between the two operating frequencies. Another practical way to increase the reliability of rectenna systems is by the use of wide band antennas. However, designing

a wide band matching network between the antenna and the microwave diode that always ensures maximum power transfer is somehow an intricate task due to the nonlinear behaviour of the diode, which has an input impedance that varies with the input power level and the operating frequency. Energy harvesting is an example of a rectenna application where power availability at the connected load or device is an important requirement.

Recent work on rectenna systems has incorporated Split Ring Resonators (SRRs) to miniaturize the size of the antenna, as in [61], and to suppress harmonics generated by the rectifier circuit, as in [25]. Ziolkowski and his group at the University of Arizona have designed an electrically small rectenna that operates at 1.5754 GHz, utilizing a metamaterial inspired structure. Using such a structure enables a dramatic reduction in the total size of the rectenna system while operating at lower frequencies, solving the problem faced in previous rectennas [62]. A detailed description of the working mechanism of SRRs and the feasibility of using them to harvest microwave energy is presented in Chapter 4.

2.3 Applications of Rectenna Systems

The advent of rectenna systems has greatly advanced many technologies that strive for energy, from powering an implantable artificial heart to tracking and identifying objects in security systems. Rectennas have countless potential applications since their primary goal is to deliver wireless DC power efficiently. Initially, rectennas were developed by Raytheon Company in response to the American Air Force requiring a device that could be attached to a helicopter and rectify microwave energy when a beam is pointed at the device. Brown and his colleagues developed a rectenna array that contains several thousands of point contact silicon diodes. The array produced a DC power level of approximately 200 W. As a result, the group were able to demonstrate a microwave-powered helicopter that can run for at least 10 hours continuously at an altitude of 28 meters above the transmitting antenna [12].

As a consequence of the success achieved in the helicopter demonstration, researchers showed a great interest in using rectennas to solve the global energy crisis by providing a clean and affordable energy source instead of using the harmful method of burning fossil

fuels. In 1968, Petter E. Glasser proposed a concept that uses rectennas to harvest energy from space in what is known by Space Solar Power (SSP). The working mechanism of the SSP concept can be understood by the following four main steps [22]:

1. Collect the solar energy from space and convert it to electricity;
2. Convert the collected power to microwaves and transmit it to Earth;
3. Receive the microwave energy and convert it back to electricity using large rectenna arrays;
4. Provide the collected energy to the power grid.

An example of rectenna array connected to the power grid is shown in Figure 2.2. The United States Department of Energy (DoE) and the National Aeronautics and Space Administration (NASA) has dedicated extensive research to examining the feasibility of such system. Results have shown a great promise for the future of energy. However, it could take decades before the SSP concept is implemented all over the world since it must outweighs the existing methods in terms of cost, reliability and sustainability.

Another vital application of rectenna systems that has excelled rapidly in the last decade is Radio Frequency Identification Systems (RFIDs). In an operational RFID system, there are two main components: a tag (transponder), which contains electronically stored data, and a reader (interrogator) that can read the stored data of the tag. First, the reader transmits RF energy to the tag; then the tag, which is attached to the object to be identified or tracked, receives the energy and sends back a coded signal to the reader. The reader then retrieves the data and responds accordingly (*i.e.,* activates an alarm) [18]. Here, the tag represents a rectenna system since it mainly consists of an antenna, a diode and a microchip. The tag can be either active or passive depending on the requirement of an internal power supply. An active tag, which requires a secondary source of energy in addition to the rectified microwaves, can read data in the range of between 20-100 meters from the interrogator. A passive tag, on the other hand, requires no internal source of energy and usually can respond to a reader at a shorter range than that of an active tag [58]. RFIDs are commonly used in industrial and commercial companies

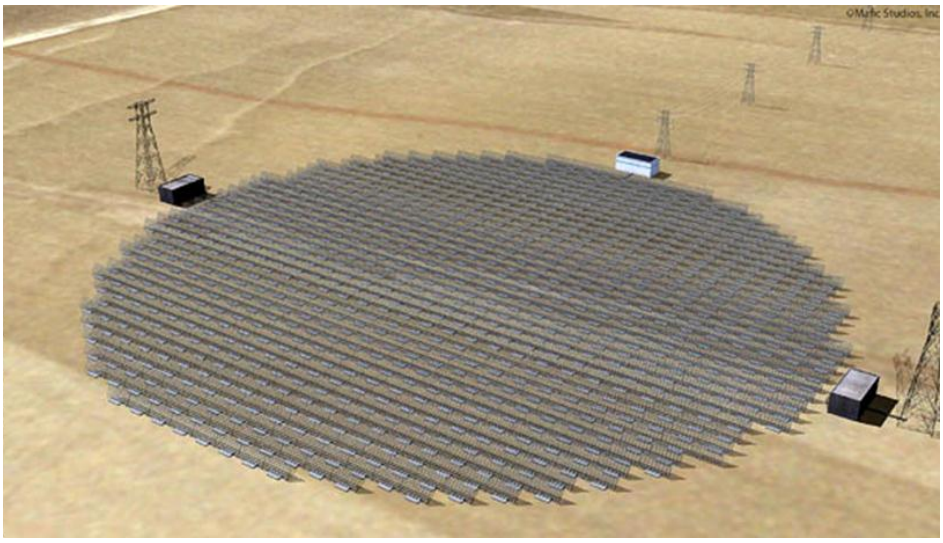

Figure 2.2: A schematic of a receiving rectenna array station connected to the grid. from:http://www.solarfeeds.com/powersat-a-new-space-solar-player/

as tracking and identifying tools for numerous objects, such as for tracking baggage in airports [3], surveillance and security systems [56], tracking pets or endangered animals [29], anti-collision systems [26], and even monitoring oil drill-pipes [51].

Other active research areas where rectennas find promising future applications include but are not limited to driving mechanical actuators at high voltages (50 V) [21], wireless power transfer to a sensor buried in concrete [48], and implantable rectennas for biotelemetry communications [28].

2.4 Operation of Rectenna Systems

A rectenna or a rectifying antenna is part of a larger system known as a wireless power transfer system (WPT). A common WPT system consists of three main subsystems: a transmitter, a travelling medium (*i.e.,* free space), and a receiver, as shown in Figure 2.3. The function of the first block, which represents a transmitter, is to convert DC power to

microwaves using a transmitting circuit and a transmitting antenna. These microwaves will radiate through the transmitting antenna and travel across free space towards a receiver represented by the third block. The receiver, which represents a rectenna system, converts the microwaves to AC power using a receiving antenna. Then the captured AC power is converted back to DC using a rectifying circuit. Hence, the name rectenna, which combines the words of the main components that comprise it. The total efficiency of the WPT system is the product of the transfer function of each functional block, which can be expressed as [40]:

$$\eta_o = \eta_t \times \eta_f \times \eta_r \tag{2.1}$$

where η_o represents the overall efficiency of the WPT system, η_f is the free space efficiency, and η_r denotes the total efficiency of the rectenna system. Usually in WPT systems, the transmitter efficiency η_t is assumed to be unity.

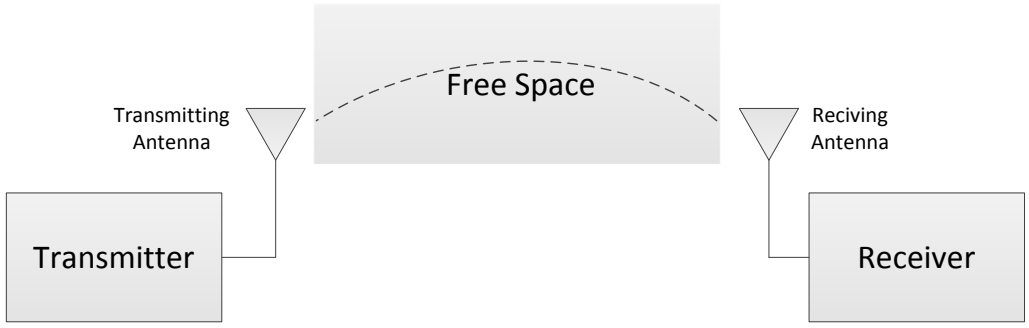

Figure 2.3: Functional blocks of a typical Wireless Power Transfer (WPT) system.

Zooming into the the third block, there are five main elements that form a rectenna system as shown in Figure 2.4. The electromagnetic energy is captured using a receiving antenna operating at the desired frequency. Then, an RF filter is used to transform the antenna impedance to that of the diode, reducing reflections caused by any impedance mismatch. The RF filter also suppresses the unwanted harmonics caused be the nonlinear

behaviour of the diode. After the AC power has channeled maximally from the antenna through the RF filter, a diode (*i.e.,* schottky diode) is used to rectify or convert the collected AC power to DC. To ensure that AC power does not reach the load, a DC filter is inserted after the diode which mainly consists of a shunt capacitor that acts as a short circuit for higher frequencies. Then, a resistive load is used to consume the DC power.

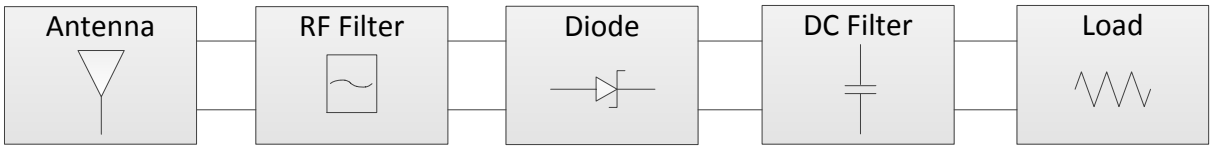

Figure 2.4: a block diagram for a generic rectenna system using an antenna as the primary collector.

The total efficiency of the rectenna system in most of the previously developed rectennas is obtained using the following relation [62]:

$$\eta_r = \frac{P_{out}}{P_{in}} \tag{2.2}$$

where the output power P_{out} and the input power P_{in} are given by:

$$P_{out} = \frac{{V_L}^2}{R_L} \tag{2.3}$$

$$P_{in} = \underbrace{G_r \left(\frac{\lambda^2}{4\pi}\right)}_{\text{Effective Area}} \times \underbrace{\left(\frac{G_t P_t}{4\pi D^2}\right)}_{\text{Incident Power Density}} \tag{2.4}$$

where V_L and R_L are the voltage across and the resistance of the connected load. In Eq. 2.4, G_t is the transmitter gain, P_t is the transmitted power and G_r is the gain of the receiver antenna. In measurements, the rectenna under test is usually placed a distance D away from the transmitter to ensure the far field condition is satisfied.

It is of interest to note that Eq. 2.2 represents the AC-to-DC conversion efficiency, which mainly depends on the type of diode used, the input power level and the optimal

resistive load. Hence, such equations do not take into account the efficiency of the collector (*i.e.,* antenna) where the microwave energy is converted to AC power in the first place. Therefore, a new method for computing the efficiency of rectenna systems is introduced in Chapter 4. In this method, the efficiency of the collector (microwave to AC link) is considered which is missing from earlier work.

Chapter 3

Design and Fabrication of 2.45 GHz Rectenna System

3.1 Introduction

This chapter presents the procedures for designing a full rectenna system operating at 2.45 GHz. First, a patch antenna fed by a microstrip line is designed and fabricated. Then a rectifier circuit consisting of a quarter wavelength transformer, a schottky diode, and an output filter is designed for an input impedance of 50 Ω to maximize energy transfer when attached to the patch antenna. Here, the primary goal of designing a rectenna system is not maximizing system efficiency but rather understanding the design procedures and the challenges one can face when building a rectenna system.

3.2 Microstrip Antenna

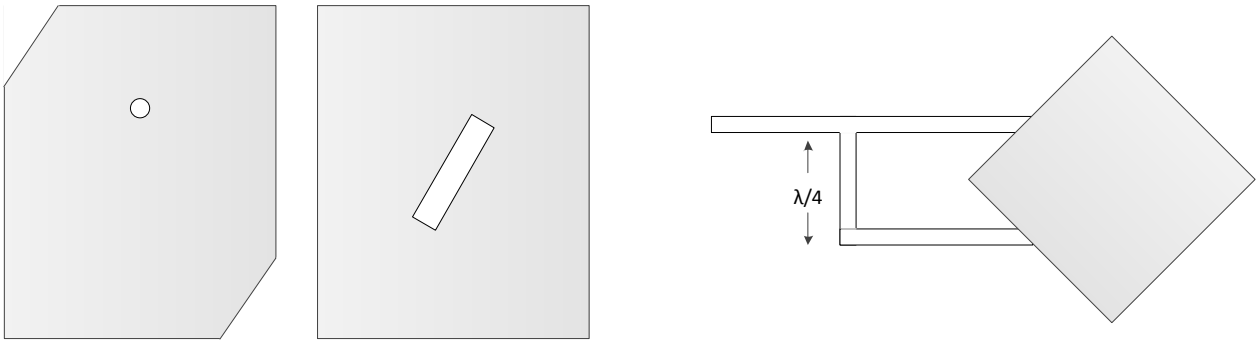
3.2.1 Theoretical Background

An antenna is one of the fundamental components in any rectenna system since it is the primary energy source that feeds the rectification circuit. Microstrip-type antennas are

widely used in communication systems due to their lightweight, low cost, ease of fabrication, low profile, conformability to planar and non-planer surfaces and mechanical robustness. However, microstrip antennas suffer from various drawbacks that limit their applications significantly such as narrow bandwidth, low power handling capability, high feed network losses and high cross polarization [23]. A great deal of research has been aimed at improving antenna characteristics and overcoming the aforementioned drawbacks of microstrip antennas. The advancements in recent antenna technology and the emergence of new concepts such as metamaterials have overcome most of these drawbacks or at least mitigated them to a certain extent. Therefore, antennas in the majority of rectenna systems if not all are of a microstrip type.

Microstrip antennas consist of a metallic layer, dielectric substrate, ground plane and feeding mechanism. Choosing the proper feeding configuration is important to achieve better impedance matching to the rectification circuit. The most common types, used in practise, are the coaxial probe, microstrip line, proximity coupling and aperture coupling [9]. Here, the microstrip line feeding mechanism is used since both the antenna and the rectification circuit can be easily fabricated in one plane. In addition, the microstrip line method is simple to match since the input impedance of the antenna can be varied by controlling the position and the width of the transmission line.

Recent rectenna research has focused on using circularly polarized (CP) microstrip antennas. Rectennas that utilize CP antennas have the advantage of constant output voltage, which is essential in applications where the connected load is rated at certain voltage levels. Furthermore, CP antennas can receive the incoming signal regardless of their position. This capability is particularly important in RFID tags where an interrogator can identify or track a certain tag irrespective of its orientation. A microstrip antenna by its nature is linearly polarized (LP) since it is designed to operate at a single mode. For an antenna to radiate circular polarized waves, two orthogonal modes must be excited, having equal magnitudes but with a 90° phase shift. This condition can be achieved by introducing some modifications to the antenna design. The common two methods to produce CP antennas are single and dual-orthogonal feeding mechanisms. CP can be obtained with a single feed by truncating the corners of a patch or by slightly perturbing some segments of the antenna as in Figure 3.1a. The main objective of these modifications is to disturb



(a) Single fed circular polarized antennas.

(b) Dual fed circular polarized antenna.

Figure 3.1: Single and dual fed circular polarized antennas.

the current density in such a way that the two modes are excited. In the dual-orthogonal feeding method, the two modes are excited by employing an external power divider circuit as in Figure 3.1b. To understand the type of polarization of any antenna, a plot of Axial Ratio (AR) vs. Frequency is used. An AR of less than 3 dB is indicative of an antenna radiating circular polarized waves within a certain range of bandwidth. The transmitter and the receiver antennas must have the same polarization, to avoid polarization mismatch and to maximize the energy collected by the receiving antenna.

3.2.2 Antenna Design

Since the goal of the work presented in this chapter is to clarify the working mechanism of rectenna systems, the basic LP microstrip-line fed patch antenna is selected.

A patch antenna is a resonance-based structure having a resonance frequency that depends on the various dimensions of the antenna, as shown in Figure 3.2. The width W and the length L can be found using the following relation [9]:

$$W = \frac{\upsilon_\circ}{2f_r}\sqrt{\frac{2}{\epsilon_r + 1}} \tag{3.1}$$

$$L = \frac{\lambda}{2} - 2\Delta L, \tag{3.2}$$

where $\upsilon_\circ$ is the speed of light, ϵ_r is the dielectric constant, and f_r is the resonance frequency of the antenna. The extended incremental length ΔL due to the fringing effect can be found from

$$\Delta L = 0.412(h)\frac{(\epsilon_{reff} + 0.3)\left(\frac{W}{h} + 0.264\right)}{(\epsilon_{reff} - 0.258)\left(\frac{W}{h} + 0.8\right)} \tag{3.3}$$

where h is the height of the substrate, and the effective dielectric constant ϵ_{reff} is given by the following:

$$\epsilon_{reff} = \frac{(\epsilon_r + 1)}{2} + \frac{(\epsilon_r - 1)}{2}\left[1 + 12\frac{h}{W}\right]^{-\frac{1}{2}}_{\text{for W/h >1}} \tag{3.4}$$

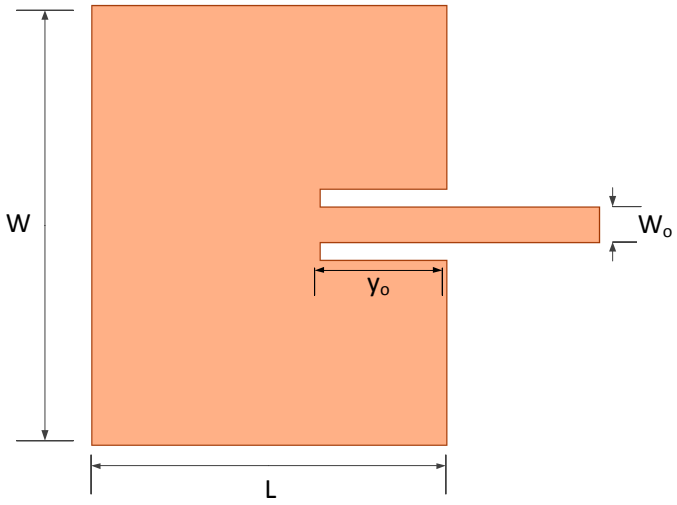


Figure 3.2: A schematic of the patch antenna showing all of its dimensions.

In Figure 3.2, the feed position $y_\circ$ and the width of the transmission line $W_\circ$ can be found using a model presented in [9]. Hence, the antenna parameters were found by solving for equations 3.1 - 3.4 and then using a full wave simulator HFSS to verify the results. Since the above set of equations will result in only an approximate result, one can fine tune the

Antenna Parameter	Value
L	31.8 mm
W	39.3 mm
$y_\circ$	11.3 mm
$W_\circ$	3.18 mm
ϵ_r	3.55
f_r	2.45 GHz

Table 3.1: A summary of the patch antenna parameters.

resonance frequency by slightly varying L and W to arrive at the desired frequency. Table 3.1 summarizes the final results of all the antenna parameters at an operating frequency of 2.45 GHz.

3.2.3 Antenna Fabrication and Measurement

The fabrication process is one of the vital stages learnt during the course of this work. The patch antenna and other structures used in this thesis were fabricated using a T-Tech milling machine available at the University of Waterloo. The fabricated patch antenna, illustrated in Figure 3.3, was etched on an RO4003 Rogers material having a relative permittivity of 3.55.

The return loss of the etched patch was measured using a Vector Network Analyzer (VNA) and, compared to the results obtained from HFSS, the measured return loss is in a good agreement with a slight frequency shift of 0.05 GHz, as shown in Figure 3.4.

3.3 Rectifier Circuit

This section discusses the main components of the rectifier circuit which will be attached to the fabricated antenna to form a full rectenna system. A number of rectifier topologies used in earlier work is reviewed. Furthermore, the input impedance of the agilent Schottky

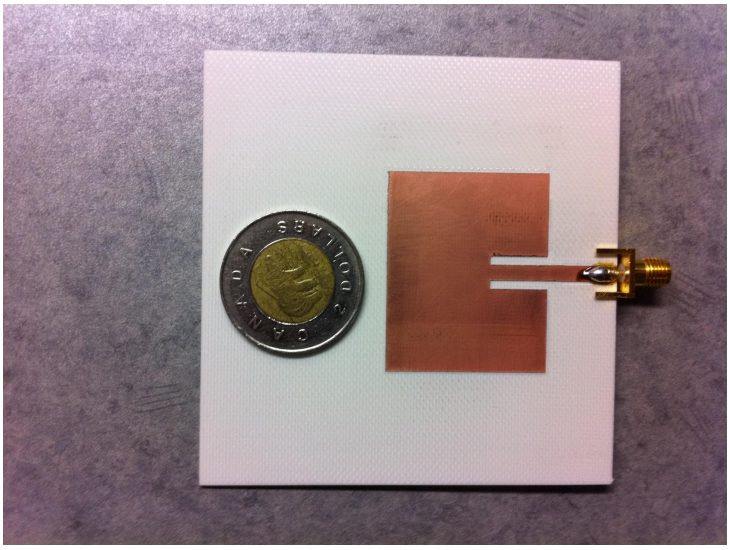

Figure 3.3: The fabricated microstrip-line fed patch antenna.

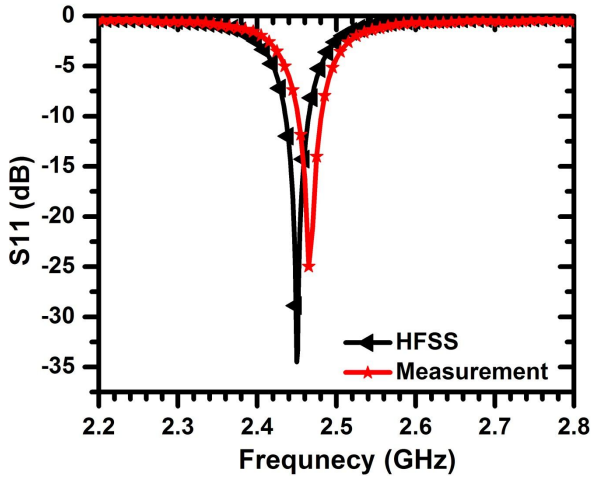

Figure 3.4: Return loss of the fabricated and simulated patch antenna.

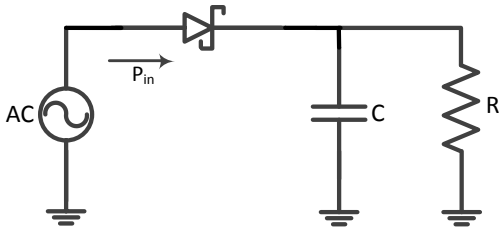
diode used is determined using a diode model developed by K. Chang's group. Finally, the designs of the RF and DC filters are presented.

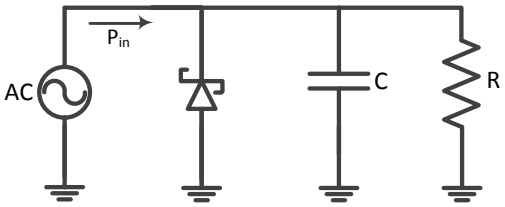
3.3.1 Rectifier Topologies

The main function of the rectifier circuit is to convert AC to DC power using a diode. Different from low frequency rectifiers, microwave rectifiers utilize surface mount diodes that operate at higher frequencies and matching networks to maximize power transfer before and after the diode. Depending on the targeted application, the rectifier circuit can employ a single or dual diodes. The three most common rectifier topologies used in the literature are the series diode, shunt diode, and Villard's voltage doubler rectifier circuits [58]. The series diode rectifier circuit consist of a diode connected in series, a capacitor and a load, as shown in Figure 3.5a. The diode blocks the negative cycle of the captured AC power, then the RC circuit smoothes out the rectified power to obtain a constant output voltage with low ripple. The series diode type of rectifier is ideal for rectennas that use a single feed antenna such as the microstrip-line fed and probe-fed patch antennas because of the simplicity of matching the diode's input impedance to that of the antenna by using a quarter wavelength transformer. The series diode rectifier is commonly used in rectenna applications such as energy harvesting [15] and RFID [55]. Similar to the series type, the shunt diode rectifier circuit consists of a capacitor, a load, and a diode, but with a parallel connection, as illustrated in Figure 3.5b. The shunt diode rectifier has the freedom of using a planar or co-planar microstrip line to link the various rectifier components. This type can usually be found in applications that utilize dual patch antennas, as in [41], or dipole antennas, as in [36]. The Villard's voltage doubler contains dual capacitors, dual diodes and a load, as shown in Figure 3.5c. As the name suggests, the Villard's voltage doubler achieves higher voltage as compared to the single diode type presented above. This can be obtained by using two cascaded diodes that rectify the AC power then, charge the dual capacitors. The Villard's voltage doubler rectifier-circuit was used in [44, 59] for energy scavenging applications.

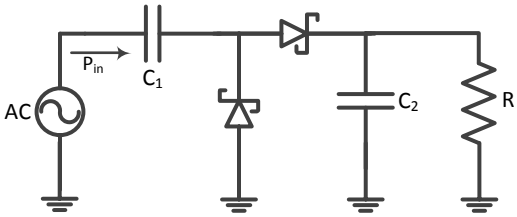
Here, the series diode rectifier circuit is used since it is the most suitable design for matching the microstrip-line fed patch antenna to the diode. In the following subsections, the type of diode used in the design and the matching networks are discussed.



(a) Series-diode rectifier circuit.



(b) Parallel-diode rectifier circuit.



(c) Villard's voltage doubler rectifier circuit.

Figure 3.5: Various rectifier-circuit topologies used in the literature [58].

3.3.2 Schottky Diode

When operating at higher frequencies (*i.e.,* 2.4 GHz), the common P-N junction diode is no longer capable of rectifying the AC signal since it has relatively slower switching capability and higher voltage drop. Instead, a Schottky diode is used to overcome these limitations. Unlike the P-N junction diode, which has a semiconductor-semiconductor junction, the Schottky Barrier Diode (SBD) is formed by plating a metal contact onto an n- or p-type semiconductor [17]. This metal-semiconductor junction acts as a diode, allowing the current to flow in one direction and blocking it in the other. The I-V curve of a Schottky diode is similar to that of a P-N junction diode, with the exception of [47]:

- Faster switching between conducting and non-conducting modes due to the absence of the minority-carrier charge storage effect
- Lower forward voltage drop

The two main classes of Schottky diodes are the n-type and the p-type Schottky diodes. The n-type Schottky diode is formed by a metal and type n semiconductor junction. This type is distinguished by having a high barrier height (indicating low saturation current) and a low series resistance. The n-type Schottky diode is used in applications where a DC bias is accessible, such as mixer and detector applications. The p-type, on the other hand, is made up of a metal and type p semiconductor, and it is characterized by a relatively low barrier height and high series resistance. This type of Schottky diode is used in applications where DC bias is not available, such as square law detector applications [54]. The diode model and proper diode-type selection are presented in the next section.

3.3.3 Diode Model

One of the most important initial steps when designing a rectenna system is determining the input impedance of the Schottky diode. This is due to the non-linear behaviour of the diode as its input impedance depends significantly on the input power level, the load impedance and the frequency of operation. Here, the diode model developed by K. Chang's

group is used due to the promising results and the great agreements between the measured and the simulated results achieved in the literature, as in [50]. For simplicity this model does not take into account the loss due to higher-order harmonics.

The equivalent circuit of a Schottky diode contains a series resistance R_s, a junction resistance R_j, and a junction capacitance C_j as presented in [34]. The load resistance R_L can be varied along with the input power level to arrive at the desired diode input impedance.

The input impedance of the diode Z_d can be found by applying Kirchoff's voltage law to the equivalent circuit of the schottky diode. The final form of the Z_d is given by [34]:

$$Z_d = \frac{\pi R_s}{\cos\theta_{on}\left(\frac{\theta_{on}}{\cos\theta_{on}} - \sin\theta_{on}\right) + j\omega R_s C_j\left(\frac{\pi-\theta_{on}}{\cos\theta_{on}} + \sin\theta_{on}\right)} \tag{3.5}$$

The turn on angle θ_{on} depends on the input power level and can be found from the following relation:

$$\tan\theta_{on} - \theta_{on} = \frac{\pi R_s}{R_L\left(1 + \frac{V_{bi}}{V_\circ}\right)} \tag{3.6}$$

where $V_\circ$ is the output voltage across the load and V_{bi} is the built-in voltage. The junction capacitance C_j is given by:

$$C_j = C_{j\circ}\sqrt{\frac{V_{bi}}{V_{bi} + |V_\circ|}} \tag{3.7}$$

A detailed derivation of Eq. 3.5 can be found in [34].

The Schottky diode selected for the rectenna under test is the Avago's HSMS2860 Schottky diode. This type of diode is optimized to operate at a frequency range of 915 MHz-5.8GHz. The diode has a breakdown voltage V_{br} of 7.0 V and a forward voltage of 0.65 V. The zero bias junction capacitance $C_{j\circ}$ and the series resistance R_s are 0.18 pF and 6.0 Ω, respectively.

A Matlab code, which makes use of the integrated optimization toolbox, is developed to solve for Z_d, θ_{on}, and C_j. Figure 3.6 shows the real part of Z_d, as the load resistance is varied from 1-1000 Ω. Z_d was found to be 170.8 Ω when the load resistance is 250 Ω. Here the choice of the load resistance is kept low to ease the fabrication process as a higher load resistance will lead to a narrower microstrip-line and ,hence, harder to fabricate. The output voltage is usually taken to be 50% of the breakdown voltage to prevent burning the diode, which would create an open circuit. Therefore, the output voltage $V_\circ$ is set at 3.5 V.

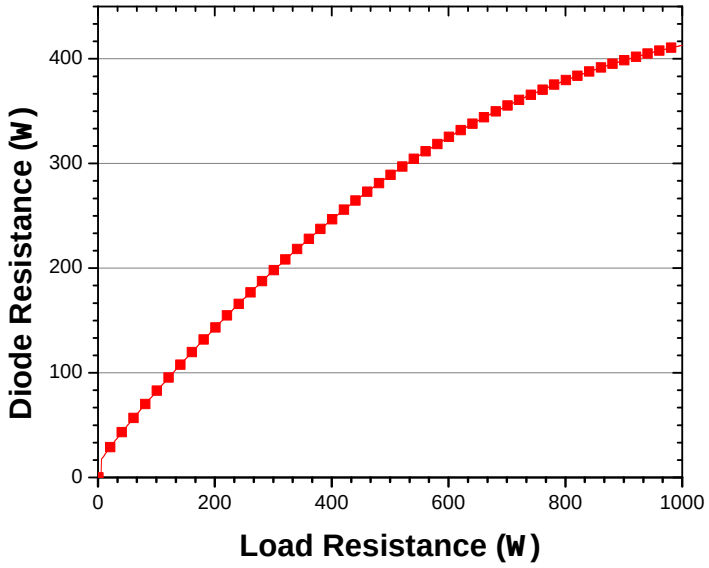


Figure 3.6: Load resistance Vs. Diode input resistance.

3.3.4 RF and DC Filter

At this stage, the two main components of the rectenna system have been designed and analysed and need to be connected through a matching network since they have different input impedances. The primary functions of the pre-rectification or RF filter are to match

the real part of the diode's input impedance to that of the antenna and to prevent higher-order harmonics caused by the non-linear behavior of the diode from radiating by the antenna. A quarter wavelength transformer is inserted between the antenna and the diode to transform the diode resistance to 50 Ω. The impedance of the transformer can be found from the following relation:

$$Z_{QWT} = \sqrt{Z_A Z_d} \tag{3.8}$$

where Z_A is the input impedance of the antenna. Using the diode resistance obtained from Figure 3.6, Z_{QWT} is found to be 92.41 Ω. Hence, using a microstrip-line calculator, the length and width of the quarter wavelength transformer are $l = 16.7\ mm$ and $w = 1.05\ mm$.

Finally, the DC or post-rectification filter is used to tune the reactance of the diode impedance and to prevent any higher frequencies from reaching the load. The DC filter generally consists of a series microstrip line and a shunt capacitor. The Advance Design System (ADS) simulator is used to optimize the capacitor value, and the length and width of the transmission line such that the magnitude of the reflection coefficient (S11) looking from the 50 Ω port into the rectifier circuit is minimized (*i.e.,* a magnitude of $S11 \approx 0$).

From the simulation, it is found that a capacitor value of $C = 56\ pF$ and a transmission line with $l = 40\ mm$ and $w = 1.9\ mm$ would yield maximum matching between the diode and the load.

Figure 3.7 shows the fabricated rectifier circuit with an LED that mimics a load. The rectifier was tested with a high frequency power source; however, the LED did not glow since not enough voltage was developed across it to turn it on.

3.4 Conclusion

The procedures for designing a rectenna system from the antenna to the load were presented. The input impedance of the Agilent diode was determined from a Schottky diode model available in the literature. A quarter wavelength transformer was designed to match

the real part of the diode to that of the antenna. Then, using an ADS simulator, a DC filter was designed to tune out the reactance of the diode impedance. A surface mount LED was used instead of the load as an indicator to test the rectifier circuit. However, the LED did not turn on as the rectifier circuit was not able to deliver enough voltage to the LED. To overcome this issue, some modifications can be made, such as the use of a Villard's voltage doubler circuit for higher voltage levels, and the use of better collector to capture more energy, as will be discussed in the following chapter. Even though the LED did not turn on, the goal for this chapter was achieved since this work is meant to be a preliminary for future work explained in the next chapter.

Chapter 4

Electromagnetic Energy Harvesting Using Metamaterial Particles

4.1 Introduction

This chapter presents a novel energy collector based on metamaterial particles in what is known as a Split Ring Resonator (SRR). The subject of metamaterials is briefly introduced, then a feasibility study of SRRs to harvest energy is presented. To prove the concept, a 5.8 GHz SRR is designed and fabricated and then tested using a power source, an Infiniium oscilloscope and a commercially available patch antenna array. In addition, a new efficiency concept is introduced, taking into account the microwave-to-AC conversion efficiency which is missing from earlier work. Finally, a 9X9 SRR array is compared with a 2X2 patch antenna array, both placed in a fixed footprint.

4.2 Metamaterial Background

The emergence of metamaterials has drawn considerable attention from physicists and engineers researching in a wide range of streams. The fact that metamaterials can produce media with negative permittivity and/or permeability has originated numerous or

enhanced existing applications such as creating perfect lenses and absorbers [31, 39], decoupling and modifying antenna characteristics [8, 20, 5], improving the efficiency of solar cells, and detecting cracks [4], to name but a few. Metamaterials can be defined as "artificial media with unusual electromagnetic properties" [49]. Metamaterial particles are formed by assembling electrically small resonators that can take various shapes, geometries and compositions. One of the most common types of resonators is the SRR, which is a metallic inclusion with one or more splits. An SRR can be made of (single or multiple) and (concentric or parallel) electrically small rings. It also can take various shapes, such as those shown in Figure 4.2, or many others analysed in the literature. This work investigates the feasibility of only a single loop resonator to harvest energy, but generalization can be made to any structure available in the literature. When modelling a single-loop SRR (Figure 4.1), it can be realized as a simple LC circuit where the size of the gap (gxw) and the arm length of the metallic ring (L) contribute mainly to the total capacitance and inductance of the structure, respectively. Hence, by varying such dimensions, one can design an SRR to resonate at the desired frequency. A detailed study of the effect of varying the mentioned parameters on the SRR's resonance frequency can be found in [6]. The next section presents a study of the feasibility of such a resonator to harvest electromagnetic energy.

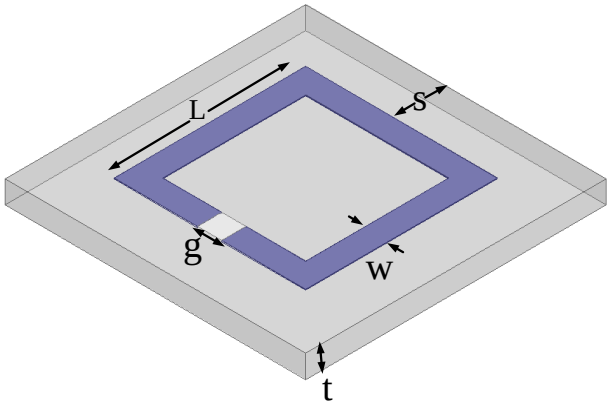

Figure 4.1: Split Ring Resonator unit cell.

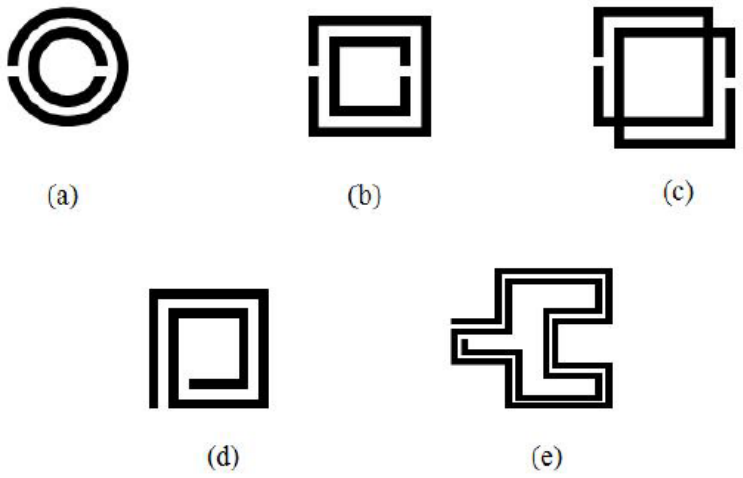

Figure 4.2: Various shapes of metamaterial particles proposed in the literature [7].

4.3 Feasibility of SRRs to Harvest Electromagnetic Energy

When an SRR is excited by a magnetic field normal to its plane, a highly concentrated electric field is developed across the gap of the structure, as indicated by the red color in Figure 4.3. Equally interesting is that the SRR can be excited by an incident magnetic field with various polarizations, as discussed in section 4.5. This concentration of a high electric field is indicative of a build up of high voltage across the gap of the SRR. Hence, this work proposes harvesting this energy by means of a load placed across the gap. To realize this concept using HFSS, a resistive sheet is placed across the gap of an SRR cell, resonating at 5.8 GHz. The designed SRR has dimensions of l =5.9 mm, w = 0.55 mm and g= 0.8 mm. Since the optimal resistance value is not known, the resistive sheet is assigned a variable resistance value ranging between 100 Ω - 10,000 Ω. The SRR is excited by a plane wave such that the H field is perpendicular to the SRR plane. The efficiency of the SRR is then calculated by using the proposed efficiency concept presented in section 4.5. It was found that a single SRR cell has an efficiency of around 40%, with an optimal

resistive load of 2.3 KΩ. This result suggests that the voltage developed across the gap is mostly dissipated by the resistive sheet. Therefore, such SRR structures can potentially be used for harvesting electromagnetic energy.

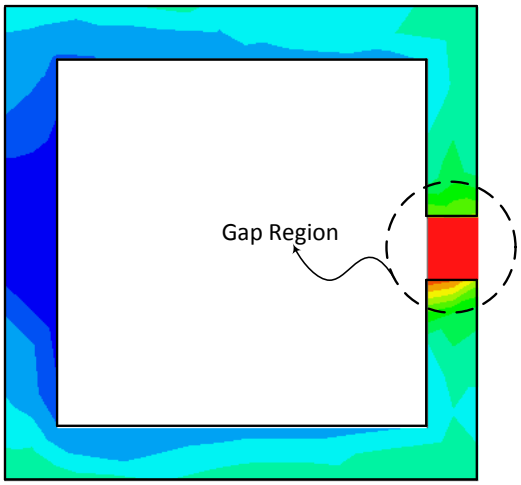

Figure 4.3: Electric field distribution on the plane of the SRR at resonance frequency.

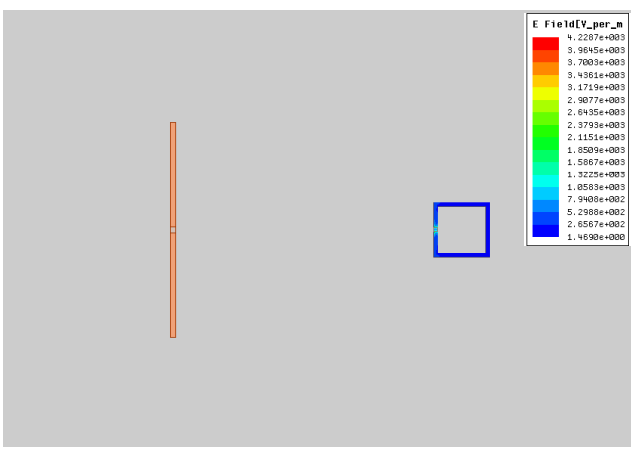
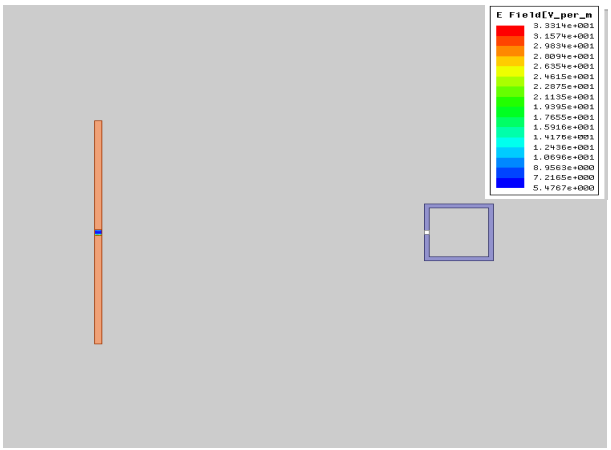
For any radiator to receive energy, it must obey the reciprocity theorem. This theorem states that "in any network composed of linear, bilateral, lumped elements, if one places a constant **current***(voltage)* generator between two **nodes** *(in any branch)* and places a **voltage** *(current)* meter between any other two **nodes** *(in any branch)*, makes observation of the meter reading, then interchanges the locations of the source and the meter, the meter reading will be unchanged" [9]. To ensure that the theorem is not violated, an experiment in HFSS is conducted by designing two radiators, a dipole antenna and a single loop SRR both resonating at the same frequency. The experiment is divided into two cases:

1. A dipole antenna is excited by a current source placed at its feed; then the voltage across the gap of the SRR is recorded (Figure 4.4a).



(a) A snapshot of the simulation for case 1.



(b) A snapshot of the simulation for case 2.

Figure 4.4: A simulation that verifies the reciprocity therm using a dipole antenna and an SRR.

2. An SRR is excited by a current source placed across its gap; then the voltage across the feed of the dipole antenna is recorded (Figure 4.4b).

The voltage of both cases can be found by

$$V = E \times d \tag{4.1}$$

where E denotes the electric field, and d is the length of the feed (for the dipole) and the length of the gap (for the SRR). Therefore, the voltages for both cases are

$$V_1 = E_1 \times d_1 = (5.988 \times 10^4) \times (0.8 \times 10^3) = \mathbf{47.907\ V}\ \text{for case 1} \tag{4.2}$$

$$V_2 = E_2 \times d_2 = (3.8562 \times 10^4) \times (1.23 \times 10^3) = \mathbf{47.43\ V}\ \text{for case 2} \tag{4.3}$$

It is evident from the voltage values of both cases that the SRR obeys the reciprocity theorem and therefore can be used for collecting electromagnetic energy.

4.4 Proof of Concept

Now, that the simulation analysis has resulted in promising conclusions, the feasibility of using an SRR to harvest electromagnetic energy is validated by testing and measurements. First, the single loop SRR simulated above was fabricated using a Rogers Duroid RT5880 substrate with thickness of 0.79 mm. Then the SRR was loaded with a surface mount resistor of 2.7 KΩ as shown in Fiqure 4.5. Here, the resistor used in the experiment is different from that of the optimal resistor (2.3 KΩ) obtained from the simulation since the latter was not available at the time of the experiment. An experiment was then conducted using the following measurement setup (Figure 4.6):

1. A commercially available 19 dBi gain array antenna operating at 5.8 GHz.
2. An Agilent Infiniium 91304ADSA 12 GHz oscilloscope equipped with a single-ended probe.
3. A high frequency 30 dbm power source.
4. The fabricated single loop SRR.

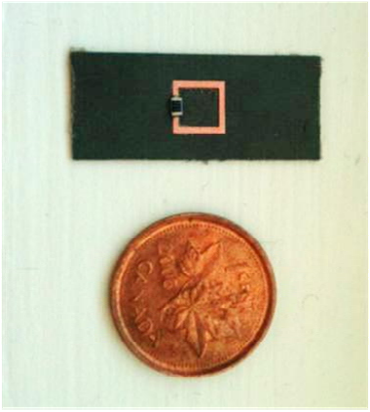


Figure 4.5: Fabricated SRR loaded with a 2.7 KΩ resistor placed at the gap.

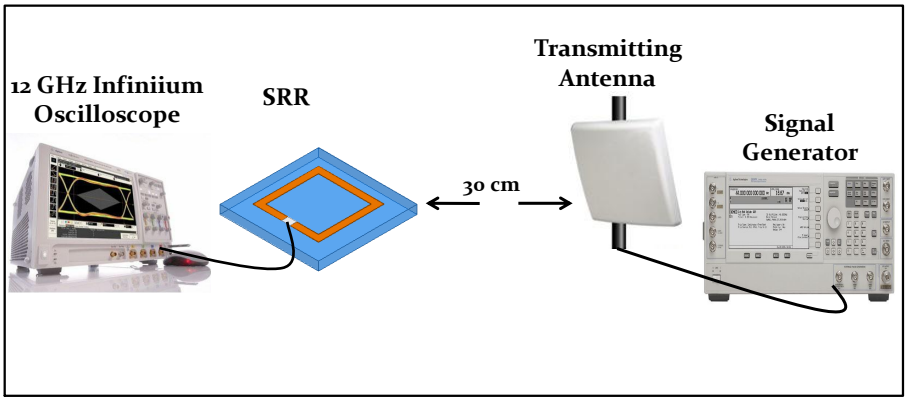

Figure 4.6: Experimental setup.

The SRR was placed 30 cm away from the antenna, and was positioned in such a way that the H-field of the illuminated wave was perpendicular to the plane of the structure. The antenna was excited by a power source with a power level of 24 dbm. Then the voltage across the resistor of the SRR was measured using a single-ended probe of the oscilloscope. A snapshot of the voltage readings (Figure 4.7) shows that the voltage measured across the resistor was 611 mV.

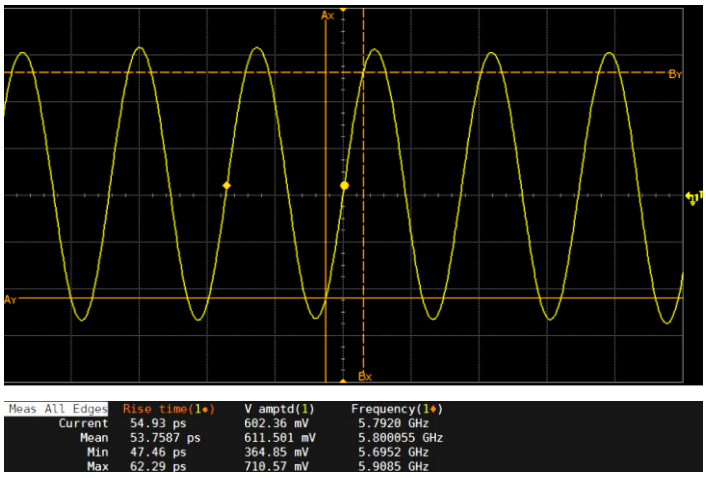

Figure 4.7: A snapshot of the voltage across the gap of the SRR.

4.5 SRR Array Vs. Patch Antenna Array

In this section, a new method for calculating the efficiency of electromagnetic energy collectors such as antennas and SRRs is proposed. Then a comparison in terms of the total microwave-to-AC conversion efficiency between an array of SRRs and an array of antennas placed in the same footprint or area is presented.

As mentioned in Chapter 2, the efficiency of rectenna systems reported in literature does not take into account the microwave-to-AC conversion efficiency of the energy collector. Here, what is meant by microwave-to-AC link is The efficiency of the antenna to convert all the power incident on a specific footprint to available power at its feed position. Therefore, a footprint in square meters must be defined, over which a number of collectors is placed in such a way that the power collected is maximum. Hence the efficiency of a collector as defined above can be found as follows:

$$\eta = \frac{P_{av}}{P_{area}} \tag{4.4}$$

where P_{area} is the total time-average power incident on the footprint, and P_{av} is the the maximum available time-average ac power received by the collector or all collectors occupying the specific footprint under consideration and is available at the feed terminal of the receiving collector. Therefore, P_{av} is given by the following relation:

$$P_{av} = \sum_{i=1}^{n} \frac{V_i^2}{R_i} \tag{4.5}$$

where V_i and R_i are the voltage across and the resistance of collector i. The total number of collectors on a specific footprint is denoted by n.

Considering the efficiency definition just introduced, a demonstration is presented comparing the efficiency of an array of SRRs with an array of patch antennas placed in the same footprint as shown in Figure 4.9. The array of SRRs contained 81 single loops, all of identical size and designed to resonate at around 5.85 GHz. In addition, an array of 2 X 2 identical patch antennas was placed in the same footprint, each resonating at the

same frequency of around 5.85 GHz. The total footprint area was 85 X 85 mm^2. It was reported in the literature that antennas need to be separated by at least $\lambda/2$ to retain their characteristics such as radiation pattern and gain [32]. Therefore, the 4 antennas were separated by a distance of around $\lambda/2$ to ensure maximum power collection by the antennas. In addition, each antenna was fed by a coax probe from beneath. The performance of a probe-fed patch antenna is greatly dependent on the feed position. Hence, the feed position was first analysed by varying the location of the coax with a distance r away from the center of the patch and along the axis that is parallel to the largest dimension of the patch antenna, as shown in Figure 4.9. It was found that the best performance for all of the 4 antennas was achieved when the probe was placed a distance of $r = 2$ mm away from the center of the antenna, as shown in Figure 4.8.

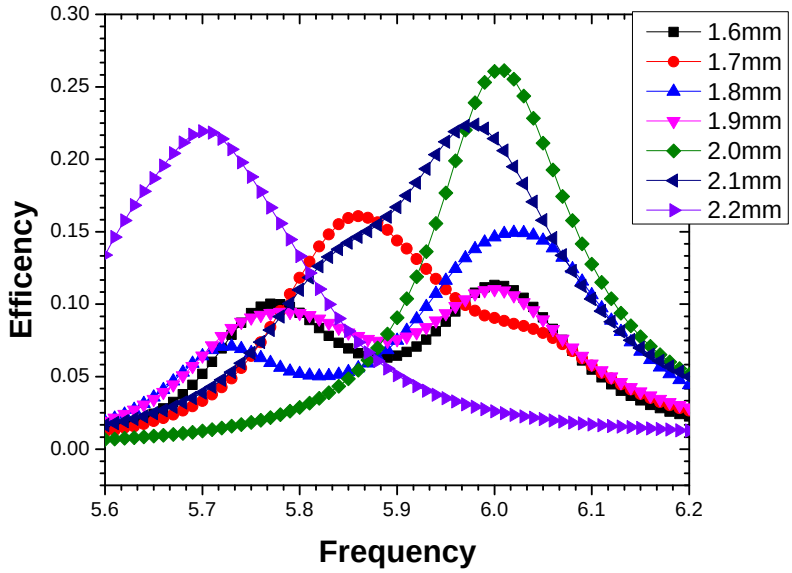

Figure 4.8: The efficiency of the patch antenna with varies coax-probe positions.

In the demonstration, each array was excited by a horn antenna placed a distance of 120 cm away from the array to ensure that the far field condition was satisfied, and a plane wave was incident on the array. Since both the antenna and the SRR are polarized

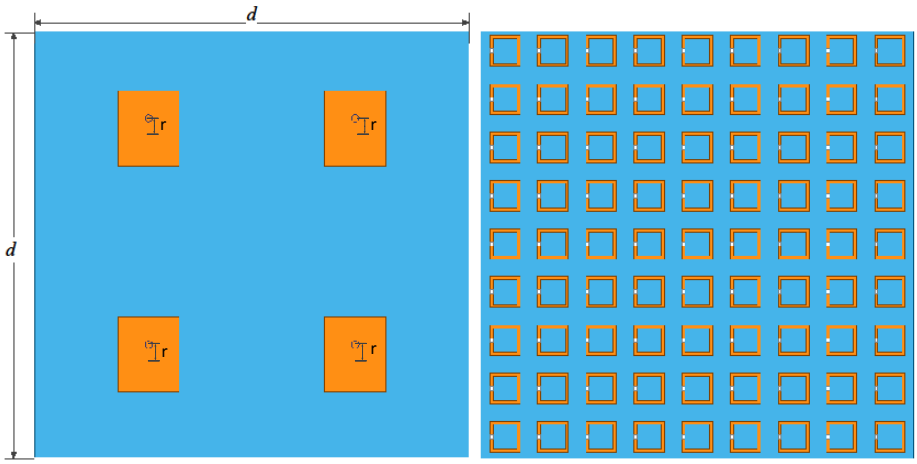

Figure 4.9: a 9 x 9 SRR array and a 2 X 2 patch antenna array occupying the same footprint.

differently, each array was tilted an angle ϕ with respect to an axis normal to the plane of the array, as indicated in Figure 4.10. Three tests were conducted for each array, with angles of 30°, 45°, and 60°. Figures 4.11, 4.12, 4.13 show the efficiency of the antenna array and the SRR array at an angle of $\phi = 30°$, 45° and 60°, respectively.

The following conclusion can be drawn:

- The SRR array resulted in higher efficiency in all three cases.
- The SRR structure is much smaller in size than the antenna in the specific footprint mentioned above, which can contain either 81 SRRs or only 4 patch antennas.
- The bandwidth over which the energy is collected is much wider than that of the antenna array.

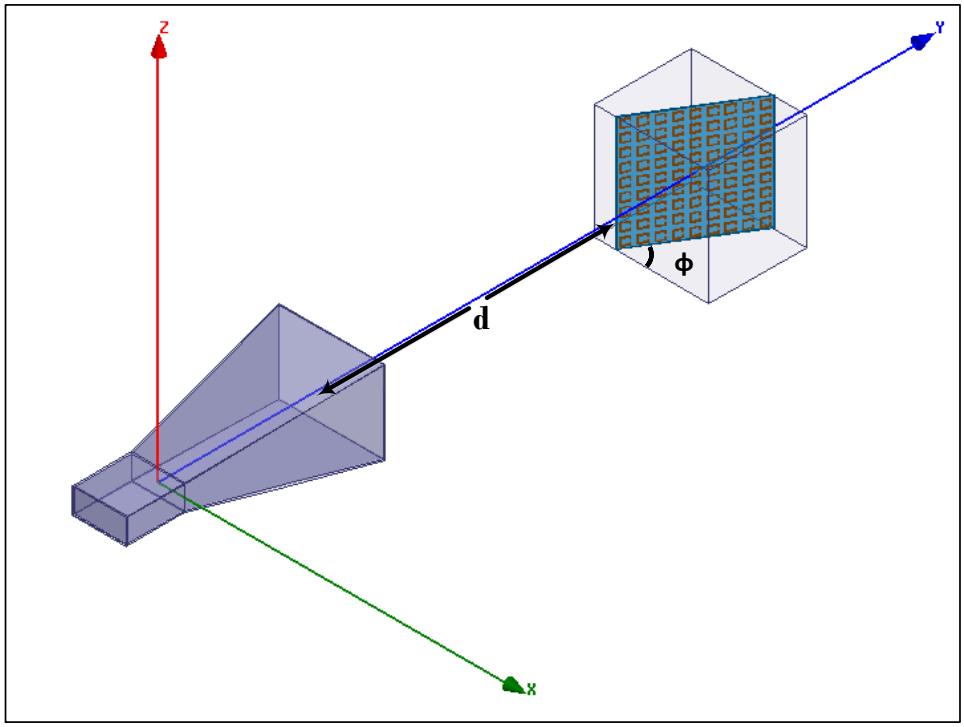

Figure 4.10: Simulation setup for energy harvesting using a horn antenna as the source of radiation and an SRR array as the collector.

4.6 Conclusion

This chapter proposed a new method using SRR cells for collecting electromagnetic energy. The feasibility of using SRRs to harvest microwave energy was studied through simulation by first placing a resistive load across the gap of the single loop SRR, then calculating the power dissipated across the resistor. It was found that around 40 % of the power incident on the single cell SRR is harvested and dissipated by the resistive load. In addition, a simulation experiment was conducted to ensure that the reciprocity theorem is not violated, and the SRR can indeed be regarded as a receiver. An experiment was then conducted to test the feasibility of SRRs to harvest microwave energy. The fabricated SRR cell was excited by an antenna placed 30 cm away, and then the voltage across the gap was measured using a high-frequency oscilloscope. A voltage of 611 mV was observed across the gap when

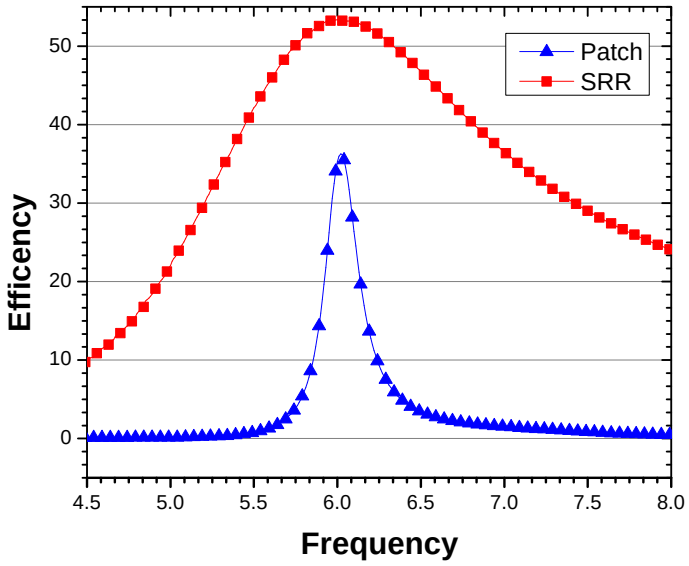

Figure 4.11: Energy harvesting efficiency of the 9 x 9 SRR array Vs. a 2 X 2 patch antenna array both tilted at 30°.

24 dbm power level was pumped into the antenna feed. Finally, the efficiency of an array of SRRs was compared to that of an array of antennas occupying the same footprint. The SRR array resulted in at least 25% more efficiency and a wider energy collection bandwidth than the antenna array.

Chapter 5

Conclusion and Future Work

5.1 Conclusion

In this thesis, a review of energy harvesting systems, which in the literature lies under the topic of WPT and rectenna systems, was presented. Then, detailed procedures for designing and fabricating a full rectenna system were provided. A new energy collector based on metamaterial particles was proposed for the purpose of replacing the existing collector (antenna) that has lower efficiency and much larger size than an SRR unit cell. An experiment was conducted both in simulation and in measurements to examine the feasibility of SRRs to harvest microwave energy. The results from both tests show that such metamaterial structure can indeed be used as an energy harvester. Finally, the efficiency of an array of 9 X 9 SRRs was compared to that of an array of 2 X 2 patch antennas placed over an identical area. At least 25% more efficiency and a wider energy collection bandwidth were achieved by the SRR array.

5.2 Future Work

The following suggestions are worth pursuing for future work:

- Improve the design of the rectenna system to provide more output power and hence higher efficiency.
- Investigate the efficiency of various SRR structures such as the those shown in Figure 4.2.
- Study the effect of coupling on the efficiency of both antennas and SRRs.
- Integrate an SRR array, as the one shown in Figure 4.14, to a rectifier circuit for a full Microwave to DC conversion system.

16. Abstract

The program had two general objectives. The first objective was to develop the two plane rectenna format for space application at 2.45 GHz. The resultant foreplane was a thin-film, etched-circuit format fabricated from a laminate composed of 2 mil Kapton F sandwiched between sheets of 1 oz. copper. The thin-film foreplane contains half wave dipoles, filter circuits, rectifying Schottky diode, and DC bussing leads. It weighs 160 grams per square meter. Efficiency and DC power output density were measured at 85% and 1 kw/m^2, respectively. Special testing techniques to measure temperature of circuit and diode without perturbing microwave operation using the fluoroptic thermometer were developed.

A second objective was to investigate rectenna technology for use at 20 GHz and higher frequencies. Several fabrication formats including the thin-film scaled from 2.45 GHz, ceramic substrate and silk-screening, and monolithic were investigated, with the conclusion that the monolithic approach was the best. A preliminary design of the monolithic rectenna structure and the integrated Schottky diode were made.

SUMMARY

This contract had two major objectives. The first was to refine the rudimentary technology of the 2.45 GHz thin-film, etched-circuit rectenna with particular emphasis upon its space applications. The second was to examine the kinds of rectenna technology best suited for rectenna operation at frequencies of 20 GHz and higher.

The status of thin film rectenna technology at the start of the study was a single individual rectenna element made from a laminate of mylar and one ounce copper. The rectenna element was inefficient and otherwise unsatisfactory. The current study revealed why the structure was inefficient and found that a laminate of Kapton F and copper was a much better material. The proper masks were designed and individual rectenna elements fabricated. The rectifying diodes were added and the individual elements tested in a closed system where an overall efficiency of 85% was achieved.

Then arrays of up to 30 rectenna elements on one continuous laminate were constructed. These arrays were thoroughly checked for power handling capability up to 5 watts average output per rectenna element. In addition, the power handling capability of individual elements was evaluated as a function of velocity of air flow over the rectenna surface. The diode temperature was simultaneously monitored by a unique, non-invasive test instrument, the fluoroptic thermometer. From this data, reliable estimates could be made of the power handling capability of a complete rectenna array as a function of air density and air flow velocity. A 25 element section was sent to LeRC for test and evaluation.

A preliminary study was made of the deployment of the rolled up rectenna into a flat plane for space use. Various problems were investigated and several formats examined.

The study of the various approaches to fabricating a high frequency rectenna revealed that the thin-film, etched-circuit rectenna format was not a sound approach and stimulated an investigation of placing the foreplane of the rectenna on a solid dielectric substrate such as alumina ceramic. This ceramic could serve as both a separator from and a heat conducting path to the reflecting plane where heat could be removed by flow of a coolant. Further study indicated that a monolithic structure based on the use of a GaAs substrate on which both diodes and circuits were formed would be the best approach for constructing a rectenna at frequencies of 20 GHz and higher. A diode was designed for the monolithic structure, and theoretically evaluated in terms of efficiency and power handling capability. An initial design of a monolithic rectenna was carried out.

1.0 INTRODUCTION

1.1 General Objectives

The contract had two general objectives. The original objective dealt exclusively with the development of the thin-film, printed-circuit rectenna for space use at a frequency of 2.45 GHz. A principal part of this objective was concerned with improving the basic properties of a rectenna format that had resulted from earlier embryonic efforts to develop a thin-film rectenna. The second general objective, which was the subject of a contract extension, was to examine the application of the rectenna principle to high frequency rectennas at 20 GHz and above.

For purposes of discussion it will be desirable to handle these two objectives separately. The first objective, that having to do with the improvement of the 2.45 GHz rectenna and its application to space will be discussed first.

1.2 Improvement of the 2.45 MHz Thin-Film, Etched-Circuit Rectenna and Its Application to Space

The more detailed objectives of the work carried out under this subject are described in the first four items in the statement of work given in Section 2.0. In the introduction we will discuss the work in more general terms.

The approach to carrying out the task was based upon an extension of an approach introduced under NASA contract NAS6-3006(1). This approach was based upon the use of conventional thin-film printed circuit technology, in which all elements of the circuitry, excluding the rectifying diode and the reflecting plane, were "printed" on the two surfaces of the film without the ncessity of any interconnects between the circuitry on the two surfaces. This fabrication method is consistent with the objective of producing very large areas of the rectenna at a low cost per unit area and with a high ratio of power output to mass of the structure.

However, the technology for the thin-film rectenna had proceeded only to the point of making and testing individual elements made from a laminate composed of mylar covered with thin sheets of copper. The efficiency was much less than expected, and the mylar was very vulnerable to both ultra violet degradation and high temperature operation.

The general work effort related to this first general objective consisted of analyzing and refining the thin-film, etched-circuit rectenna at the single rectenna element level for use in space and then fabricating relatively large areas of the rectenna for evaluation and test. Another aspect of the work related to storage of the rectenna while enroute to space and the deployment of it in space. Still another aspect was the aid given to LeRC in the design of a facility for testing the rectenna.

The results of the effort to improve the rectenna in a format more suitable for space were very successful. It was found that the use of Kapton F material as the core of the laminate material greatly extended the permissible operating temperature as well as making the rectenna highly resistant to deterioration from ultra violet ration. In addition it was determined that Kapton F greatly reduced the losses that were inherent in the mylar itself as well as in the lossy adhesive used to join the mylar to the copper.

One of the interesting developments related to the diode rectifier. No portion of the rectenna is more important than the diode. Fortunately, the basic development of the diode had already taken place during earlier rectenna work. The rectifier is a Schottky barrier diode that utilizes GaAs as the semiconductor material. The series resistive loss in this material is much less than that of silicon, the only other candidate material, so it is considerably more efficient. The diode also uses a heat sink that is fabricated on the metallic side of the Schottky barrier to provide a low impedance path for heat flow from the active and heat generating portion of the diode.

The packaging of the diode has taken several formats. The first successfully used package was of the ceramic pill type. In the interests of greatly reducing the production cost of the diode for use in the Solar Power Satellite application a glass packaging technique was introduced. It had been expected to use this packaging format for the thin-film rectenna; in fact, it was used in the early phase of the work effort. However, the tooling for the glass diode became unavailable and it was necessary to shift back to a ceramic package. On subsequent analysis it was discovered that the thermal conduction from such a package is about twice that from the glass diode so that heat is conducted more efficiently to the printed circuit which presents the surface from which the heat is radiated to space. The result is that the power handling capability of a rectenna built from such diodes is considerably better than anticipated, resulting in the prospect of the rectenna working at considerable higher power density in space than originally anticipated.

It was not feasible within the constraints of the contract funding to test the rectenna in vacuum. However, the opportunity did arise to check the rectenna under known rates of a convective flow of air, while simultaneously monitoring the temperature of the diode. The results of this investigation were important in feasibility studies of microwave powered aircraft that would fly at high altitudes where the air was much less dense but where the aircraft flight speeds resulted in convection cooling rates similar to those taken in the laboratory under sea level air conditions. Furthermore, one data point in the studies was for zero convective air flow. Even under these conditions the temperature rise in the diode remained below 100°C for two watts of DC power output per rectenna element and diode.

It was possible to make the interesting results of this experimental evaluation of the power handling capability and efficiency of the thin film rectenna publicly available in a timely fashion through two oral presentations

and printed papers at two international microwave symposia.[2,3] The technological approach as well as the test results were described in these papers.

The work carried out under this portion of the contract brings the thin-film, etched-circuit rectenna to a high level of maturity, available for aircraft applications and serious consideration for space use. There are problems remaining, however. One is the radiation of harmonics. In addition the generation of spurious signals having to do with parametric oscillations in the rectenna have unexpectedly been found. This is the first known incidence of such parametric oscillations in rectennas after many years of development and application so that they are probably the function of the particular design of the rectenna. This is a phenomena that will need attention in future activity.

1.3 Evolution of Rectenna Technology that Provided the Foundation for the Thin-Film, Etched-Circuit Rectenna Concept

The thin-film, printed-circuit rectenna approach to be described in this report has evolved directly from the circuit format used in the conventional rectenna in response to a need for a lower cost, lighter weight, and more flexible rectenna that will operate efficiently at relatively low power levels. There have been several distinct steps in the technological evolution.[4,5]

The first step involved a transition from a three plane rectenna construction format as shown in Figure 1-1 to a two plane format shown in Figure 1-2 and 1-3 in which nearly all of the rectenna functions are carried out on the foreplane.[6] A physical realization of this is shown in Figure 1-4. The second step in the evolution involved redesigning the rectenna element to operate at a higher impedance level to retain good efficiency at relatively low incident microwave power densities that were felt to be desirable for rectennas in the upper atmosphere, in space, or at the edges of the rectenna for the solar power satellite concept.[7]

1.4 Origin of the Thin-Film Etched Circuit Concept

The factor that led directly to active work on the thin-film printed-circuit concept was the need expressed by personnel at the Wallops Flight Facility for a flexible rectenna that could be used at an altitude of 70,000 feet and at reasonably low power density levels on a balloon. The latter requirement suggested the use of the electrical circuit previously developed in a bar type construction format as the electrical circuit prototype for the thin-film printed-circuit rectenna.[1,6]

The transformation of the mechanical design of the rectenna element from the bar-type format to the thin-film format represents a different and perhaps unique approach to printed circuit design. The foreplane is a balanced circuit that does not use a ground plane (the reflecting plane, located a quarter wavelength behind the foreplane, is not a ground plane in the "slot-line" sense). The mechanical design of the thin-film format seeks to simplify

Figure 1-4. The Item of Interest in this Photograph is the Connection of the Bar-Type Rectenna Elements into a Linear, Planar Structure, to Function as the Foreplane of the Two Plane Structure. This Format was Checked Out Electrically in Considerable Detail During a Previous Study. Shown also are the Environmental Shields, Not Needed for Space or High Altitude Atmospheric Platform Applications of the Rectenna.

fabrication by the elimination of any connections such as plated feed-throughs between the microwave circuits on the two sides of the film. It does this by etching the dipole antenna, the inductive sections of the low pass filters, and the DC bus bars on the top surface of the thin film. On the other surface the copper is etched to leave just enough material to form the capacitors associated with the low pass filters and the DC blocking capacitor. Figure 1-5 illustrates this arrangement.

Using this approach, a thin-film, etched-circuit rectenna was fabricated from a sandwich material consisting of one mil mylar bonded with an adhesive to one ounce (1.5 mil) copper on both faces. The resulting product is shown in Figure 1-6.

The electrical tests made upon a rectenna element cut from the larger sheet and tested with the special fixture to be described later indicated a moderate level of success but its efficiency was considerably lower than expected. Mylar as a base material also had the deficiencies of a relatively low softening temperature and of being sensitive to deterioration from ultra violet light.

The work performed under this LeRC contract may be considered as a major step in the evolution of the thin-film, printed-circuit rectenna. It has concentrated upon making the rectenna element (and therefore the rectenna) more efficient, and upon the use of plastic materials better suited for space application than mylar. The effort has also involved additional diode development which will favorably impact the performance of the rectenna.

1.5 Investigation of Rectenna Design for Frequencies of 20 GHz and Greater

Tasks six and seven of the work statement deal with investigating the rectenna principle at much higher frequencies and examining in some detail the design of a rectenna at 20 GHz.

The pursuit of these tasks was necessarily based upon the rectenna technology that had been developed at 2.45 GHz. However, it was found that a rectenna designed by simply scaling the rectenna from its 2.45 GHz thin-film, etched-circuit format did not appear attractive at such high frequencies because of a host of problems. Perhaps the most serious one was the large number of rectenna elements per unit area, because their density scales as the square of the frequency. Even if small diodes could be constructed in large numbers economically, the problem of assembly and carrying heat away from the diodes remained.

Because of scaling problems having to do strictly with the scaling of the thin-film circuit the use of a substrate on which the circuits could be silk screened became attractive. The standard substrate for such silk screened films is alumina ceramic. But alumina is a fair, if not good, conductor of heat so that filling the space between the foreplane and reflecting planes with

Figure 1-6. Photographs of the First Thin-Film Printed-Circuit which Forms the Foreplane of the Rectenna. The Dielectric Substrate Used was Mylar which was Found to have Several Shortcomings as a Substrate for a Thin-Film Rectenna.

alumina ceramic would be an attractive solution to the problem of cooling an array. Cooling surfaced early as a problem because a high frequency rectenna must operate at a high power density to be efficient, and a combination of the higher density and the lower efficiency of a high frequency rectenna necessarily generates a large amount of waste heat per unit area.

Because alumina has a high dielectric constant of about nine, it also became evident that the half wave dipoles of the rectenna would become considerably shorter with the result that there would be more elements per unit area. But it was noted that any development involving a silk screened circuit on an alumina ceramic would be also applicable to a semiconductor substrate of silicon or GaAs which have about the same dielectric constant as alumina.

Over the time period that the contract was active, the technology of monolithic GaAs circuits had advanced so rapidly that at the time this report is being written the prospects of being able to build a monolithic rectenna on a wafer of GaAs became a reasonable possibility. For the future, a completely monolithic circuit is very attractive.

If the development of such a rectenna were begun now there would probably be a significant percentage of the diodes that would be inoperative, perhaps as high as ten percent, because of the imperfect nature of the GaAs wafer technology. However, the monolithic rectenna circuit could be so designed to tolerate the failure of such a percentage of the diodes. And over the near future it is expected that the quality of the GaAs substrate, which is a basic problem in much more complicated and currently much more important monolithic circuits, will be rapidly improved.

Ten years ago, there appeared to be no need for a high frequency rectenna because no high power cw transmitter technology existed at these frequencies. That situation has changed dramatically. The introduction of the gyrotron electron tube assures the availability of several hundreds of kilowatts of cw power at 20 to 35 GHz. And large mechanically-steerable 70 meter parabolic reflectors are being readied to be used with such tubes for deep space radar purposes. It is logical to expect that these breakthroughs in technology will be examined for their application to power transmission. The interest in rectennas for this application may be expected. It would be timely to consider undertaking monolithic rectenna developments at this time, even though there are still imperfections in GaAs technology.

2.0 MAIN TEXT: REPORT ON TECHNOLOGY PROGRESS BY TASKS

There were seven tasks to be performed under this contract. The report on technology progress will by task as outlined in the work statement of the contract with the exception of Task 5 which is the Review and Reporting Requirement. As indicated in the Introduction there were two main objectives, one associated with further development of the thin-film, etched-circuit rectenna at 2.45 GHz and the other associated with an extension of rectenna technology to much higher frequencies at 20 GHz and beyond.

The first four tasks are associated with the first general objective. Tasks 6 and 7 are associated with the second objective. The work statements associated with all of these tasks are presented below.

Task 1 - Single Element Printed Circuit Rectenna

The Contractor shall investigate and define the microwave and printed circuit design techniques that will be used to fabricate a single element printed circuit foreplane rectenna for evaluation. Using existing rectenna models, the Contractor shall establish electrical and mechanical requirements for the solid state component, and address thermal requirements for operation of the element in a vacuum environment.

The fabrication of the rectenna element shall include three recyclings of the artwork: the first to include the output bypass capacitor, and the second to fine tune the design, and the third to optimize the efficiency. Performance testing to determine such factors as efficiency, line and load characteristics, transient response, and standing wave ratios would be confined to a single element.

Task 2 - Design of a Complete Rectenna Array

The Contractor shall investigate the design of a combined foreplane, reflecting plane, and a separator. As part of the effort, methods of deploying a printed circuit rectenna array shall be considered. Mechanical, electrical, and thermal characteristics of various separator configurations shall be addressed.

After examining the various approaches, the Contractor shall select the "best" design and fabricate a small section of the combined array. This combination array shall consist of five foreplane structures without microwave diodes mounted on the substrates. No electrical testing will be performed on this combined array section.

Task 3 - Fabrication of a Large Area Sample Rectenna

Using the results of Tasks 1 and 2, the Contractor shall fabricate two sample rectenna structures less than 0.2 M^2 suitable for operation in vacuum.

This array shall be tested electrically in an ambient environment. After passing the electrical performance check, the sample rectenna array shall be sent to Lewis Research Center for operational tests in both ambient and vacuum environments.

Task 4 - Design of an RF Test Facility

The Contractor shall provide a suitable design for an rf test facility to be built at Lewis Research Center. The critical component requirements and performance specifications of the major rf excitation equipment and microwave measurement equipment shall be specified. As part of this task, the Contractor shall recommend rf components and advise the NASA Project Manager during the fabrication of the Lewis microwave test facility.

Task 6 - 20 GHz Printed Circuit Rectenna Study

The Contractor shall investigate the feasibility of developing a rectenna element capable of performing in the K-band region. This order of magnitude increase in operating frequency will allow the physical size of the rectenna to be reduced accordingly.

The study shall include, but not be restricted to, the effects of dielectric loss, semiconductor performance, diode technology, critical design parameters, and photoetching/layout techniques.

Task 7 - Preliminary K-Band Rectenna Design

The Contractor shall investigate and define the microwave and printed circuit design techniques that would be necessary to realize a K-band printed circuit foreplane rectenna.

This design will include the selection of an operating frequency/ substrate combination as to optimize the element's performance, specification of the proper rectifying diode, and preliminary artwork of the complete rectenna.

2.1 Single Element Printed Circuit Rectenna (Task 1)

This section will be organized by first establishing what the single rectenna element is and how it is tested. This will be followed by an account of finding the causes for the unexpected inefficiencies in the first rectenna elements made under NASA contract NAS 6-3006. This, in turn, will be followed by an account of developing a highly efficient rectenna element that is also greatly improved from the point of view of power handling capability and durability by a change in the film material.

2.1.1 The Single Rectenna Element and Test Procedures for It

Historically, rectenna development has proceeded by a test procedure that allows a detailed evaluation of a single rectenna element in a closed system that simulates the cell area that the element occupies in the rectenna. By this procedure, an accurate measurement of its efficiency can be made, and its impedance as seen by the incoming microwave beam closely approximated.

In the two plane format the rectenna element consists of a repetitive unit of the rectenna foreplane as shown, for example, in Figure 1-3 together with the metallic reflecting plane which is positioned about one quarter wavelength behind the foreplane section. The repetitive unit of the rectenna foreplane (Figure 1-3) consists of halfwave dipole antenna that couples to the incoming microwave beam or to incident microwave power in the special test fixture to be described later. The power from the antenna flows into a two section low pass filter which serves the dual function of energy storage for the half wave rectifier which follows it, and to attenuate the flow of harmonic power from the rectifier to the antenna. The rectifier is shunted across the output terminals of the low pass filter and its capacitance resonated out by a short section of transmission line which is terminated by a large bypass capacitor. The capacitor serves both as an effective short circuit termination of the transmission line and as a capacitor filter to minimize any microwave ripple on the DC power output of the element. The DC power output is collected on the two conductor strips that connect one element with another. The conductor strips serve a dual function of collecting the DC power as well as functioning as inductive sections of microwave transmission lines within the rectenna element itself.

The properties and performance of the rectenna element as just described is presented in great detail in References 1 and 6, including detailed mathematical modeling and computer simulation of performance that provides information on current and voltage waveforms, efficiency, harmonic content, etc. Reference 1 provides design procedures for the filter sections. It will not be the purpose of this report to go into similar detail.

For testing purposes the rectenna is mounted on a hinged door as shown in Figure 2-1. The door becomes part of an expanded waveguide test fixture shown in Figure 2-2. In turn the fixture becomes part of a closed measurement

system shown in Figure 2-3 in which accurate measurements of incident microwave power, reflected microwave power, and DC power output can be made.

Efficiencies can be computed from the measurements of the parameters shown in Figure 2-4. Efficiency may be stated in terms of overall efficiency defined as the ratio of DC power output to incident microwave power, or, electronic efficiency defined in terms of the ratio of DC power output to the microwave power absorbed in the rectenna element.

Measurements are also frequently made of the impact that DC load resistance and the microwave power input level have upon the input impedance level to the rectenna as measured at or near the plane of the foreplane. This information can be plotted on a Smith Chart.

Special attention is given to the validity and accuracy of the measurements. An effort is made to calibrate the microwave input accurately. This includes the elimination of the impact of harmonics in the calibration procedure by the use of low pass filters placed between the microwave generator and the system to be calibrated. Harmonic filters are also placed to eliminate the impact of harmonics generated by the rectenna element upon both the directional coupler with its power meter and the standing wave detector. Details of the system are given in Reference 6.

2.1.2 Determination of the Source of Inefficiency in the Original Thin-Film Etched-Circuit Rectenna Element

The first thin-film, etched-circuit rectenna element was modeled from a bar type rectenna element shown in Figure 2-5. Data on this element is given on pages 56 and 57 of Reference 6. The performance of this bar type rectenna with respect to efficiency as a function of microwave power absorbed is shown in Figure 2-6. Reflected power was so low that efficiency as function of incident power would have been nearly as high. The corresponding performance of the thin-film, etched-circuit rectenna element developed under the Wallops Flight Facility Support (Reference 1) is shown in Figure 2-7. There was a substantial difference in efficiency amounting to 13% between the anticipated efficiency and that which was experimentally measured.

Normally, a difference in efficiency of 13% could be tolerated. However, in the solid bar model case the inefficiency was 16% while in the first thin-film model it was 29% or almost twice as great. The power handling capability of the rectenna element will be determined by the power it must dissipate and dissipation must be by means of radiation alone if the element is in the vacuum of space. The application for the thin-film rectenna as stated in this study was to be in space. Moreover, the melting temperature of mylar from which the first element was made is relatively low, making dissipation an even more critical factor.

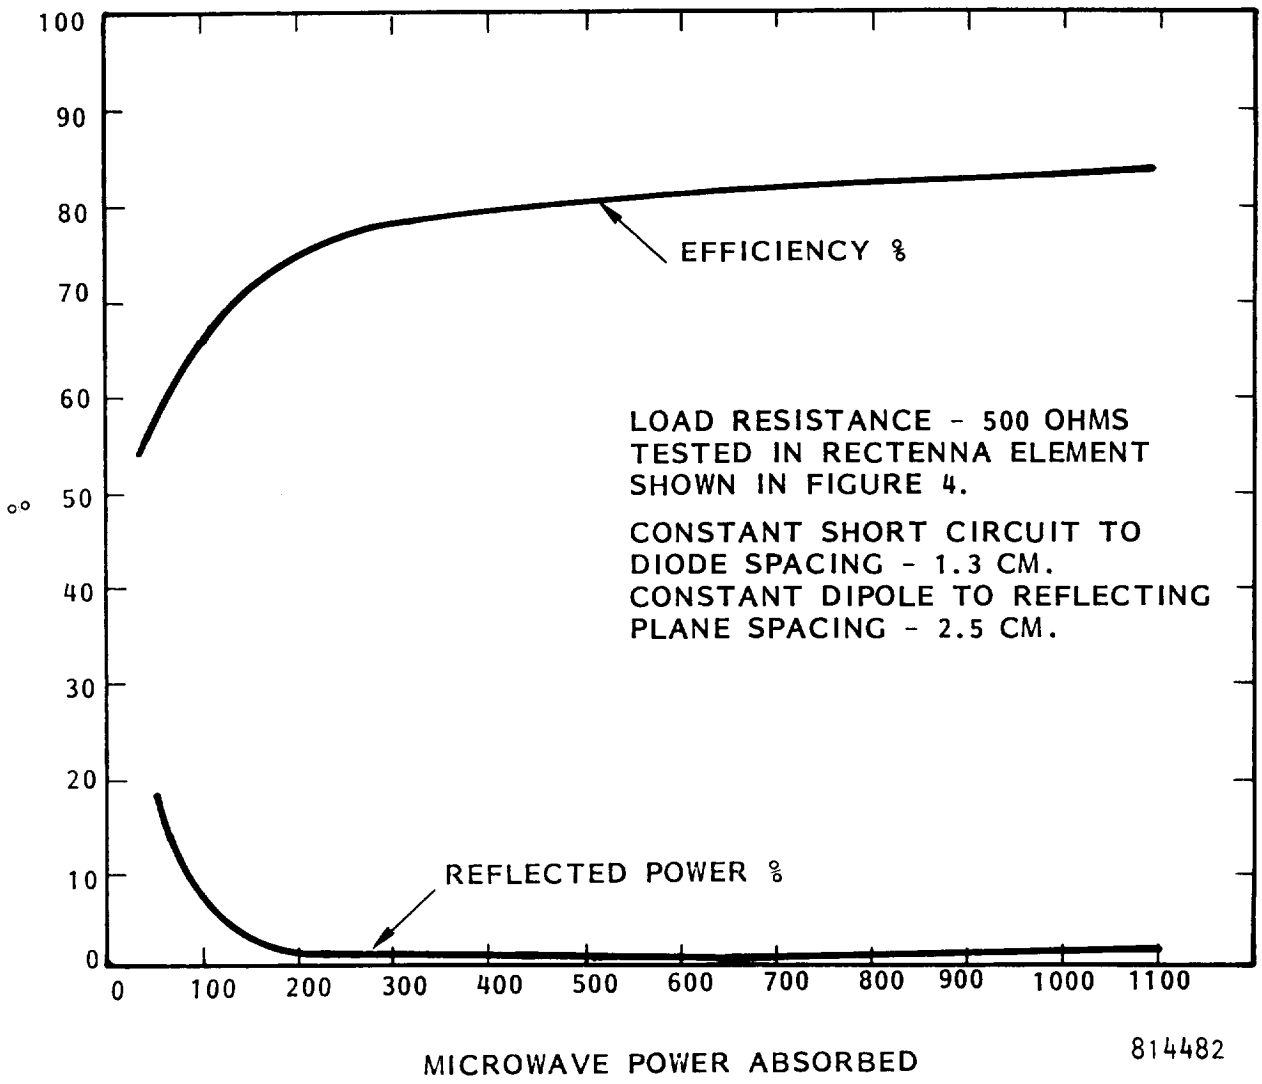

Figure 2-6. Efficiency and Reflected Power as % of Absorbed Microwave Power for the Combination of Specially Designed Microwave Diode and the Rectenna Circuit of Figure 2-5.

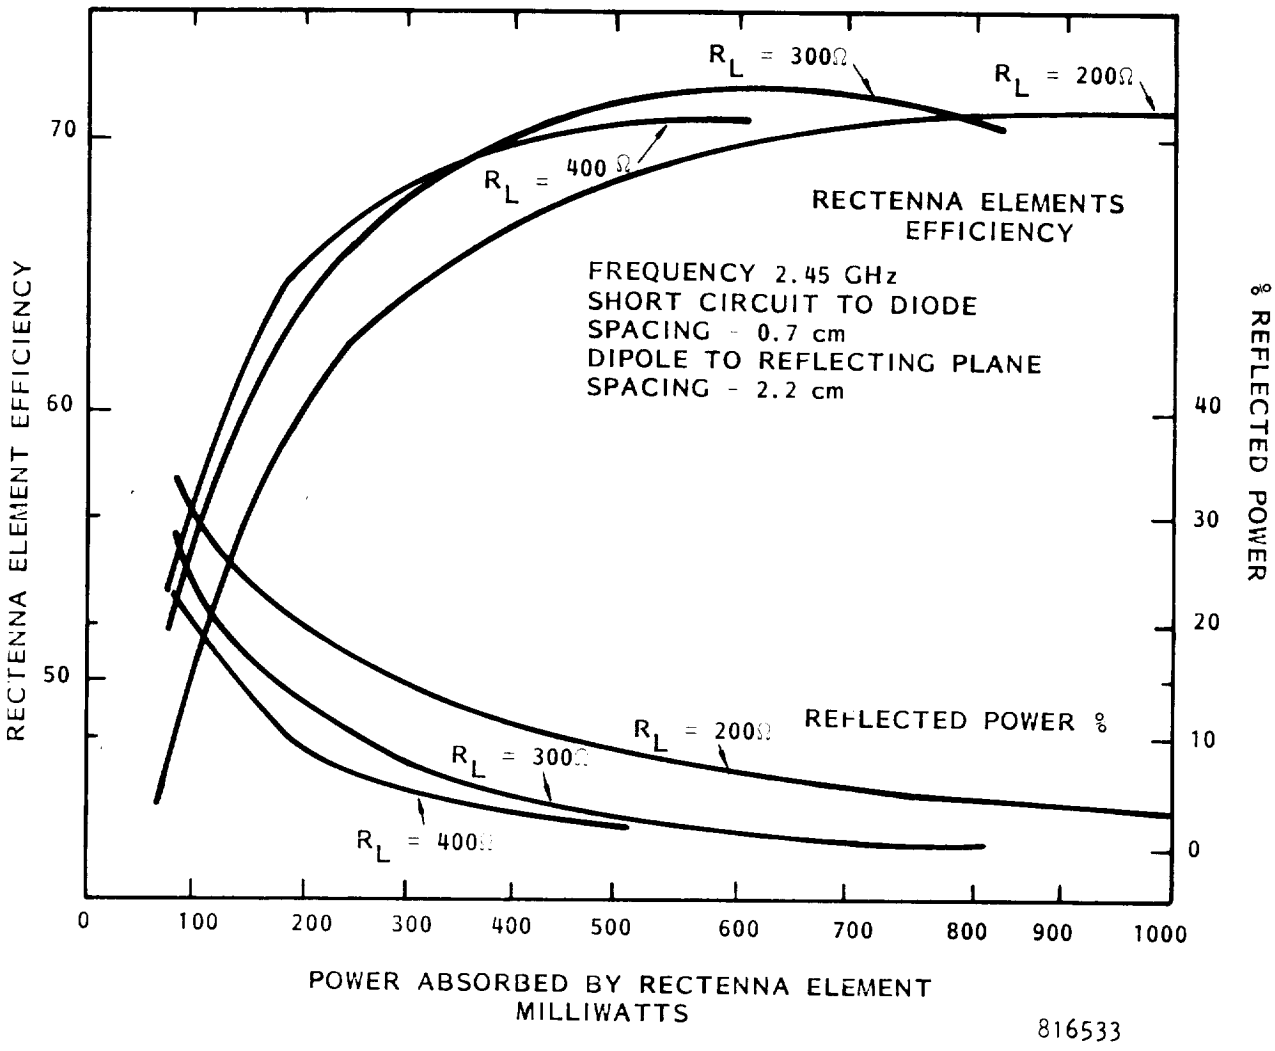

Figure 2-7. Test Results on Thin-Film Rectenna Element with Microwave Circuit of Bar-Type Rectenna Element Shown in Figure 2-5. Efficiency is Considerably Lower than that of Bar-Type Configuration.

Therefore, the first concern was with determining the source of the inefficiency, and then with correcting and improving the design, if possible.

Because the data for the bar type element and film type element were obtained using different diodes from a production lot of diodes, the first step under the new contract was to eliminate the diode as a variable by using the same diode in both the bar and film type elements. The resulting data was nearly identical, so that the diode could be eliminated as the cause.

After eliminating the diode as a potential source of inefficiency, the early effort under this contract was devoted to making measurements on the rest of the rectenna element design to determine the source of the excessive losses. These measurements involve making special test fixtures.

The first special test fixture that was made is shown in Figure 2-8, and shown again as it was inserted into the Hewlett Packard network analyzer in Figure 2-9. Basically the test fixture adapted the balanced configuration of the rectenna element to the unbalanced configuration of the coaxial connection to the network analyzer by splitting the balanced structure in half and holding one half above the ground plane which was a continuation of the outer conductor of the coaxial connection. The capacitor patches on the bottom of the element (see Figure 1-5) are clamped to the ground plane, as they should be electrically, and so adequately support the rectenna element mechanically. The characteristic impedance of the rectenna element is cut in half by this arrangement and comes close to matching the 50 ohm impedance of the network analyzer. The phase shift versus frequency properties of the rectenna element are not impacted.

The measurements of reflected power and transmitted power as a function of frequency made with this arrangement indicated poor transmission both because of resistive losses and because the cutoff frequency of the rectenna network was lower than anticipated from the electrical design. The resistive attenuation losses were greater than were anticipated from assumed properties of the dielectric material in the capacitors which was the only suspected source of loss.

To directly investigate the dielectric loss a technique for making direct measurements of capacitance and loss tangent on the capacitor used in the microwave circuit was developed. This involved the use of a holder, shown in Figure 2-10, for a sample capacitor whose area and dielectric thickness were carefully measured. Dielectric constants and dielectric losses could then be computed from the standing wave measurements made in a coaxial standing wave detector with a moveable probe. Very useful information was obtained from these measurements. Although we had expected the possibility of larger losses in the capacitor because of the unknown losses in the adhesive that was used to join the copper to the mylar, we were surprised to find: (1) the values of capacitances to be 30% greater than the design value, and (2) that the loss tangent in the mylar itself without the adhesive was .0056 or about three times that of the value of 0.002 which had been used to calculate losses in the capacitors in the low pass filters.

Figure 2-10. Special Capsule for Mounting Specimens of Capacitors Composed of Different Dielectric Materials. The Capsule Terminates a Sensitive Standing Wave Detector that could Resolve a Loss Tangent to Better than the Fourth Decimal Place, or the Difference Between 0.0026 and 0.0027, for Example.

The design of the rectenna element had been based upon data on mylar taken from Figure 3-15 on page 178 from the book "Dielectric Materials and Applications", authored by Von Hippel and published by the Technical Press of John Wiley. This is considered to be the authoritative text on the subject. From this graph the dielectric constant was read to be 2.2 and the loss tangent to be 0.002 at 2.45 GHz.

The matter of conflicting data was resolved by a conversation with William Westphal of the M.I.T. Insulation Laboratory who gave me values of loss tangent and dielectric constant from mylar at 2.45 GHz that were at substantial variance with those from Figure 3-15 in "Dielectric Materials and Applications". These values are listed on page 13 of Volume 5 of "Tables of Dielectric Material", Laboratory for Insulation Research, Technical Report 119. These tables could be obtained in Xerox form but are not as generally available as the book "Dielectric Materials and Applications". The dielectric constant and loss tangent are listed as a function of frequency in Table II of this report.

It was noted from Table II that the dielectric constant at 3 GHz (which is sufficiently close to 2.45 GHz) is 2.79 rather than 2.2. Hence the capacitors that were designed under the assumption of the incorrect value of 2.2 for the dielectric constant gave capacitances that were 2.79/2.2 or 1.268 times the design value. This mistake resulted in a lower cutoff frequency of the low pass filter than the design value, thereby introducing unwanted attenuation at 2.45 GHz.

The loss tangent for mylar at 3 GHz is given as 0.0061 in the tables. This compares with a value of approximately 0.0056 found from measurements on mylar itself.

The conclusion that can be made from this discussion is that there is good agreement between the experimentally measured values of loss tangent and dielectric constant in mylar at 2.45 GHz made at Raytheon and the data published in the tables for mylar. It follows that the data given in Figure 3-15 of "Dielectric Materials and Applications" is in error.

2.1.3 Establishment of Kapton F as a Suitable Dielectric Film Material

In the search for better film materials, Kapton coated with FEP Teflon emerged as a promising candidate. Here the real situation with respect to the published data and assumed loss in Kapton was reversed from that of Mylar. Kapton is particularly good in space with the low absorbed water content that it would have there. According to William Westphal of M.I.T., Kapton as received has a loss tangent of 0.008 at 3 GHz because of the absorbed water. However, after a bakeout at 100°C in air, the loss tangent improves to 0.0044, and after a higher temperature bakeout in vacuum the loss tangent improves to 0.0015, or four times better than mylar as we are now using it. Furthermore, Kapton will withstand a much higher operating temperature so that the operating temperature of the diode which can be as high as 200°C becomes the limiting factor in the

amount of the heat that can be radiated. The great improvement in the power handling capability of a rectenna in space made possible by changing to Kapton from Mylar is immediately evident.

Kapton, however, will not adhere tenaciously to copper cladding of the thickness that is needed and even when a thin copper film deposit is made in vacuum the subsequent addition of a thickness of electroplated copper results in an unsatisfactory product. The current technology, therefore, is to apply a thin adhesive to the Kapton before bonding copper to it, usually by compression at elevated temperatures. This adhesive is quite often Teflon. DuPont makes a commercially available product designated Type F Kapton with the Teflon already coated to the Kapton.

According to the DuPont Engineering Technical Service Type F Kapton bonds well to copper but we found there are no copper to Kapton F laminates commercially available because the bonding of the copper to the teflon requires high pressure at temperatures so high that an electrically heated press is necessary. Commercial laminates using copper bonded to Kapton use a bonding agent that will bond at the lower temperatures of steam heated presses. The low temperature bonding agents normally used are lossy at microwave frequencies.

Fortunately, we found suitable electrically heated presses within the Raytheon organization that could perform the bonding although the area of the press was limited which presented a limitation to the number of rectenna elements that could be incorporated into a single fabricated rectenna section.

The first laminates attempted with this equipment used only 0.1 mil of teflon film on the 1 mil Kapton core. The bonding was not satisfactory. The teflon thickness was increased to 0.5 mil on each face of the Kapton. These laminates were quite satisfactory and were used for subsequent work.

Measurements at 2.45 GHz were made of the loss tangent and the dielectric constant of the Kapton F material when bonded to copper. The loss tangent was established as 0.0033. This loss is considerably lower than the loss measurements of 0.0055 on Kapton alone and can be attributed to the presence of the FEP teflon which has a very low dielectric loss.

The measured value of the dielectric constant of the composite material was 3.09 or substantially higher than the computed dielectric constant of 2.63 for the composite material. This discrepancy may have been caused by improper compensation for the fringing fields surrounding the assumed one sixteenth inch diameter test capacitor or in a larger actual diameter of the capacitor than that of the mask.

2.1.4 Design of the Rectenna Element made from Kapton-F Copper Laminate

With a suitable laminate established, attention was given to the design of the rectenna element itself. There were three reiterations of the art work

that established the dimensions of the two masks that were necessary for etching the finished circuit elements on the two sides of the laminate. In addition to determining the details of the art work for the rectenna element it was necessary to make some assumptions about the spacing between rectenna elements. The assumption used was that the spacing would be the same as it was for the highly successful rectenna made from bar type rectenna elements.

The rectenna elements were spaced 7.772 cm (3.060 inches) apart in rows that were separated by 6.731 cm (2.650 inches). The 1:1 exact scale of the resulting art work for the rectenna elements is given in Figures 2-11 and 2-12. The dimensioning of the artwork may be obtained from Figure 2-13.

The electrical design of the thin-film rectenna has deviated some from that of the prototype bar-type element (Figure 2.5) in response to the difficulty of constructing mesa type diodes with zero bias capacitance, C_{to}, as low as one picofarad and in response to the experimental observation that a diode of 3.0 pfd can be positioned across the transmission line near the point of and in place of the inboard capacitor of the second section of the low-pass filter without substantially changing the performance. The physical capacitor is eliminated but is electrically replaced by a small portion of the effective capacitance of the diode when it is in operation. The larger area of the junction in the 3.0 pfd diode increases the power handling capability of the element.

The use of a higher capacitance diode implies a lower value of resistance of the dc load, which means that the voltage drop across the Schottky barrier diode becomes a more important contributor to inefficiency unless the DC power output of the element is increased to restore the same voltage across the DC load. However, it is important to note that as time has passed it has been recognized that the rectenna element, particularly in its Kapton F format will handle much more power in a vacuum environment than had been previously thought. At the same time it was found that the anticipated space and aircraft applications for the rectenna would need a fairly high power density level of from 200 to 1000 watts per square meter, or an equivalent output of from 1 to 5 watts from each of the rectenna elements. Therefore, the higher capacitance diode is desirable for space and aircraft application but not for application as an efficient element on the periphery of the ground based rectenna in a Solar Power Satellite transmission system for which the prototype element in Figure 2-5 was developed.

The electrical parameters of the final design are shown in Figure 2-13. The values of inductance for the π section equivalents of the two sections of transmission line are given at 2.45 GHz. The values of capacitance for the π section equivalent are merged with that of the patch capacitors to provide the total capacitance value shown. The procedures for deriving these values are given in Section 3.4 of reference (1).

The design calls for the second low pass filter to serve as an impedance transformer to raise the impedance level of the microwave rectification circuit. At 2.45 GHz it is designed for 90 degrees phase shift and serves as a quarter

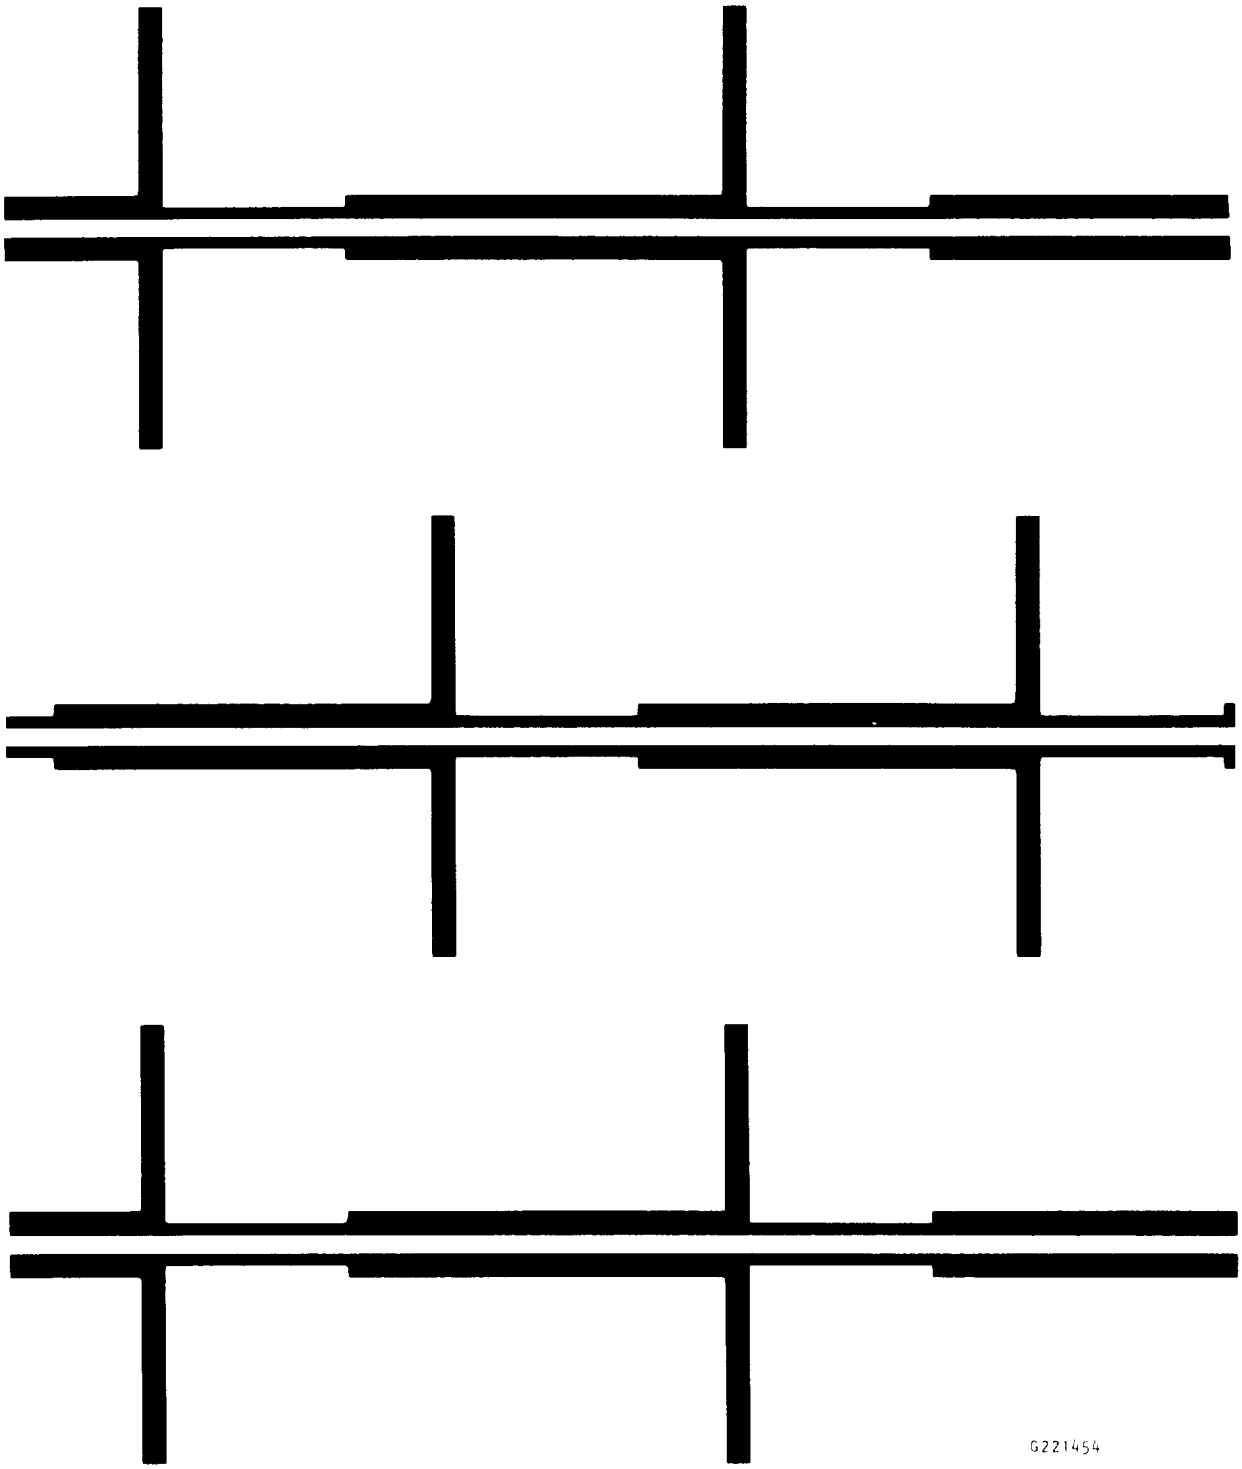

Figure 2-11. Exact Layout of Etched Circuits on Top Side of Thin-Film Rectenna. Refer to Figure 1-5.

wavelength long line of 180 ohm characteristic impedance. The antenna terminal impedance is 120 ohms and the first low pass filter also has a characteristic impedance of 120 ohms. As seen by the rectifier circuit the impedance at 2.45 GHz looking toward the antenna is therefore 270 ohms. A reflectionless match therefore implies that the microwave impedance appearing at the rectifier circuit be 270 ohms. The DC load resistance that produces the match is typically 1.2 to 1.3 times the microwave impedance.

The data of Figure 2-14 indicates that the associated DC load resistor have a value in the range of 300 to 400 ohms to produce a good match to the rectenna. But such a value produces an excessively high peak inverse voltage for the current Schottky barrier diode when the DC power output exceeds 1.6 watts. Clearly, the rectenna element needs to be redesigned for lower impedance level when producing power levels of several watts.

2.1.5 Electrical Performance of the Rectenna Element in Its Final Configuration

Considerable data was taken on the rectenna element at each design reiteration. The data of greatest interest, however, is on the final design. The kind of data of greatest interest relates to efficiency and power handling capability. There are two different efficiencies of interest. One is the rectification efficiency of the rectenna element which is defined as the ratio of DC power output to the microwave power absorbed by the element. The power absorbed is equal to the incident microwave power minus the reflected power. The other efficiency is overall efficiency which is defined as the ratio of DC power output to the incident microwave power.

Figure 2-14 shows the overall efficiency as a function of the DC power output and the value of DC load resistance used. It also shows the reflected power as a function of DC power output and load resistance. The maximum DC power output is limited by the reverse voltage breakdown of the diode which is the sum of the DC output voltage plus the peak negative of the ac voltage waveform. This sum cannot be exceeded without a drop in efficiency. If the inefficiency is too great, the diode will be burned out. It is noted that a value of 200 ohms of load resistance has permitted a DC power output of 3.5 watts before the efficiency begins to droop. Later, in Section 2.3 when the power output of a rectenna array composed of these elements is discussed, DC power outputs in excess of 5 watts per rectenna element were obtained at even lower values of load resistance.

It will be noted from Figure 2-14 that there is considerable reflected power from the 200 ohm load. When the reflected power is subtracted from the incident power the rectification efficiency of the rectenna element is 84% at 3.5 watts and 85% at 2.5 watts of DC power output.

The rectification efficiency is probably the item of greatest interest when testing the individual rectenna element because it has been established that the collection efficiency in a properly designed rectenna can approach

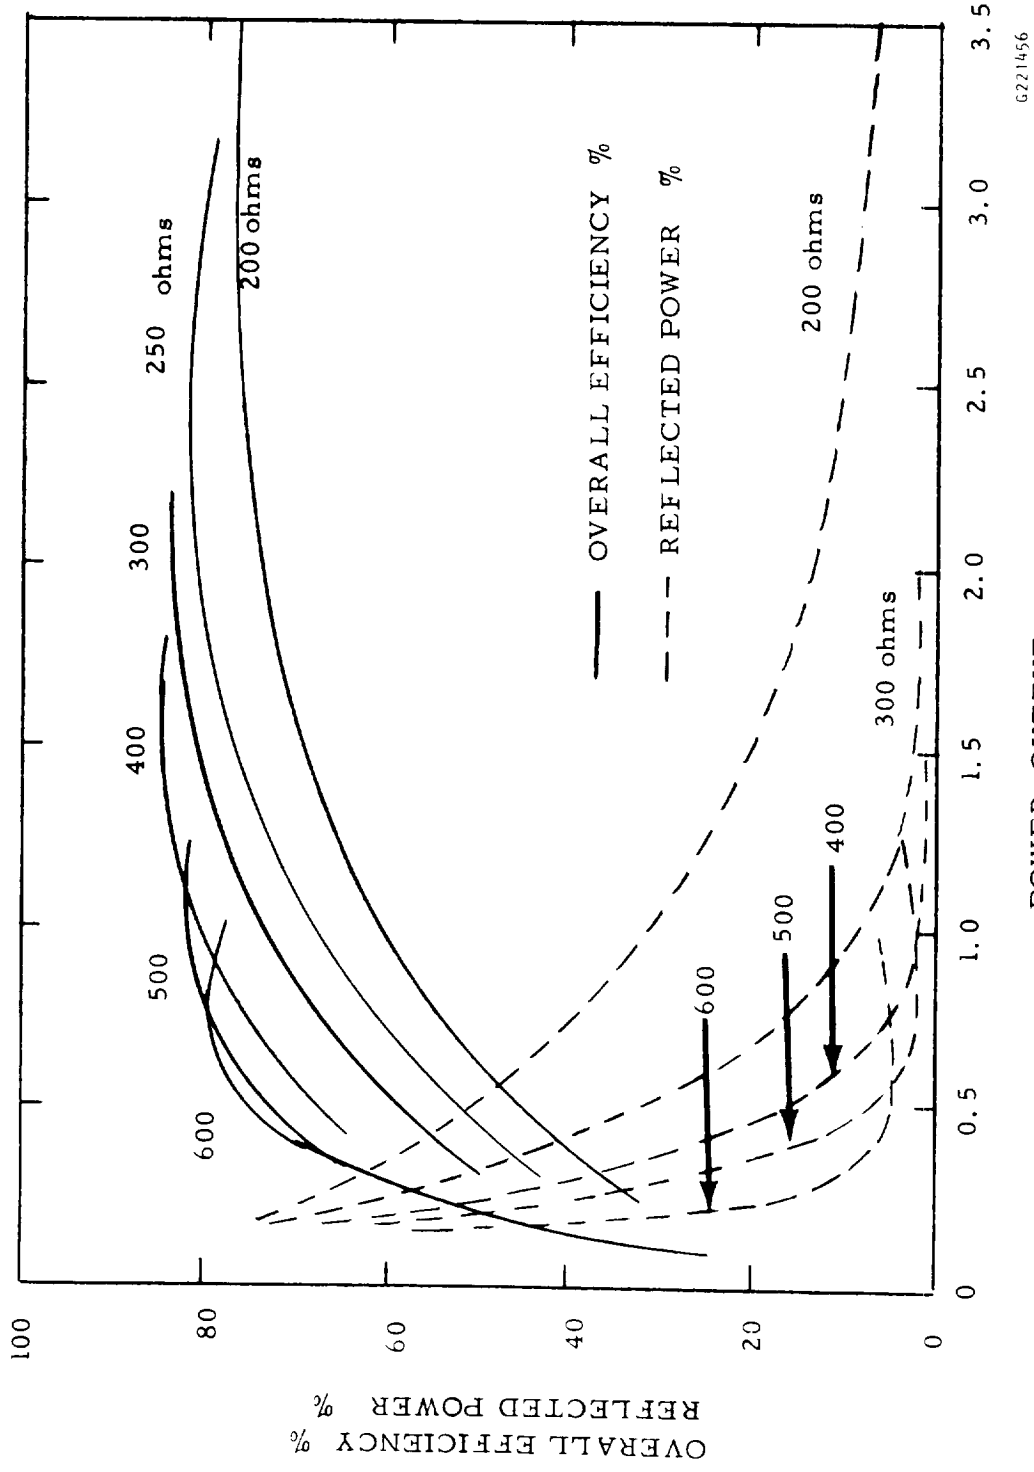

Figure 2-14. Overall Efficiency and Reflected Power Percentage are Shown as Functions of the DC Power Output and the DC Load Resistance. Power Output at Higher Values of DC Load Resistance is Limited by Start of Power Flow in Reverse Direction through the Diode. The Diode Absorbs this Power.

100%. One of the factors that must be taken into account in testing individual rectenna elements over a range of power input is that the effective capacitance of the diode is a function of operating power level so that for optimum performance the rectifier circuit should be retuned by repositioning the microwave shorting (bypass) capacitor. In a printed circuit format, however, this is not possible. The implication is that for optimum overall efficiency of the rectenna element, the operating power level must be specified.

There is considerably more test information on the power handling capability of the individual rectenna element along with that of arrays of the elements in Section 2.3.

2.1.6 Diode Development and Procurement

The Schottky barrier diode is an essential element in the rectenna. The use of GaAs as the base material is especially important in the rectenna application because of the high efficiency of diodes made from this material and because of its capability to withstand considerably higher operating temperatures than silicon. Because these diodes are not used for any other purpose, their development has always been part of the rectenna development effort.

The basic Schottky diode for the rectenna application was developed under contracts with MSFC and JPL in the 1972 and 1975 time period. However, the diode was packaged in a format not suitable for use in the thin-film printed-circuit rectenna. In the decision making process as to how the diode would be repackaged, the ultimate cost of the diode in large production volume was considered and it was decided to package it in a miniature glass package that is commonly used for mass production of all forms of diodes. This form shown in Figure 2-15 was used during the thin-film, printed-circuit, rectenna development for Wallops Flight Facility and during the early phases of the current LeRC activity. It worked out well and it was intended to use this for the entire LeRC activity. However, during a move of the Special Microwave Devices Operation from Waltham to Northborough the tools were lost to make these diodes. Because of the cost of replacing these tools, it was decided to repackage the diode in a ceramic pill package of the format shown in Figure 2-15. At the same time it was decided to increase to zero bias capacitance of the diodes to reduce the scrap involved in making the mesa type diodes.

The impact of this design change in packaging and the increase in capacitance upon the design of the rectenna element was considerable. For the rectenna element to perform satisfactorily it was found necessary to eliminate the inboard capacitor and reposition the diode as shown in Figure 2-13. In the final format shown in Figure 2-13 the performance actually appeared to be better than for the glass diode.

The new diode is considerably better from the heat dissipation point of view than is the glass diode because there is little resistance to heat flow

from the diode to the transmission line upon which the diode depends for the conduction and radiation of heat. In the glass diode there is considerable resistance because of the dumet lead which is a relatively poor heat conductor. It is also of interest that the heat flows out of the ceramic package in both direction in about equal amounts because of the excellent heat conduction properties of the alumina ceramic shell.

The diode specifications that were used for the procurement of the didoes is as follows:

- Semiconductor material - type n GaAs.
- Plated heat sink for good conduction of heat away from junction.
- Metal used at junction - platinum.
- C_{t0} (zero bias capacitance) - 3 pf $\pm$ 10%.
- V_b (reverse voltage breakdown) - 60 - 70 volts.
- Reverse Leakage - 10 microamperes at 80% of breakdown voltage.
- Slope of voltage current characteristic - 1.5 ohms maximum at 100 milliamperes of DC current.
- To be packaged in Raytheon ceramic package #3000119.
- 0.040 inch wide ribbons to be attached to both covers of ceramic package.

The electrical portion of these specifications is considerably relaxed from that used for comparable diodes for the large rectenna array designed and manufactured for a microwave power demonstration on the Mojave desert in 1975. The motivation was reduced cost achieved by eliminating rigorous quality control procedures. However, for any procurement where high reliability is needed it is recommended that a more restrictive specification be used.

In particular, it is essential to specify the voltage drop across the entire diode at very low current conduction in the forward direction, because the slope of the voltage current characteristic at 100 milliamperes does not necessarily guarantee a low voltage drop across the diode. For example, another Schottky barrier can be used in place of a low resistance ohmic contact. While this will automatically double the voltage drop across the diode at low currents and drastically reduce the efficiency of the diode it will not greatly impact the slope of the voltage-current characteristic at high currents.

2.1.7 Summary of Activity on Task 1

- The causes of low efficiency in the thin-film, etched-circuit rectenna element were found and identified as unexpectedly high loss in the mylar and expected losses in adhesive.

- In a search for better film materials Kapton Type F was found and projected to result in a much superior rectenna element in terms of efficiency and ability to operate at high temperatures.

- Three reiterations of the rectenna element design were made before finalizing the printed circuit masks in the third reiteration.

- Substantial changes were made in the Schottky barrier diode design. The package was changed from glass to ceramic; the area of the junction was increased three fold to improve diode yield and to be more in accord with the trend towards operation of rectenna elements at higher power levels for space and high altitude air vehicle applications.

- Electrical tests were made on the final design of rectenna element over a wide range of microwave power input and DC load resistance. Efficiency and reflected power were noted. An overall efficiency of 85% at 1.5 watts DC/output was obtained and a rectification efficiency of 84% was obtained at 3.5 watts of output. Limitation in power output and efficiency was the reverse voltage breakdown of diode.

2.2 Design of a Complete Rectenna Array (Task 2)

2.2.1 Introduction

One of the attractive features of the rectenna for space use is the assumed relative ease with which it may be deployed. For example, in the scenario assumed in Reference 8 all the rectenna that would be necessary for a 50,000 square meter array in space, enough to conservatively generate at least 10,000 kilowatts for an electric powered interorbital vehicle like that shown in Figure 2-16, could be carried into low earth orbit in one shuttle payload.

The rectenna would be carried into space in rolls that are 18 meters long to fit within the shuttle payload bay. Each roll would contain a rectenna that is 200 meters in length wound on a spool that is 30 cm (1 foot) in diameter. The outside diameter of the spool would be 71 cm (2.33 feet). These dimensions allow for a spacing of 0.165 cm (0.065 inch) between turns which accommodates a special construction that allows the rectenna, consisting of a foreplane and reflecting plane, to collapse when it is wound on the spool. Since each of the rolls is 18 meters long, the number of rolls needed to comprise the 50,000 square meter rectenna area is 14. The rolls could therefore be stored within a cross sectional area of 7 square meters or in about 35% of the 20 square meter cross section of the cargo bay. The estimated mass of the complete rectenna is 10,000 kilograms, and a more conservative figure of 15,000 kilograms would require about one half the payload mass of the shuttle.

The foregoing example of deployment in space represents a good starting point for a more general discussion of deployment, and in introducing a general problem in deploying the rectenna. The general problem of deploying the rectenna is that to capture energy efficiently the rectenna must be a two plane structure. Behind the thin-film etched-circuit foreplane there must be a reflecting plane about 0.2 wavelengths or 2.5 cm behind the foreplane. The foregoing example assumes that this distance is collapsed down to 0.165 cm, a ratio of 15.

Alternative means of deployment that come to mind are (1) taking the rectenna up in panel form, (2) deploying the foreplane from one roll and the reflecting plane from another roll, (3) deploying both from the same roll. The first alternative has many objections, including the necessity of very large storage space in the shuttle, increased mass, and high cost. The second alternative resolves the need to collapse the thickness of the rectenna but leaves unresolved the need to maintain the spacing of the reflecting plane from the rectenna foreplane. Both of these options do not seem very attractive.

2.2.2 An Approach to a Collapsible Rectenna

The example of deployment of a collapsed rectenna from a single roll also illustrates that the collapse does not have to be that complete. A complete collapse of the rectenna foreplane and the reflecting plane without the consideration of the diode would be only 3 mils. The eventual diode

MICROWAVE POWERED OTV

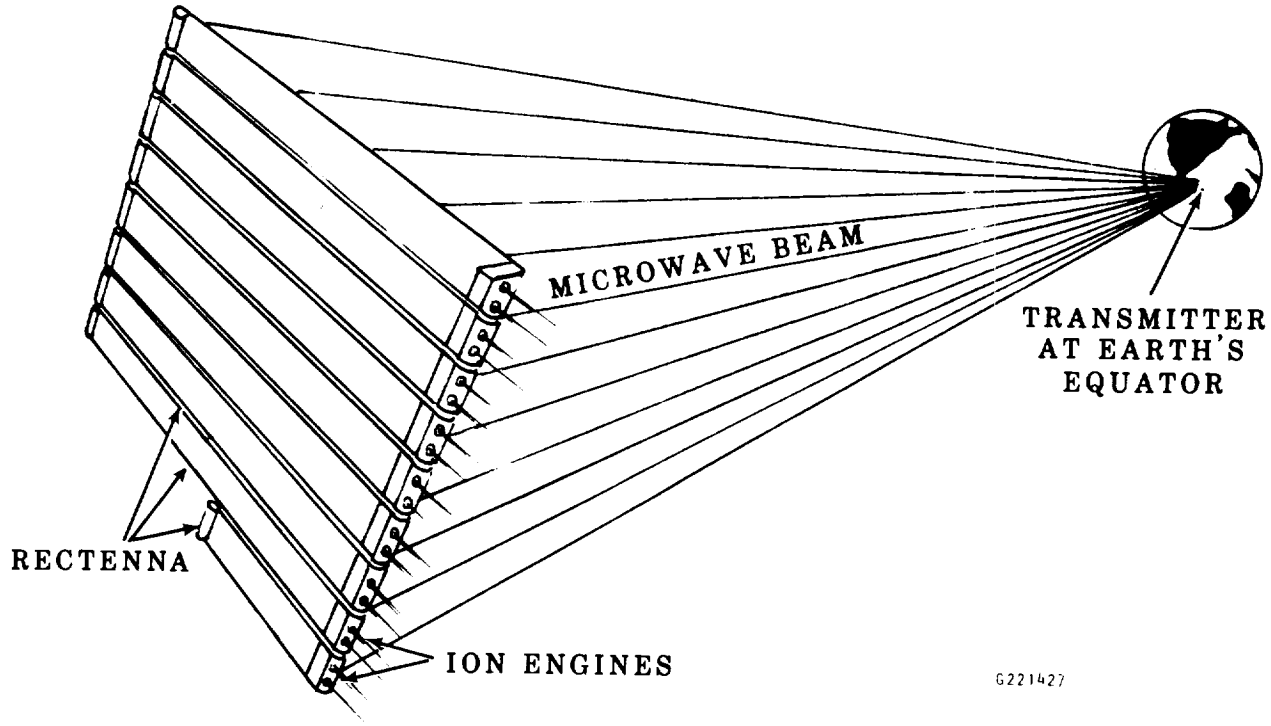

Figure 2-16. Concept of a Microwave-Beam Powered Transportation Mode from Low-Earth to Geosynchronous Orbit. Microwave Power is Beamed from a Ground Station to the Vehicle which has a Large Rectenna to Absorb the Microwave Power and Convert it into DC Power to Energize the Electrical Propulsion Engines. The Vehicle is Transported in Modular Form within the Cargo Bay of the Shuttle and Assembled in Low-Earth Orbit. Each Module Contains Ion Engines Together with Their Supporting Rectenna Sections which are Stowed in Rolled Up Form During Transportation in the Shuttle.

developed for this application should not exceed ten mils in thickness; so that a collapse to 20 mils in thickness should eventually be possible.

However, the present height of the diode is 60 mils. It may be useful to use this as a starting point and assume that the resulting collapsed thickness would be 0.065 inch. This distance of 0.065" then permits about 0.062 inch for the collapse of some kind of compression spring.

In the stowed position, the spring is collapsed but in the deployed condition the spring is still under some compression and its extended length is constrained by a string attached to the foreplane and reflecting plane. The length of the string, fully extended, represents the desired distance between the foreplane and the reflecting plane.

Although the use of a metal spring may be considered, a moment's reflection would suggest that there are potential complications and that a plastic spring might therefore be preferable. Although plastics as a spring material are greatly inferior to metal, the application under discussion does not demand repeating flexing; nor does the spring in its extended position need to exert much force.

In making a search for the best plastic material, it might be well to start with Kapton itself to see how it might be used. Kapton is already being used in the rectenna. It also has some interesting mechanical properties. It has a combination of a yield point and a modulus of elasticity that allows it to be wrapped around a mandrel of small diameter in relationship to the thickness of the Kapton before the Kapton takes a permanent set. Or, expressed another way, the ratio of the radius of curveature to the thickness of the material before it takes a permanent set is relatively low. Low enough to suggest that rolled up circular loops of Kapton film two to six mils thick may be flattened to 60 mils; and then spring out to their original diameter, or near it, when the compression is released.

An experimental program to investigate this was undertaken. Kapton of different thicknesses was obtained, rolled up into loops, the ends of the loops sealed together with scotch tape. These loops were then compressed between two flat metal plates. One of the plates had two side rails of 0.062" thick material to limit the amount of loop compression to that assumed that it would undergo when being wrapped up in a roll. With this amount of compression it was found that three mil Kapton took no set at all, while 5 mil Kapton took a small amount of set.

After the loops were so compressed, they were mounted between two plates, the top plate being very light in weight and free to move with respect to the bottom plate. Weights were added to the top plate and force-deflection data taken on the loops. From these force-deflection curves, it was noted at what force the height of the loop was 2.5 cm, the expected distance between the

foreplane and reflecting plane of the rectenna. Pepresentative data obtained from this experimental procedure is given in the following table.

Compression characteristics of circular loops of Kapton.

Diameter of Loop (cm)	Thickness of Kapton (mils)	Force Required to Compress Loop to the Normal Separation Distance of 2.5 cm Between Foreplane and Reflecting Plane (Grams per cm Loops Width)
4.13 (1.625 inch)	5	6.2 grams
4.13 (1.625 inch)	3	1.0 grams
5.08 (2.0 inch)	5	5.3 grams

From this data it is noted that a loop one centimeter wide made from 5 mil Kapton exerts a force of five or six grams between the two planes at a separation distance of 2.5 cm. In a "gravity free" space environment, it is assumed that this is enough force to always keep the constraining strings taut. How many of these would be needed per unit area would have to be determined eventually by some experimental work performed in a gravity free environment.

Figure 2-17 shows how such loops of Kapton could be applied to the foreplane of the rectenna. Each of the loops would have a length of string inside it that corresponded to the desired separation distance between foreplane and the reflecting plane.

2.2.3 Considerations Involved in Spooling the Collapsed Rectenna

From the past discussion it appears that there is a straight forward method of maintaining the separation distance between the reflecting plane and the foreplane that still permits compressing the rectenna to a thickness of 0.165 cm (0.065 inch). However, it must be recognized that when the rectenna is rolled up there will be a difference in the circumference of the two surfaces equal to 6.28 times the separation distance between the two planes. This distance is accumulative over the entire length and could amount to several meters.

There are two potential solutions to this problem. One solution is to roll the reflecting and foreplanes together but leave the reflecting plane unattached. In this case some force must be found to press the reflecting plane against the supports extending from the foreplane. One mechanically simple way is to use electrostatic attraction between the two films that could be established by a voltage applied between the two surfaces. A potential of 1000 volts would provide an attractive force of several grams per square meter, enough to hold the reflecting plane to the foreplane supports.

OF POOR QUALITY

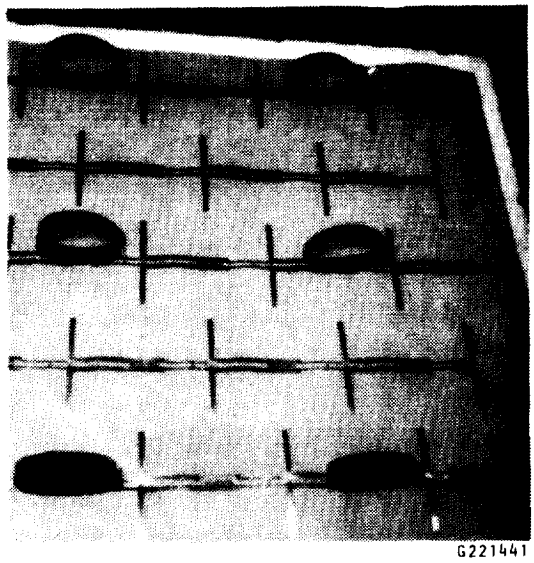

Figure 2-17. Photograph of Rectenna Foreplane with Loops of Kapton Attached to Separate Foreplane from Reflecting Plane. Loops are Compressed During Roll-Up on Spool, but Return to Original Shape when Compression is Released. A string in Center of Each Loop Limits Height to Separation Distance Needed between Foreplane and Reflecting Plane.

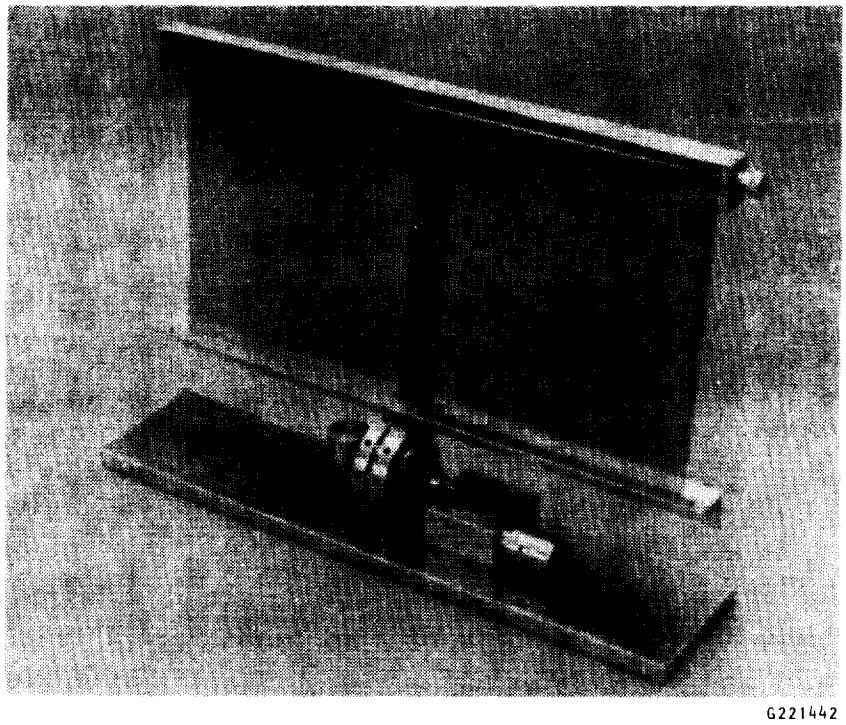

Figure 2-18. Model Showing Deployment of "Rectenna" from Rolled Up to Extended Form by Means of a Support Member which can also be Rolled Up but which becomes Rigid when Unrolled. Model Used a Carpenter's Rule to Illustrate the Principle.

A second approach would be to attach the planes to each other but to wind up the rectenna while retaining some slack in the reflecting plane in the rolled up condition. Still another alternative is to put the reflecting plane toward the outside and deliberately apply some tension to it while it is being rolled up. The reflecting film is the film that should be manipulated because it will have a small fraction of the mass and strength of the foreplane.

Related Considerations Involving Support of Rectenna in Space When Unrolled

The selection of a construction format for the two plane rectenna depends not only upon how it is stowed before deployment but also upon how it is deployed. In general, there would be two kinds of deployment. The first would be to unroll it onto some kind of a supporting structure. The second would be to have the rectenna combined with some mechanical boom that would also roll up into a cylinder immediately adjacent to the rectenna. At this time it is too early to determine which is the preferred method, and the method used may well depend upon the space application.

The second mode of deployment is that portrayed in Figure 2-16 and in a photograph of a model of such deployment (Figure 2-18). The model uses a thin, curved, metal strip that is rigid when extended but that can be rolled up to conserve space. It is, in fact, a commercially available 6 foot carpenter's rule. In space, of course, with no steady state forces acting on the boom, such a boom might be 100 meters or more in length. It should be possible by means of tethers to slightly bow the boom so that the reflecting plane would be on a convex surface. In that case, the reflecting plane could be kept in contact with the separators by a slight tensile force exerted at the two ends of the reflecting plane.

The first mode of deployment might very well be used in connection with a much larger structure that would either be a permanent low earth orbit around the equator, or that could be used as a heavy transport vehicle for orbital transfer. Such a structure if it were used for manufacturing might receive all of the electrical power it needed from transmitters located at the equator on the surface of the earth. Or if used for interorbital transport, such a large aperture would make it efficient and useful well beyond geosynchronous orbit, perhaps even to the moon. Such a platform would no doubt have some kind of rigid support truss. This would make for easy deployment of the rectenna and forming it into a slightly convex surface to permit stretching of the reflecting plane over the rectenna.

2.3 Fabrication and Testing of a Large Area Sample Rectenna (Task 3)

2.3.1 Introduction

In several respects, the fabrication and testing of a large area sample rectenna was the principle objective and task of the first activity covered in this final report. The objective is to assemble rectenna elements of an identical optimized design, into a very light weight (low mass) rectenna foreplane of considerable area that can be easily fabricated and that will operate at high efficiency and at relatively high power density levels with long life and high reliability.

Although a 14 element foreplane had been fabricated from a design based on the use of mylar as the thin film material under the Wallops Flight Center study only individual elements had been tested, and these had been found to be inefficient, as reported in Section 2.1.

During this new study we were able to first fabricate and test a 14 element foreplane made from a much improved sandwich material using Kapton-F film and employing diodes having improved power handling capability. No measurements of diode temperature or velocity of cooling air were made in these tests.

Then new masks were made for a larger rectenna area consisting of six rows of five elements each, or a total of 30 elements. For test purposes only, five rows of rectenna elements were used as shown in Figure 2-19.

The test set up for this 25 element rectenna was instrumented to make measurements of the velocity of the cooling air flowing over the surface and of the operating temperature of the diode case of the central rectenna element. A DC output of 120 watts from this 25 element section was achieved with a temperature rise of only 50°C with an air flow velocity of 4.8 m/sec., 15.8 ft./sec., or 10.8 Mi/hr.

The setup for testing the 25 element section was then used to test a single rectenna element. First, without microwaves being involved, measurements were made of the temperature rise of the diode as a joint function of (1) DC power injected into and dissipated within the diode and of (2) the velocity of the cooling air flowing over the rectenna. Then, with a known velocity of air flowing over the element, the microwave power beam was directed at the rectenna element and measurements of DC power output and diode temperature noted. From the use of tabulated data in the previous run which related diode dissipation to diode temperature, the rectification efficiency of the rectenna element could be approximated closely from the expression

$$\text{rectification efficiency} = \frac{\text{DC power output}}{\text{DC power output plus diode dissipation}} \quad (1)$$

ORIGINAL PAGE IS

Figure 2-19. Rectenna Array with 25 Active Elements Set Up for Test in Microwave Beam as Shown in Figure 2-20. Foreplane is Separated from Metallic Reflecting Plane by 1.8 cm of Styrofoam. Three of the Five Inboard Elements on the Rectenna are Not Active.

These efficiencies were consistently over 80%. Power output as high as 6 watts for the element was also obtained. Maximum power output was limited not by the diode temperature but by the value of reverse voltage breakdown of the diode and by the high characteristic impedance of the rectenna element structure. With a proper redesign of the diode and the balance of the rectenna element, twenty watts per rectenna element could be achieved without exceeding either the allowable operating temperature of the diode or the velocity of air flow used in these tests.

In defense of this procedure for measuring the rectification efficiency of a single rectenna element, it is noted that the edge effects are not well known and would introduce a large uncertainty into an efficiency calculated on the basis of measuring the incident power density of the beam.

2.3.2 Test Arrangement and Test Results on 25 Element Rectenna Foreplane with Forced Convective Cooling

This section discusses test results on power handling capability and efficiency of the rectenna foreplane when subjected to low-velocity convective air cooling at sea level air densities. These conditions are equivalent to cooling obtained at typical airplane flight speeds and air densities at altitudes of 40,000 feet and more.

The tests were made with the test configuration shown in Figure 2-20. The velocity of the air stream flowing across the rectenna was calibrated with a hot wire anemometer. The temperature of the diode was monitored during operation with a probe of a fluoroptic thermometer that was mounted at the diode case with precaution to shield the probe from the air stream. The great advantage of the fluoroptic thermometer is that it does not interact with the microwave field and does not conduct heat away from the source it is measuring.

In preparation for testing, the 25 element rectenna section was mounted on a test board as shown in Figure 2-19. The DC outputs of the five rows of rectenna elements were connected in parallel across a single load resistor. Each row had a zener diode shunted across it to protect the diodes in the row should the DC output voltage for any reason exceed a value that would cause the peak inverse voltage across the diodes to exceed their reverse breakdown voltage rating. An open circuit concurrent with large values of incident microwave power would be the type of fault for which the zener diodes would provide protection.

A current jack in the output of each row made it possible to monitor the operating current and power output of each row.

The array shown in Figures 2-19 was then inserted into the test arrangement depicted in Figure 2-20. So as not to exceed the reverse voltage breakdown of the diodes at high incident power, the common load resistance used was 4.7 ohms. If the 4.7 ohm resistance was equally divided among the 25

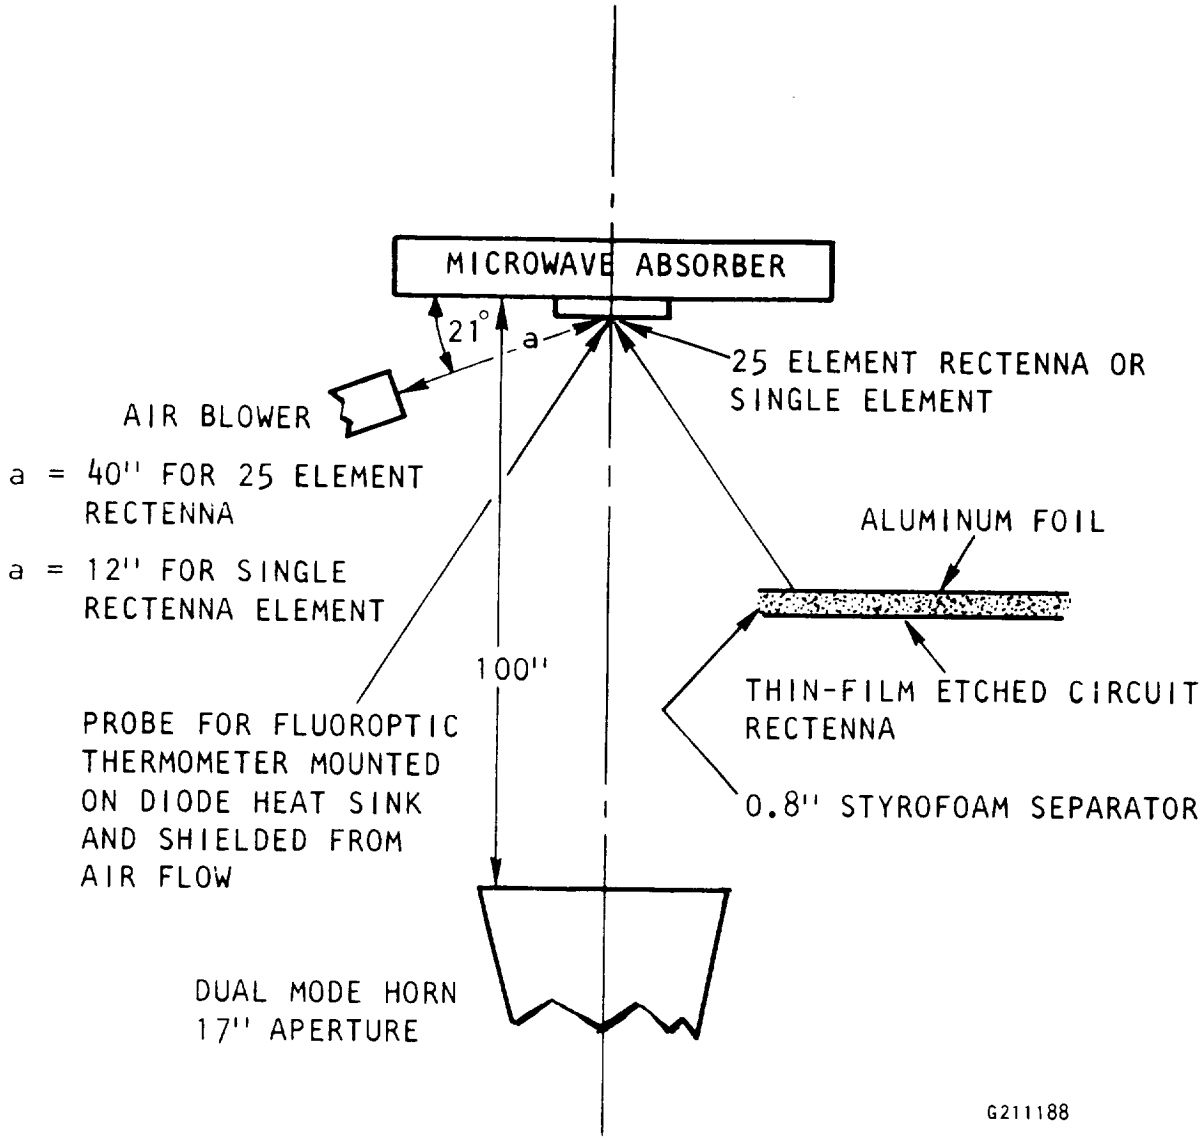

Figure 2-20. Test Arrangement for Measuring DC Power Output and Diode Temperature Rise of 25 Element or Single Element Rectenna as Function of Laminar Air Flow Velocity and Incident Microwave Power Level.

elements, each element would see a value of 118 ohms. The air flow velocity was 4.8 meters/second. The temperature of the case of the diode of the central rectenna element was monitored. For the test, the microwave power output of the illuminating dual-mode horn was varied and the DC power output of the rectenna and the temperature of the diode case were monitored.

The results of this test are shown in Figure 2-21. The maximum total power output of 123 watts corresponds to an average of 4.9 watts for each of the individual diodes. The unequal illumination of the diodes as well as the tendency of the top and bottom rows to capture more power than the internal rows means that some of the rectenna elements were producing more than 6 watts of DC power output. The highest diode temperature of 88°C is far below the 200°C operating temperature considered safe for GaAs diode operation. The temperature rise in the diode was approximately 48°C. The high temperature of 39.5°C for the diode with no incident microwave power was caused by heat stored in the microwave absorber that was placed behind the rectenna and that had absorbed energy over a period of time prior to making the run recorded in Figure 2-21. The room ambient temperature in regions removed from the absorber was 31°C.

The observation of such high DC power outputs with only relatively low air flow velocity and with such low temperature rise in the diode was an exciting experimental finding that had not been expected. It is an especially important finding for many of the applications of microwave power transmission in both aircraft and space.

The normal procedure, with the data of Figure 2-21 in hand, would be to operate the rectenna at even higher power densities, but unfortunately, the reverse voltage breakdown of the diode and the relatively high impedance design of the rectenna element precluded higher power operation. However, as indicated in the introduction it is possible to extend the data for temperature rise in the diode as a function of power dissipation within the diode and air flow velocity to provide an accurate indication of the DC power output capability of the rectenna element, if an efficiency for the element is also assumed, as will be discussed in Section 2.1.3.

A finding of considerable importance was made in testing the rectenna. It was found necessary to put all the rows in parallel. If they were put in series there was an unstable load sharing situation in which some rows capture a large amount of power while others capture very little and put out very little DC power. When the rows are in parallel there is good load sharing particularly at the higher power levels where presumably each individual element is better matched into space.

It would also be expected that the two rows of elements at the edge of the array would pick up more power than the center rows and this was found to

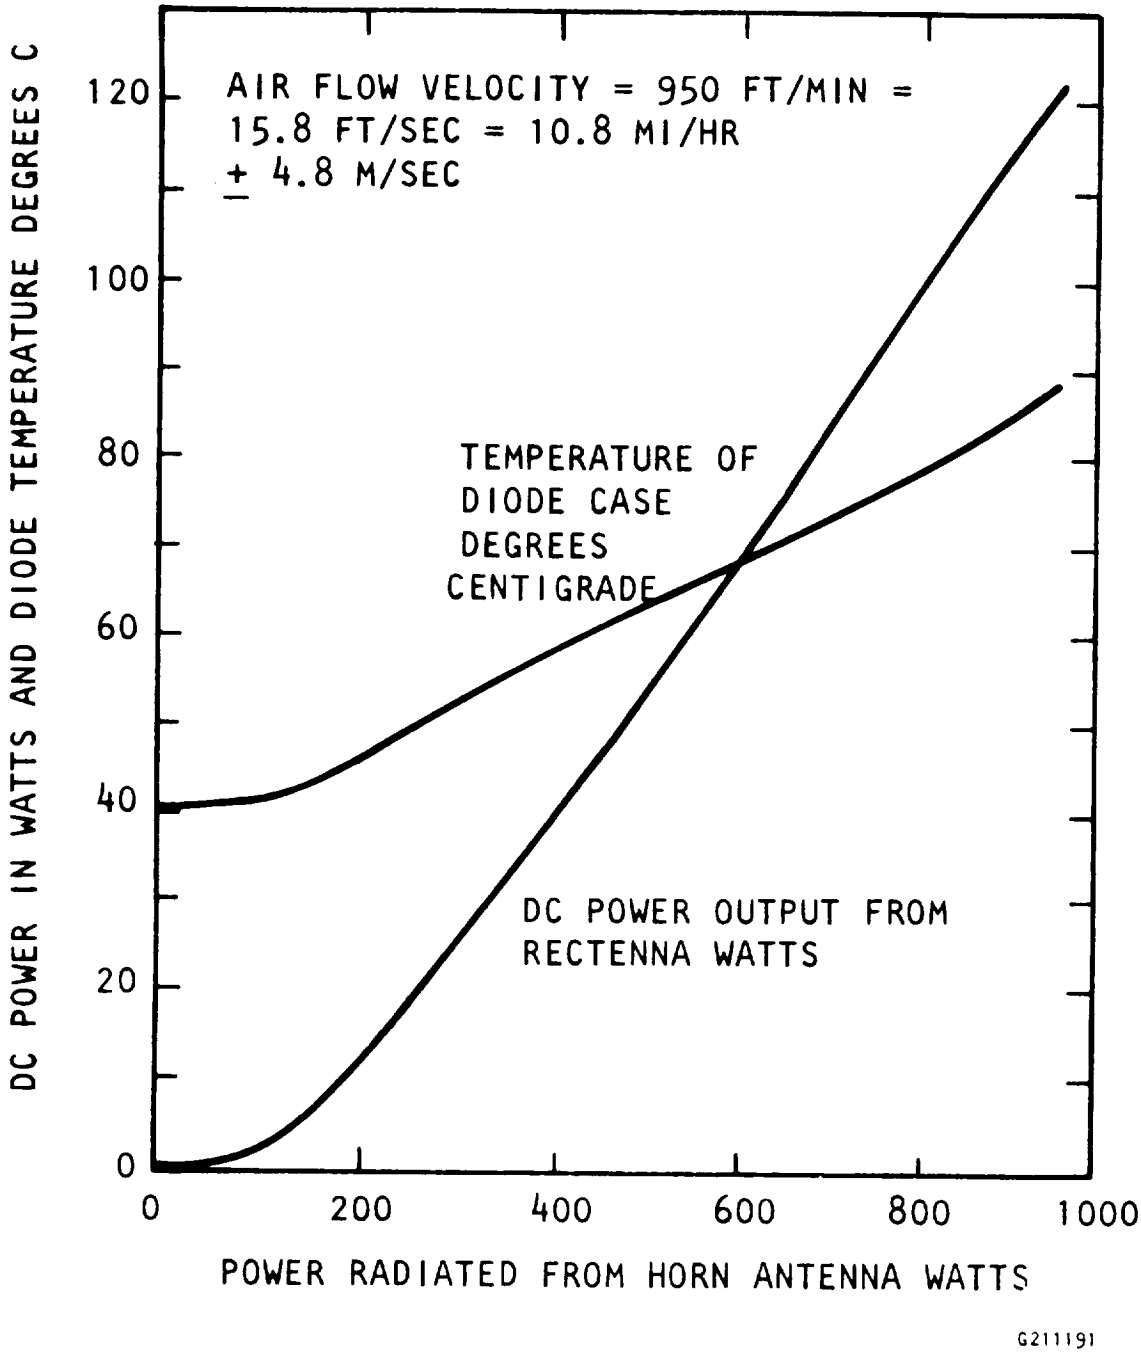

Figure 2-21. DC Power Output of 25 Element Rectenna and Case Temperature of Diode of Center Element as Function of Total Power Radiated. Only a Small Fraction of Radiated Microwave Power Impinged Upon the Rectenna. Rectenna Efficiency cannot be Computed from Data Taken.

be the case experimentally as given by the following data, where Row 1 and Row 5 are the outside rows.

	Row 1	Row 2	Row 3	Row 4	Row 5
DC Power Output	7.4	5.5	5.9	5.8	7.8

These ratios of power levels of outside strings to inside strings was found to be about the same for total DC power outputs ranging from 30 to 120 watts.

In addition to the non-uniformity of pick up of outside and inside rows, the microwave beam itself was not uniform. An attempt was made to illuminate the 25 element rectenna uniformly using a sufficient separation from the mouth of the dual mode horn to allow the gaussian beam emitted by the horn to expand to a diameter so that the intensity of the radiation across the 25 element rectenna would be relatively uniform. On the other hand, the separation distance cannot be too great because the power density of the incident beam on the rectenna could fall below that needed to evaluate the rectenna at high power level. The distance of 100 inches proved to be a good compromise. The power density at the corners of the rectenna were 0.8 below that at the center, while the maximum illumination used on the rectenna necessitated nearly 1000 watts of power being radiated from the dual mode horn.

2.3.3 Temperature Rise of Diode in Rectenna Element as Function of Injected DC Power and Velocity of Convection Cooling Air

The injection of measured DC power into the diode and dissipated there provides a heat source of known value. This heat is generated in the same area as would be heat from microwave rectification losses, and it is conducted in the same manner as would be heat generated by microwave rectification into the same radiatively and convectively cooled structure. Because the dissipation in the diode represents 80% of the total heat generated in the rectenna element, when it is acting to convert microwave energy into DC power, these other sources of heat generation were ignored in computing efficiency. It is noted, moreover, that these other losses are much more uniformly distributed throughout the rectenna element and tend to dispose of the associated heat more efficiently than the diode. Their impact upon temperature measured at the diode is therefore limited.

The experimental arrangement for taking the data is shown in Figure 2-20. The data that resulted from noting temperature rise in the diode as a function of injected DC power and the velocity of the convective cooling air stream flowing by the single rectenna element is shown in Figure 2-22. The linearity of the data given in Figure 2-22 is an indication that the air flow over the rectenna surface remained laminar for all of the test conditions.

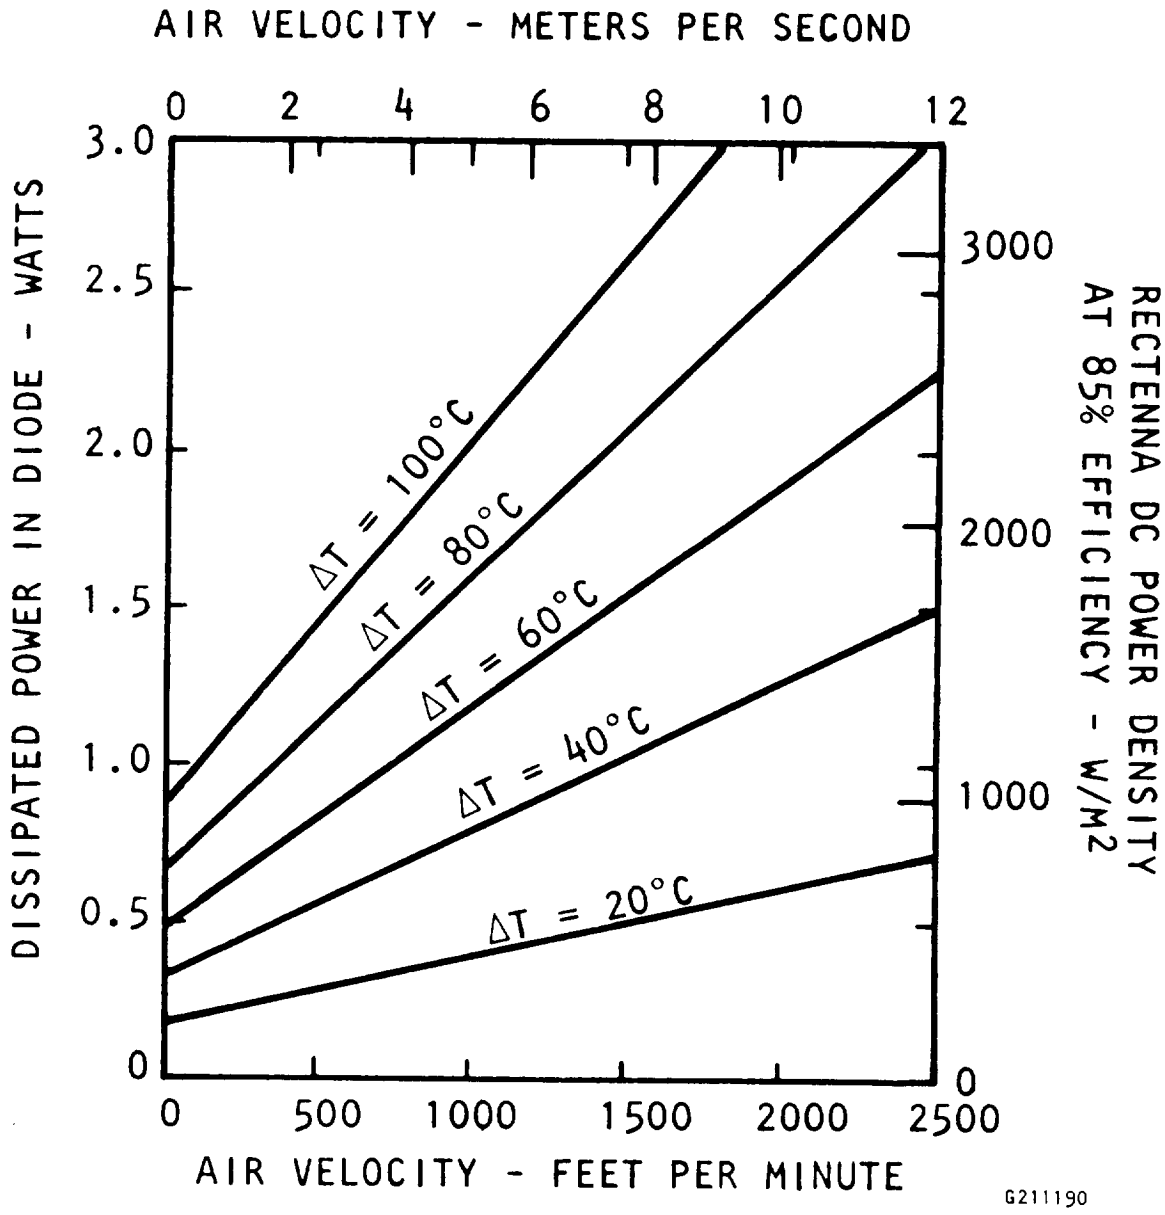

Figure 2-22. (a) Power Dissipated In Single Diode, as Function of Air Velocity and Diode Temperature (Left Hand Scale). (b) Equivalent Rectenna DC Power Density at 85% Efficiency (Right Hand Scale).

The data in Figure 2-22 can be used to develop equation 2 for diode dissipation as a function of air velocity and temperature rise of the diode case. The equation has two components. One component is that associated with convective cooling. The other is associated with residual cooling at zero air velocity and is assumed to be largely radiative cooling. Note that the linearity of the data and the low Reynolds number associated with the air velocity indicates laminar air flow at all time.

$$W = 1.125 \times 10^{-5} \Delta T_1 V + 0.009 \Delta T_2, \text{ where} \qquad (2)$$

W = power dissipated in diode in watts

V = air velocity in feet per minute

ΔT_1 = °C increase in temperature of diode case above ambient air temperature

ΔT_2 = °C increase in temperature of diode case above temperature of sink for radiated power

Now if we know or make an estimate of the rectenna element efficiency, n, we can multiply equation (2) or the ordinate data on the left side of Figure 2-22 by the factor n/1-n to obtain the DC power output of each rectenna element. For an assumed efficiency of 85%, a typical value for the rectenna element operated in the one to five watt output region, this factor will be 5.7. The corresponding DC power for one square meter which contains 200 elements is shown as the right hand ordinate of Figure 2-22 as a function of air velocity and diode temperature rise.

Equation (2) was derived from experimental data using mass flow rates of air at sea level density. If the term V in equation 2 is replaced by $V\rho/\rho_o$ where V and ρ are the air velocity and air density at any altitude and ρ_o is the air density at sea level the same mass flow rate of air is maintained. If the assumption is made that convective cooling is proportional to mass flow rate of air alone, then the modified expression is applicable to any altitude and can therefore be applied to high altitude airplanes or balloons.

The expression becomes interesting when applied to very high altitude airplanes with the rectenna exposed to the air flow. Although the air density at an altitude of 20 kilometers is only 5% that at sea level, an airplane must fly at a velocity of about 70 meters/sec. to maintain altitude. This would be equivalent to an air velocity of 3.5 meters/sec. (714 ft./min.) at sea level. Figure 2-22 indicates that at this sea level velocity, and an assumed operating temperature of the diode case of 100°C above ambient, nearly 2000 watts of DC power output could be obtained from the rectenna, if the additional assumption is made that the diode efficiency is 85%.

The assumption of diode efficiency of 85%, corresponding to an inefficiency of 15%, is a conservative one. In Section 2.0 of Reference 6, diode losses were accurately measured to be 8% of the incident microwave power when the diodes were operating in the 6 to 10 watt region.

Although a minimization of cost analysis of microwave power transmission systems for the applications examined to date favor a moderate DC power density level from the rectenna, it should be noted that the power output from a single rectenna element could, with convective cooling, be easily upgraded to 25 to 50 watts of DC power output. This could be achieved by redesigning the rectenna element to match into a much lower DC load resistance, of the order of 30 ohms. The redesign should be relatively straightforward and would result in an optimum diode that would have a much larger diode junction area further increasing the power handling capability of the diode.

The final test performed on the single rectenna element was to illuminate it with microwave energy and note the DC power output and the temperature rise in the diode at a fixed air flow velocity. From this data, and with the use of Figure 2-22 and equation (1), it was possible to compute the operating efficiency of the rectenna element. The resulting data is shown in Figure 2-23. The similarity of this data with that obtained from a closed system for the rectenna element and presented in Figure 2-14 is of interest.

The technique of measuring diode temperature as a function of DC input power dissipated within the diode is of particular significance in determining the power handling capability of the rectenna in vacuum without having to apply any microwave power in vacuum. The procedure would be to first check the efficiency of the rectenna element outside the vacuum using test equipment similar to that shown in Figures 2-2 and 2-3.

The rectenna element is then inserted into the vacuum environment and its case temperature noted as a function of DC power injected into the diode to be dissipated there. Then at a specific case temperature, the power dissipation is known and the DC power output under assumed microwave radiation conditions can be found from the expression.

$$\text{DC Power Output} = \frac{n}{1 - n} \text{ (Power Dissipated in Diode)}$$

where n is the measured efficiency outside the vacuum.

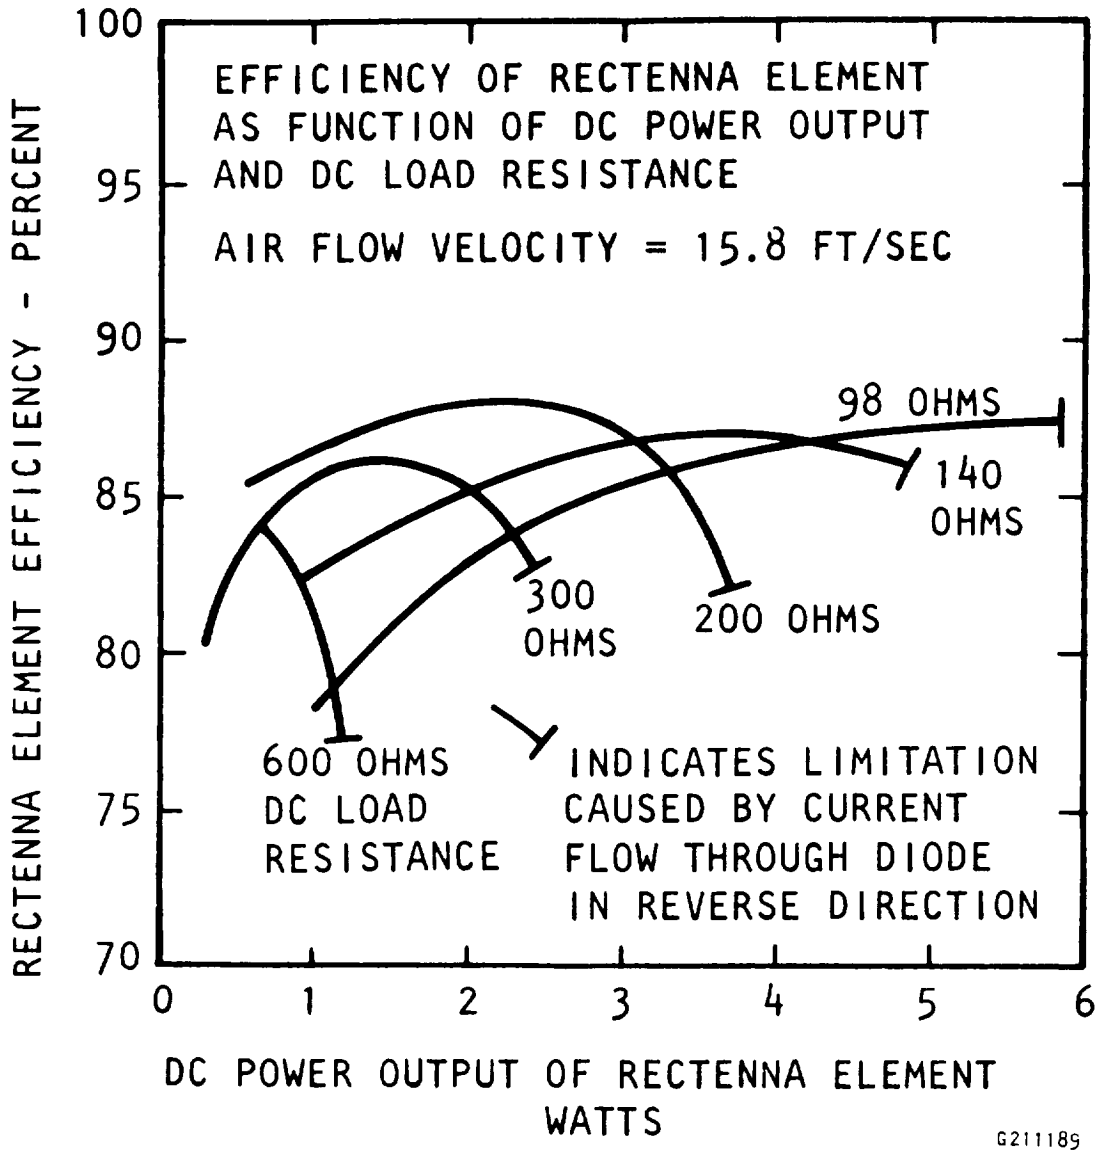

Figure 2-23. Efficiency of Rectenna Element as Function of DC Power Output and DC Load Resistance as Computed from Measured Dissipation in Diode and DC Power Output. Compare with Data of Figure 2-14 for Same Rectenna Element Measured in Closed Test Fixture in which Microwave Power Input could be Accurately Measured.

2.4 Design of an RF Test Facility (Task 4)

This task concerned the design of a suitable rf test facility to be built at Lewis Research Center for the purpose of testing the rectenna. The task was concerned not only with advice about the rf test equipment to be used but also with certain aspects of the testing procedure. A major consideration was that the tests were to be made in vacuum.

A testing procedure to be carried out in vacuum requires the measurements of DC power output from the rectenna and the operating temperature of the rectenna, with special emphasis upon noting the operating temperature close to the rectifying diode which will be the major source of heat and which is the most susceptable to heat damage.

It is also desirable to know the operating efficiency of the rectenna but it may be difficult to measure the incident energy of the microwave beam inside the vacuum.

However, it is possible to obtain efficiency values indirectly but quite accurately by passing a known amount of DC power through the diodes from an external source and noting the temperature rise of the diode case as noted in Section 2.3.2. With such a calibration, the efficiency of the rectenna with microwave power incident upon it can be calculated by noting the DC power output and the dissipated power that corresponds to the temperature at which the rectenna is operating.

The efficiency is given by:

$$\text{Rectenna Efficiency} = \text{DC Power Output}/(\text{DC Power Output} + \text{Dissipated Power})$$

A similar procedure of passing DC current through the diode for calibrating losses in the diode was used in the execution of a previous contract with LeRC.[6]

Considerable thought went into the matter of a suitable source of microwave power. The objective was to provide an economical source of power that can range from only a few milliwatts of power to as much as several hundred watts. The latter may be needed for subsequent testing of relative large sections of rectenna within the vacuum. The only economical way that such a goal can be approached is to make use of the microwave oven magnetron, which is readily available at low cost. A block diagram of the equipment involved in using the magnetron is shown in Figure 2-24.

The approach to achieving the immediately needed low power portion of the wide range power was to operate the magnetron into a matched waveguide resistive load through a ferrite circulator and to tap off a small portion of the total power through a probe penetrating into the waveguide. The power

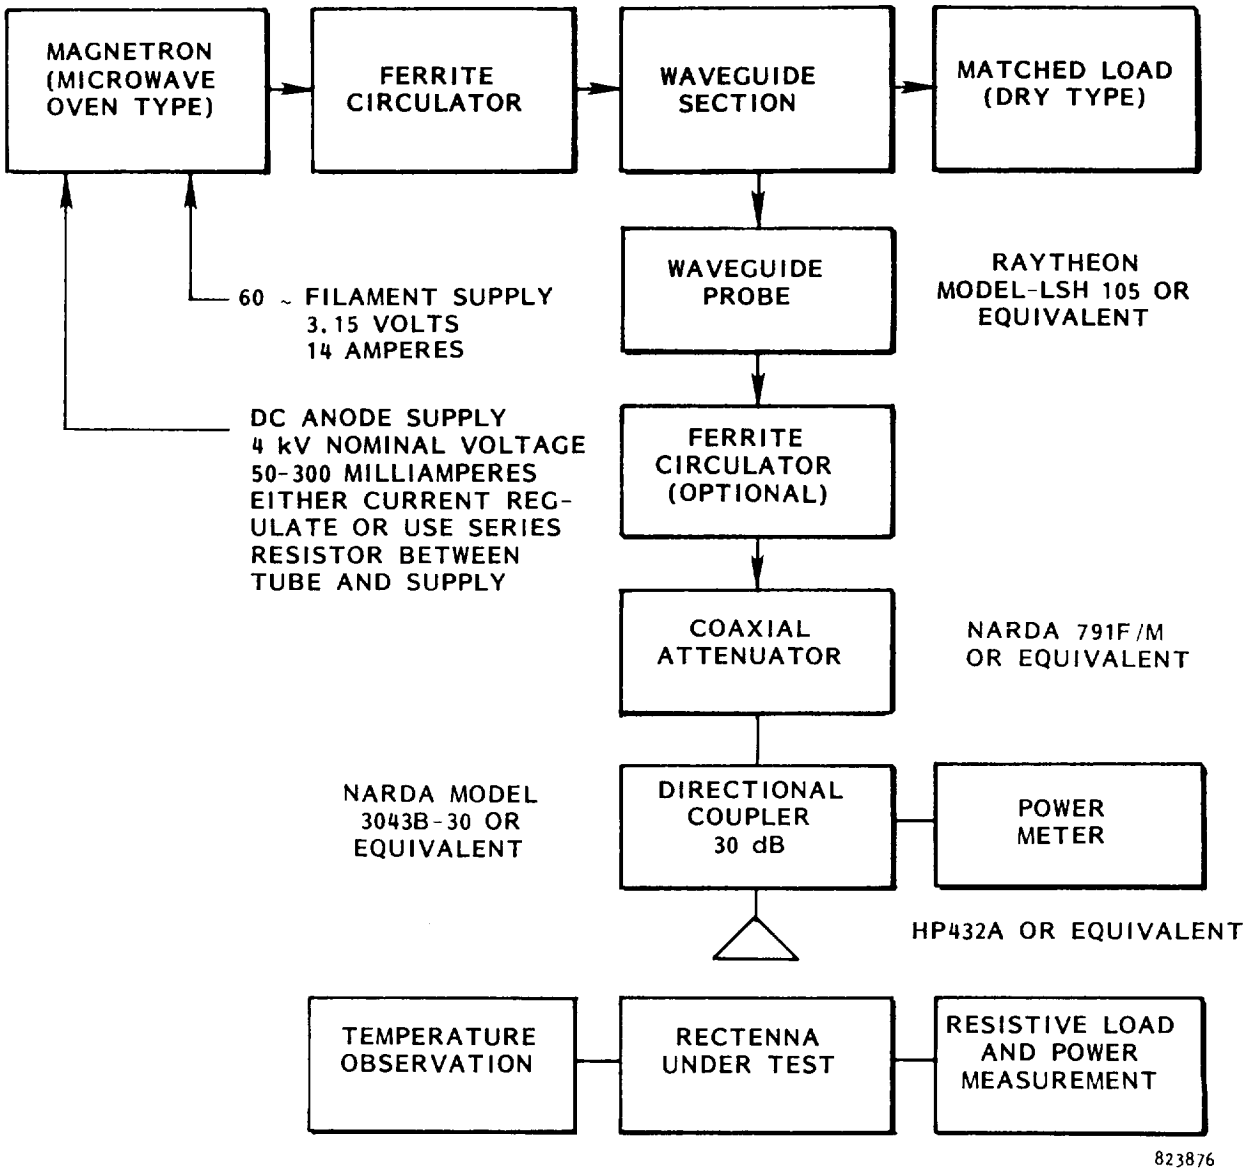

Figure 2-24. Schematic of Test Arrangement.

picked up by the probe could be varied by the length of the probe and by the power level at which the magnetron was operated.

Once the power is picked up by the probe terminating a coaxial fitting, the power can be readily measured in a coaxial system that makes use of coaxial directional couplers and attenuators. This equipment is readily available in most laboratories, but it is also available at reasonable cost from many suppliers. The desired power may then be fed into a gain horn, open ended waveguide, or some other means of funnelling the power into the vacuum chamber. Substantial power may be reflected from the window, depending upon its thickness and dielectric constant. This power may be re-reflected from the probe end of the coaxial system and upset the power reading of the directional coupler. It would therefore be desirable to have a small coaxial ferrite circulator inserted between the coaxial probe fitting and the rest of the coaxial system.

The coaxial system can be used up to a power level of at least 25 watts, which should be adequate for the planned initial testing of a single rectenna element. For higher power levels the waveguide resistive load may be removed and the power fed directly into a suitable radiating device. The waveguide circulator will then absorb any power that may be reflected. If the reflected power level is high it will be necessary to apply a small fan to the resistive elements of the ferrite circulator.

In addition to helping plan the testing arrangements at LeRC, a magnetron, waveguide, and ferrite circulator were sent to LeRC without charge and with recommendations to buy a DC power supply for the magnetron. However, LeRC elected to a buy a PGM-10X. This piece of equipment contains a DC power supply and a 90 watt CW magnetron. This power level is adequate for a broad range of testing, but for higher levels of testing the 500 to 1000 watt output of a microwave oven magnetron may be desirable.

2.6 20 GHz Printed Circuit Rectenna Study (Task 6)

2.6.1 Introduction

The purpose of this study was to investigate different approaches to constructing a rectenna at 20 GHz, and to recommend a specific approach for which the design of a single rectenna element would be developed under Task 7 (Section 2.7 in this report). Two approaches or formats were considered in the proposal submitted. One of these was to scale the present 2.45 GHz thin-film etched-circuit format to 20 GHz. The other was to use an interdigital format to form the capacitances and to keep all circuits on one side of the film to avoid a difficult dilemma in directly scaling the present structure. Both approaches would require the use of a beam lead diode.

After starting the actual study, however, it became quite clear that other approaches should be considered. Among these was a completely monolithic approach in which the diodes as well as all the circuitry are built up on a substrate of gallium arsenide or silicon. This would certainly be necessary at very high frequencies but the technique may be excessively expensive in the 20 GHz region.

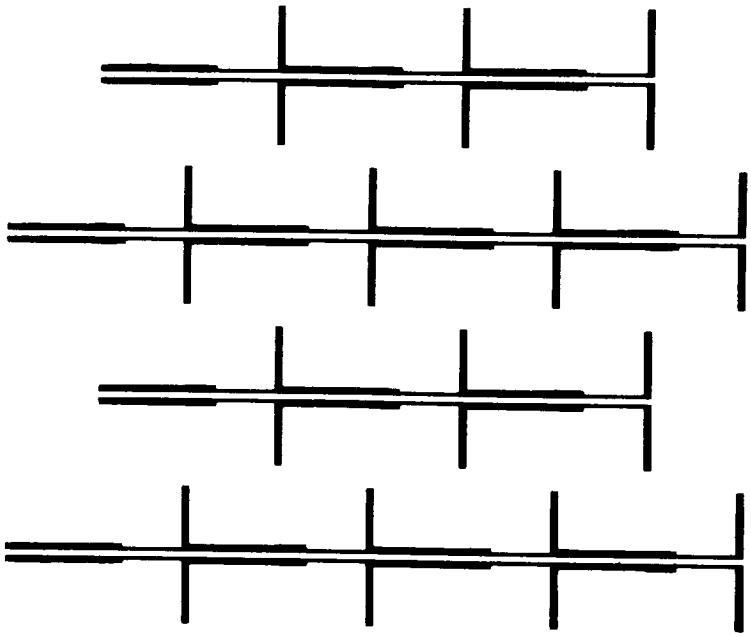
It appeared that a good compromise might be to build a 20 GHz structure on an alumina ceramic substrate which closely resembles a semiconductor substrate in terms of dielectric constant. Beam lead diodes would then be bonded to the resulting structure. The approach was additionally attractive because of current thin and thick film technology based upon the use of alumina ceramic.

These different approaches are discussed in more detail in the following material, but it may be helpful to first approach the study from a more general point of view which is done in Sections 2.6.2 and 2.6.3. Section 2.6.2 discusses the frequency scale in terms of geometry, packing density, etc. Section 2.6.3 discusses the impact of any planning for future higher frequency scaling.

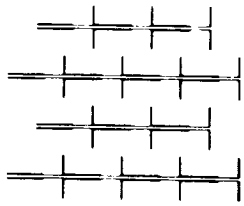
2.6.2 Significance of the Frequency Scale

The starting point for this study is the rectenna technology that exists at 2.45 GHz. However, the shift in frequency, a factor of 8.16, is so great that parameters of the resulting structure at 20 GHz are greatly modified.

Concentration of dipole antennas and diode elements. An exact scale of the 2.45 GHz structure to 20 GHz results in 13,300 elements per square meter instead of 200. The scale at 20 GHz along with a more reasonable scale at 8 GHz is shown in Figure 2-25. If placed on a high-dielectric material, the concentration of elements may be considerably greater than that shown in Figure 2-25 as examined in Section 2.7.3 and 2.7.4, perhaps as big as 30,000 elements per square meter.



2.45 GHz Rectenna Scaled to 8 GHz



2.45 GHz Rectenna Scaled to 20.0 GHz

G221451

Figure 2-25. Large Scale Rectennas can be Scaled to Shorter Wavelengths by Simple Photographic Reduction. Above Material Illustrates Approximate Size of Rectenna for Different Frequencies when Scaled from Existing 2.45 GHz Format.

Spacing between foreplane and groundplane. An exact scale from the present 2 cm spacing at 2.45 GHz would place the new spacing at 0.245 cm or 96 mils. If a high-dielectric material were used to separate the foreplane from the reflecting plane, the separation will be even less.

Dissipation density capability. The power dissipation density increase because of the greatly increased number of rectenna elements even though the dissipation capability of the individual rectenna element is less.

If cooling the foreplane structure is aided by thermal conduction coupling to a continuous reflecting plane, the dissipation density can be greatly increased over that of the current 2.45 GHz thin film structure.

Efficiency. Efficiency must necessarily decrease. The losses in the diode will be considerably greater and the losses in the scaled circuit structure will become greater by the square root of the frequency scaling factor because of skin losses. The importance of efficiency in reducing heat dissipation problems is offset to some degree by the more effective conduction cooling of the scaled structure.

Power density levels. It may be that to keep the diode efficiency high it will be necessary to operate at DC power output levels per element of over 100 milliwatts. But the scale factor then would place the minimum DC power output at a power density level of 1340 watts per square meter. The DC power density level could be considerably greater than this if it were desired, particularly if the diodes were in good contact with a conductive substrate.

Rectenna cost. Rectenna cost per unit area will increase sharply, which of course favors using the device at its highest normal power density.

2.6.3 Significance of the Consideration of Work at Even Higher Frequencies Upon the Direction of the 20 GHz Experimental Program

The tendency of a high frequency scaled device to have a high packing density of diodes with a small junction area argues strongly toward an eventual monolithic approach in which the diodes and circuits are produced on the same substrate. This means a substrate of either gallium arsenide or silicon. This was an argument toward basing the 20 GHz work, upon a material whose dielectric constant is close to that of silicon or gallium arsenide. Alumina is such a material.

2.6.4 Discussion of the Different Approaches to a 20 GHz Rectenna

This section consists of the discussion of three approaches: (1) the direct scale of the thin-film, etched-circuit, 2.45 GHz rectenna; (2) use of the interdigital finger approach and the pedestal support which allows the complete

circuit to be laid down on one side of the dielectric substrate; and (3) the use of an alumina ceramic as the circuit substrate that fills the void between the foreplane and the reflecting plane of the rectenna and upon which the microwave circuit is printed. Conclusions and recommendations are then made in Section 2.6.6.

2.6.4.1 Direct Scale of the Thin-Film, Etched-Circuit 2.45 GHz Rectenna

Scaling the present structure is attractive in some respects but is unattractive in several others. One problem is that in a true scale the dielectric substrate would have to be decreased in thickness by the scale factor of about eight. Because of the lack of bonding materials (that bond the copper to the dielectric film) that are both very thin and of acceptable dielectric loss, it would be impractical to reduce the present sandwiched material from 2 mils to one quarter mil.

To compensate for the inability to scale the thickness, the capacitors in the low pass filter circuit section can be increased in area from the normal scale size but then they become quite large. It appears to be impactical to scale the shorting capacitance in the rectifier circuit to a larger area than the scaled size so that the capacitor would lose much of its effectiveness as a low impedance shunting circuit.

2.6.4.1.1 Application of Commercial Process for Vaporizing Metal on Thin-Film. One way to cope with the scaled thickness problem is to use a different process for putting metal on a dielectric film. One approach is to vaporize a thin film of metal onto a thin dielectric film in vacuum. This general approach is commercially used in depositing a thin aluminum film on one or both sides of a dielectric film for the diverse uses of thermal insulation and food preservation. Such material is available in the form of aluminum deposited on Kapton only 0.3 mil thick, and on mylar only 0.25 mil thick.

The thickness of the metal film is, of course, very important in any potential microwave rectenna application, both from the viewpoint of conducting heat away from the diode to a radiating surface, and from the viewpoint of electrical conductivity. From the conductivity point alone, the deposit should be at least equal to the skin thickness which, at 20 GHz and for aluminum, is 57 microns. However, the commercial material is only available with a maximum thickness of about 8 microns. The material is put on with a thickness of about 1.5 microns per pass, so that it would take about forty passes to establish the minimum thickness desired. But a more important limitation is that, after a few successive passes, the adhesion between the aluminum and the dielectric film becomes poor. The reasons for this is not clearly understood, but because the present commercial markets do not need a thick film, there apparently has not been a substantial effort to develop an understanding.

From a technical point of view, it is relatively straightforward to deposit copper on a thin film in the same way that aluminum is deposited. However, it is not done commercially because no need has developed to do so.

One of the interesting possibilities to build up the thickness of the metal on the side of the film on which the dipoles and bus bars are etched is to first etch the microwave pattern on the metalized film and then to use the bus bar circuits to conduct current into an electroplating bath to build up the thickness of the microwave pattern to the desired thickness. If the plating operation were technically feasible, and it would be certainly so if the film first deposited was copper, the process would be a very economical way to produce a rectenna if the microwave circuits were all on one side of the film. There is, of course, no way to contact the patches of metalized material on the other side of the dielectric film that form the microwave capacitors for the low-pass filters. For this reason, the technology of placing the circuitry on one side of the dielectric film that is discussed in Section 2.2.4.2 is of interest. However, the resistive loss in the metal patches as laid down by the vaporization process may be acceptable under certain circumstances, but more study would be needed, possibly in the process of investigating the losses in Kapton at 20 GHz.

Going to this thin film makes it possible to design an adequate shunting capacitor in the rectifier circuit and it may not be necessary to put a patch on the other side of the film for this capacitor if the supporting pedestal approach discussed in the following section is used.

2.6.4.1.2 Application of the Pedestal Support Technique for Better Heat Dissipation and for Separating the Foreplane from the Reflecting Plane. A technique for improving the heat dissipation capability of the rectenna was discussed in the proposal. The suggested technique was to bond the electrically neutral patch associated with the shorting capacitor to a metallic projection or pedestal from the reflecting plane. The outstanding advantage of this technique is that it "short circuits" the heat flow that would normally be along the transmission line and into the antenna dipoles for radiation. Instead, the heat is conducted efficiently into the ground plane where the entire ground plane can be used for effective heat radiation.

Even though the patch is separated from the conductor that is directly attached to the diode by two mils of Kapton F whose heat conductivity is only 4×10^{-4} calories per second, per centimeter, per degree C, the thermal resistance in the 2.45 GHz case is only 10°C per watt of transmitted heat--considerably lower than the drop between the diode and the top of the capacitor. A direct scale to 20 GHz would increase this resistance to 80°C per watt of transmitted heat.

It is easy to visualize a reflecting plane with many support pedestals about 0.100 inch high that have been precision milled as a monolithic structure. The pedestals will now be so close together as to function as the sole support for the rectenna foreplane.

From a microwave circuit point of view, it is possible to employ this technique because of the balanced nature of the microwave circuit. The patch

that represents an essential part of the shorting capacitor in the rectifier circuit is at neutral or zero microwave potential and is not connected to the DC circuits. Hence, placing it in full metallic contact with pedestals from the ground plane does not impact the DC circuits and theoretically does not impact the microwave behavior of the device.

To experimentally check this assumption, the capacitor patch was bonded to the end of a one-half inch diameter aluminum rod whose other end was attached to the cover plane of the standard test fixture (see Figures 2-1 to 2-3). The cover plate serves as the reflecting plane of the rectenna. The test results, over a wide range of incident microwave power and DC load resistance, were nearly identical to the test made on the same element in which the capacitor patch was separated from the reflecting plane by two centimeters of air.

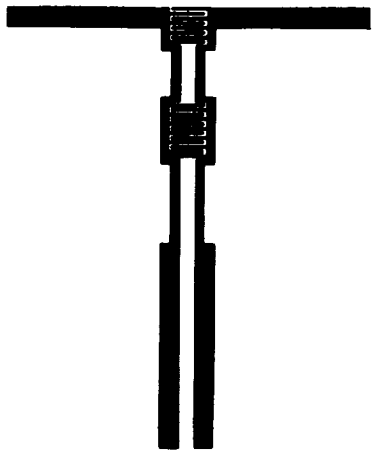
2.6.4.1.3 Registration of Microwave Circuit Patterns on Opposite Sides of the Dielectric. Although there is now no trouble in getting registration between the pattersn on the opposite sides of the thin film at 2.45 GHz, it may be difficult to achieve registration at 20 GHz. But this does not mean that it cannot be accomplished.

2.6.4.1.4 Bonding the Beam Lead Diode to the Circuit. Normally, beam lead diodes are attached to circuits by thermal compression bonding. But the substrate is usually a hard material such as ceramic. The experience that the writer has had is that the Kapton is a soft material compared to ceramic and that the necessary pressure to make the bond pushes the copper circuit to which the beam lead is being welded into the Kapton. This is an area that would have to be studied further before proceeding with this general approach.

2.6.4.2 Use of the Interdigital Finger Approach to Forming Capacitors that Allows the Complete Circuit to be in One Plane

Figure 2-26 shows what the resulting circuit, except for the large shorting capacitor in the rectifier circuit, would look like if the interdigital capacitor technique were applied to the existing rectenna circuit at 2.45 GHz. One of the advantages of the etching of the microwave circuits in a single plane is that very thin dielectric film with vaporized metal coating on one surface only and as described in Section 2.6.4.1.1 may be used. Such a technology is also desirable for a monolithic approach to the construction of the rectenna element, as will be discussed in Section 2.6.4.3. And some of the objections to using the technique on a very thin film disappear when the interdigital fingers are placed on a thick substrate with a high dielectric constant, as would be the case in a monolithic structure.

2.6.4.2.1 Procedure for Designing Capacitors Formed by Interdigital Fingers. The design procedure for microwave capacitors formed by interdigital fingers is based upon the use of a formula for capacitance between many parallel flat strips of infinitely thin metal, with alternate strips constituting two sets,



G221458

Figure 2-26. Application of Intedigital Finger Technique to Form Capacitors on One Plane as Applied to a Rectenna Element at 2.45 GHz.

each set conductively tied together and representing one side of the capacitor. The capacitance per unit length between any two of these fingers is as follows.

$$C = \frac{\pi\varepsilon}{2 \ln \left[2 \cot \frac{\pi}{4} \frac{f}{f + d}\right]} \text{ Farads per centimeter}$$

where:

$$\varepsilon = \frac{1}{36\pi} \times 10^{-11} \text{ Farads per centimeter} \quad (1)$$

d = spacing between finger edges

f = width of each finger

This formula was experimentally checked out by measuring the capacitance between a set of 14 interdigital fingers, each 5 cm long, that were made from thin 0.40 cm wide copper strips spaced the same distance (0.40 cm) from each other on a thin piece of mylar. It was assumed that the mylar would have negligible impact upon the capacitance measurements. The measured value of the set of interdigital fingers was 5.5×10^{-12} Farad, which compares with a calculated value from the formula of 5.72×10^{-12} Farad.

The design of the capacitor then consists of a compromise between the number of fingers, their length, and their separation to provide the desired value of capacitance, using the expression (1).

2.6.4.2.2 Application of Interdigital Capacitor to Thin Film Rectennas. The difficulty in applying this technique to interdigital fingers on film so thin that it is assumed that the capacitance between fingers is not appreciably affected by the higher dielectric constant of the film is that the area taken up by the capacitor either has to be sizeable or the separation between fingers has to be very low. In Figure 2-26, the separation between fingers is 15 mils or 0.375 millimeter. This would scale to approximately 2 mils between fingers at 20 GHz.

The microwave shorting capacitor used in the rectifier circuit presents a difficult problem because the interdigital finger approach would require ten times the area of the capacitors for the low pass filter and would not therefore be practical. However, if the support pedestal discussed in Section 2.6.4.1.2 is used, then there may be no need for an interdigital capacitance in the rectifier circuit. The problem then, without a metal patch on the back, will be to position the pedestal so that the proper tuning of the rectifier circuit results.

2.6.4.2.3 Application of Interdigital Capacitor to Circuits on a Ceramic Substrate. If the interdigital fingers were completely immersed in dielectric material with a dielectric constant greater than unity, the capacity per unit length, as given by expression (1) in Section 2.6.4.2.1, would increase by the dielectric constant. If the material is alumina, the increase is a factor of 8.8. However, if the fingers are printed on top of an infinitely thick ceramic, the increase will be less than this. It cannot be assumed that the increase will be exactly half of the 8.8 or 4.4.

The capacitance between infinitely thin interdigital fingers on an infinitely thick slab of high dielectric constant material is undoubtedly an interesting theoretical problem. However, for design purposes, the increase can be experimentally measured. After mounting the set of interdigital fingers, used to check the expression for capacitance (in Section 2.6.4.2.1) on an alumina ceramic substrate, it was found that the capacitance had been increased by a factor of 5.22. Hence, the effective dielectric constant is 5.22 instead of 4.4.

The higher dielectric constant makes the use of the interdigital finger approach to a single plane circuit much more practical. The filter capacitances can be made without difficulty. And it is reasonable to expect that a solution can be found for the capacitor in the rectifier circuit with the much larger capacitance between a given set of fingers.

2.6.5 Use of Alumina Ceramic as a Microwave Circuit Substrate and as a Filler Between Foreplane and Reflecting Plane

This section discusses the advantages and disadvantages of the use of alumina ceramic, and in particular discusses the great advantage of transferring heat from the diode to a large heat sink. The increase in heat transfer is so dramatic that it is discussed separately in Section 2.6.5.2.

2.6.5.1 General Listing of Advantages and Disadvantages to the Use of Alumina as a Substrate

There are many advantages and comparatively few disadvantages in the use of alumina ceramic as a substrate. The advantages are:

- It eliminates an assembly operation of the foreplane to a supporting structure—certain to be difficult because of the small dimensions involved.
- It provides a hard surface for the thermal compression bonding of beam lead diodes to the structure.
- It provides an excellent low resistance thermal path for the dissipated power from the diode to flow to the reflecting plane which can be highly thermally conducting and treated to radiate heat efficiently. This is treated separately in Section 2.6.5.2.

- The high dielectric constant of an alumina substrate greatly increases the capacitance between fingers of an interdigital capacitor and makes their physical realization much easier.

- The microwave losses in pure alumina are quite low. Alumina in nearly pure form but with enough glass in it to make it vacuum tight has been satisfactorily used as windows in high powered microwave tubes for many years.

- The dielectric constant of alumina, 9, is close to that of silicon (11.8) and gallium arsenide (10.9). Such semiconductor material would presumably be used in a monolithic construction in which the diodes were constructed on the substrate. Using a ceramic substrate is a good intermediate step toward a monolithic structure.

- There is a large base of both thick and thin film circuit technology associated with ceramic substrates.

- The resulting structure is very compact--only one millimeter or less in thickness.

The disadvantages of an alumina substrate appear to be minimal. One problem is related to single plane circuitry, that of designing enough capacitance into the microwave shorting capacitor that tunes the rectifier circuit. However, the use of a high dielectric substrate makes it less of a problem. What is needed in this case is an investigation of the effectiveness of a very large number of interdigital fingers distributed over a substantial length of line. This will not look like a lumped capacitance at microwave frequencies but could possibly be as effective as a lumped capacitance. Even the present arrangement in the 2.45 GHz rectenna is not a lumped capacitance in the microwave sense.

Another possible disadvantage is the increased density of the elements. In a truly monolithic circuit with the diodes formed on the substrate, this would not be a disadvantage. And the power handling capability of the rectenna will increased with the packing density of the elements. It does become a disadvantage if it were desired to operate the rectenna at a low power density and to spread it over a large area, particularly if the diodes were separately constructed.

The ceramic construction might initially appear to be more expensive than other forms, and it certainly is at low frequencies, but it may well be the most economical at 20 GHz and above because it eliminates several difficult alignment and assembly steps that would have to be taken with other technologies.

2.6.5.2 Discussion of the Alumina Substrate as a Conductive Cooling Mechanism for the Diode

The bonding of the diode to a metal surface, probably gold, immediately above the alumina provides a cooling mechanism that is basically different from the approach currently used in cooling the 2.45 GHz thin-film, etched circuit rectenna, and even the pedestal technique (discussed in Section 2.6.4.1.2) where the heat still has to flow through a section of the transmission line before reaching the pedestal. When a ceramic substrate is used, the heat can flow directly from the diode to the reflecting plane where it can be radiated or transferred to a convective coolant.

Because alumina ceramic is a good heat conductor, 0.055 calories/degree C/cm/sec, and the space between the foreplane and the reflecting plane is only about 1 millimeter for a 20 GHz rectenna, the resistance to heat flow from each diode to the reflecting plane is relatively low. This fact, along with the high packing density of the diodes, allows several kilowatts of heat to be transferred for each square meter of surface area of the rectenna.

This conclusion may be supported by a simple mathematical model of heat flow from the heat-sinked diode to the reflecting plane. The model assumes that heat flows through a 90° truncated cone from the diode to the reflecting plane. The quantitative results of the use of this model are expected to be close to those for a much more complicated model that would simulate the real situation.

The resulting expression is:

$$W = (0.72) \frac{x_1 x_2}{x_2 - x_1} (\Delta T) \qquad (1)$$

Where

- W is the heat flow in watts from each diode.
- ΔT is the temperature difference between x_1 and x_2.
- x is the distance from the tip of the cone.
- x_1 is the position of the heat sink of the diode, and because of the 90°C cone assumed, is also the radius of the heat sink.
- x_2 is the distance of the reflecting plane from the tip of the cone, and is equal to the thickness of the ceramic plus x_1.

If the assumption is made that the radius x_1 of the heat sink of the diode is 0.00125 cm and the thickness of the ceramic is one millimeter, x_1 and x_2 become 0.00125 cm and 0.10125 cm respectively. When these are inserted into expression (1)

$$W = 0.0009 \Delta T \quad (2)$$

If ΔT = 100°C, certainly a conservative value, W becomes 0.09 watts for each diode. As indicated in Section 2.6.2, there could be 30,000 diodes per square meter in a 20 GHz rectenna. Thus, there could be 2,700 watts of heat flow for each square meter of rectenna. If the rectenna were only 60% efficient, it could handle 4,050 watts of power per square meter. Semiconductor substrates have a higher coefficient of heat transfer. For the same dimensional parameters and efficiency 12.5 kW/m^2 could be obtained with GaAs (see Section 2.7.2.2).

However, the reflecting plane to which the heat is transferred would have to be convectively cooled with air or liquid, since its radiation capability for a scenario of 150°C surface temperature, 30° ambient temperature, and emissivity of 0.5 is only 669 watts for one side and 1338 watts for both sides.

2.6.6 Conclusions and Recommendations

A firm conclusion resulting from this task was that the 20 GHz rectenna should use a solid dielectric separator between the rectenna foreplane and the reflecting plane. Two different constructions were considered. One was a hybrid construction consisting of an alumina substrate, silk screened circuits, and beam lead diodes. The other was a monolithic construction utilizing a semiconductor substrate. But because of the anticipation of actually constructing at least one rectenna section, with the only possible available form of diode being the beam lead diode, the hybrid construction was favored.

This approach proceeded to the point of making a search for beam lead diodes and procurement of ceramic substrates. However, as an appreciation of the difficulty of the task of putting just one element together grew, the enormity of the task of building a large rectenna area with the hybrid technology also grew. As indicated in the introduction to the next section (2.7) the monolithic construction turned out to be the recommended approach even though the recommended material GaAs was still an imperfect material. However, most of the work in Section 2.6 is applicable to the monolithic construction, including the interdigital approach to a single surface microwave circuit and the determination of diode dissipation capabilities.

2.7 Preliminary K-Band Rectenna Design (Task 7)

2.7.1 Introduction and Summary

The investigation of various approaches to the design and construction of a 20 GHz rectenna carried out in Section 2.6 (Task 6) found that the best approach for a non-monolithic structure would be a ceramic substrate with the microwave circuits silk screened upon it. The capacitors in the low pass filter circuit would be interdigital as shown in Figure 2.6.2 and as discussed in Section 2.6.4.2.3. The diodes would be beam lead diodes bonded to the silk screened gold transmission lines by thermal compression. The metallic reflecting plane would be deposited on the back side of the ceramic substrate. One remaining problem would be the bypass capacitor which would be of the order of one picofarad and could not be built in the interdigital format.

It was felt, however, because of the very large number of diodes that would be needed per unit area, that a completely monolithic structure would probably be the eventual answer with the diode fabricated on a silicon or GaAs substrate. In fact, at the time of writing the final report, GaAs monolithic technology was moving rapidly enough to perhaps justify the bypassing of the non-monolithic technology altogther if only a few rectenna elements were to be constructed for evaluation and demonstration purposes.

When the study in Section 2.6 was performed there was the hope of actually fabricating one or two non-monolithic rectenna elements including diodes at 20 GHz, and testing them during Task 2.7. That objective, together with the state of monolithic technology, less mature than now, encouraged the study in Task 6 focus on non-monolithic technology. That situation has changed.

There has also been the tendency to steer away from monolithic technology because of its perceived high cost. But it should be recognized that rectennas made at 20 GHz and higher with any technology will be expensive. Monolithic technology may not only be better than non-monolithic technology at 20 GHz but it is the only approach at frequencies significantly above 20 GHz.

The next section of this report, 2.7.2, will contain approaches to the fabrication of the monolithic rectenna as suggested by the Raytheon Research Division, who currently are fabricating what they feel are much more complex monolithic circuits than that represented by the rectenna. According to them, it would be quite feasible to fabricate a few rectenna sections on a selected area of a GaAs wafer. However, the quality of the material throughout a 3 inch GaAs wafer is currently not good enough to utilize the whole wafer without probably having an appreciable percentage of defective diodes.

Section 2.7.2 will be followed by Section 2.7.3 which is devoted to a scaling of the antenna portion of the K-band rectenna element as designed for an alumina or GaAs substrate to 2.45 GHz where extensive cold tests were made

to match the rectenna structure to space. From this work, the length of the rectenna dipole and the thickness of the ceramic substrate were determined.

The match was then checked out in "hot test" with the balance of the thin-film rectenna element in the 2.45 GHz exapnded waveguide test fixture. The "hybrid" element was found to perform at high rectification efficiency and with an acceptable amount of reflected microwave power.

In concluding the summary aspect of the introductory section it is necessary to point out that the rectenna design presented here is the first iteration of the design. During this first iteration unexpected inputs occurred when the individual rectenna element was integrated into the complete rectenna. This was caused in part by the early emphasis upon attempting to make a rectenna element for test, and in part by the successfully used procedure in the past to concentrate upon the individual element development before consolidating it into the rectenna.

The unexpected difficulty encountered in this instance was the bus bar loss caused by the much smaller cross section because of the scaling and the generally higher power density of the DC power output. To keep the bus bar power losses to within reasonable limits, 2 to 5%, the thickness of the bus bar would have to be 2 to 3 mils thick. This would undoubtedly cause difficulties first in building up such a layer on the gallium arsenide substrate and then in the mechanical sheer stresses at the interface caused by the difference in the coefficient of expansion. The coefficient of expansion of GaAs is $5.9 \times 10^{-6}/°C$ while copper and gold are $9\text{-}10 \times 10^{-6}/°C$.

Fortunately, there may be a solution to the problem by connecting the DC outputs of the elements in series rather than in parallel. There is some precedent for this in that the rectenna elements of early successful rectenna were connected in series. However, this possible solution would have to be investigated in more detail, particularly in the context of rectenna stability.

Another element that was recognized later in the study was that the sections of transmission line that are needed as the inductive element in the low pass filter have a low characteristic impedance because they are laid down on a material with a high dielectric constant. This low characteristic impedance makes it difficult to make a low pass filter with a sufficiently high characteristic impedance to match the rectenna element into a high value of DC load resistance, for example, 200-400 ohms. The indication then is a lower resistive load, perhaps in the 100 ohm range.

It is difficult to predict the results of a reiteration of design that takes a lower impedance level into account. There are benefits as well as non-benefits. A low characteristic impedance means that the C_{to} of the diode can be made larger, thereby increasing the capacitance of the diode and reducing the series resistance and increasing the thermal dissipation of the diode-both

benefits. On the other hand, the DC voltage output will be less so that the Schottky barrier losses become more important. It can be concluded, however, that operation at a high power density level is highly desirable for efficiency purposes.

2.7.2 Conceptual Design of a Monolithic Rectenna at 20 GHz

The design of the physical layout of a monolithic rectenna at 20 GHz and higher frequencies consists of two part. The first part is making the diode on the semiconductor substrate so that it can be connected properly to the microwave circuit. The second part is the layout and construction of the microwave circuit. We will review the design of the diode first.

2.7.2.1 Diode Design for 20 GHz Monolithic Construction

The diode design will be reviewed from the viewpoints of fabrication procedure, specification of design parameters such as C_{to}, reverse breakdown voltage, etc., and dissipation capability. An extrapolation will also be made to higher frequencies.

Fabrication Procedure

The construction of a Schottky barrier diode by epitaxial growth and metallization on a semiconductor substrate base is shown in Figure 2-27. It is assumed that the substrate is Gallium Arsenide but the construction would be similar for silicon. The first thing that is done is to lay down as highly a doped layer, "N"+, as possible by epitaxial deposit on the substrate to serve as a low resistance conduction path. Then an epitaxial layer of "N" GaAs that is doped in the proper amount and to the allowable minimum thickness is set down. Then small areas of "resist" (to resist etching) that correspond to the appropriate area of the Schottky barrier interface are laid down and the underlying structure is etched away to include some of the N+ area. An upward projection of the diode like a "mesa" results and gives the "mesa diode" its name.

A metal contact is then deposited on top of the mesa to form the Schottky barrier itself. This metal is often platinum but it can be other material. Tungsten is a material that results in a lower voltage drop across the Schottky barrier and therefore improves the efficiency of the diode, particularly at low DC voltage output of the diode.

The diode itself is now complete but it will be necessary to make a contact between the metal side of the Schottky barrier and one side of the microwave circuit, and to make a contact between the back side of the diode and the other side of the microwave circuit.

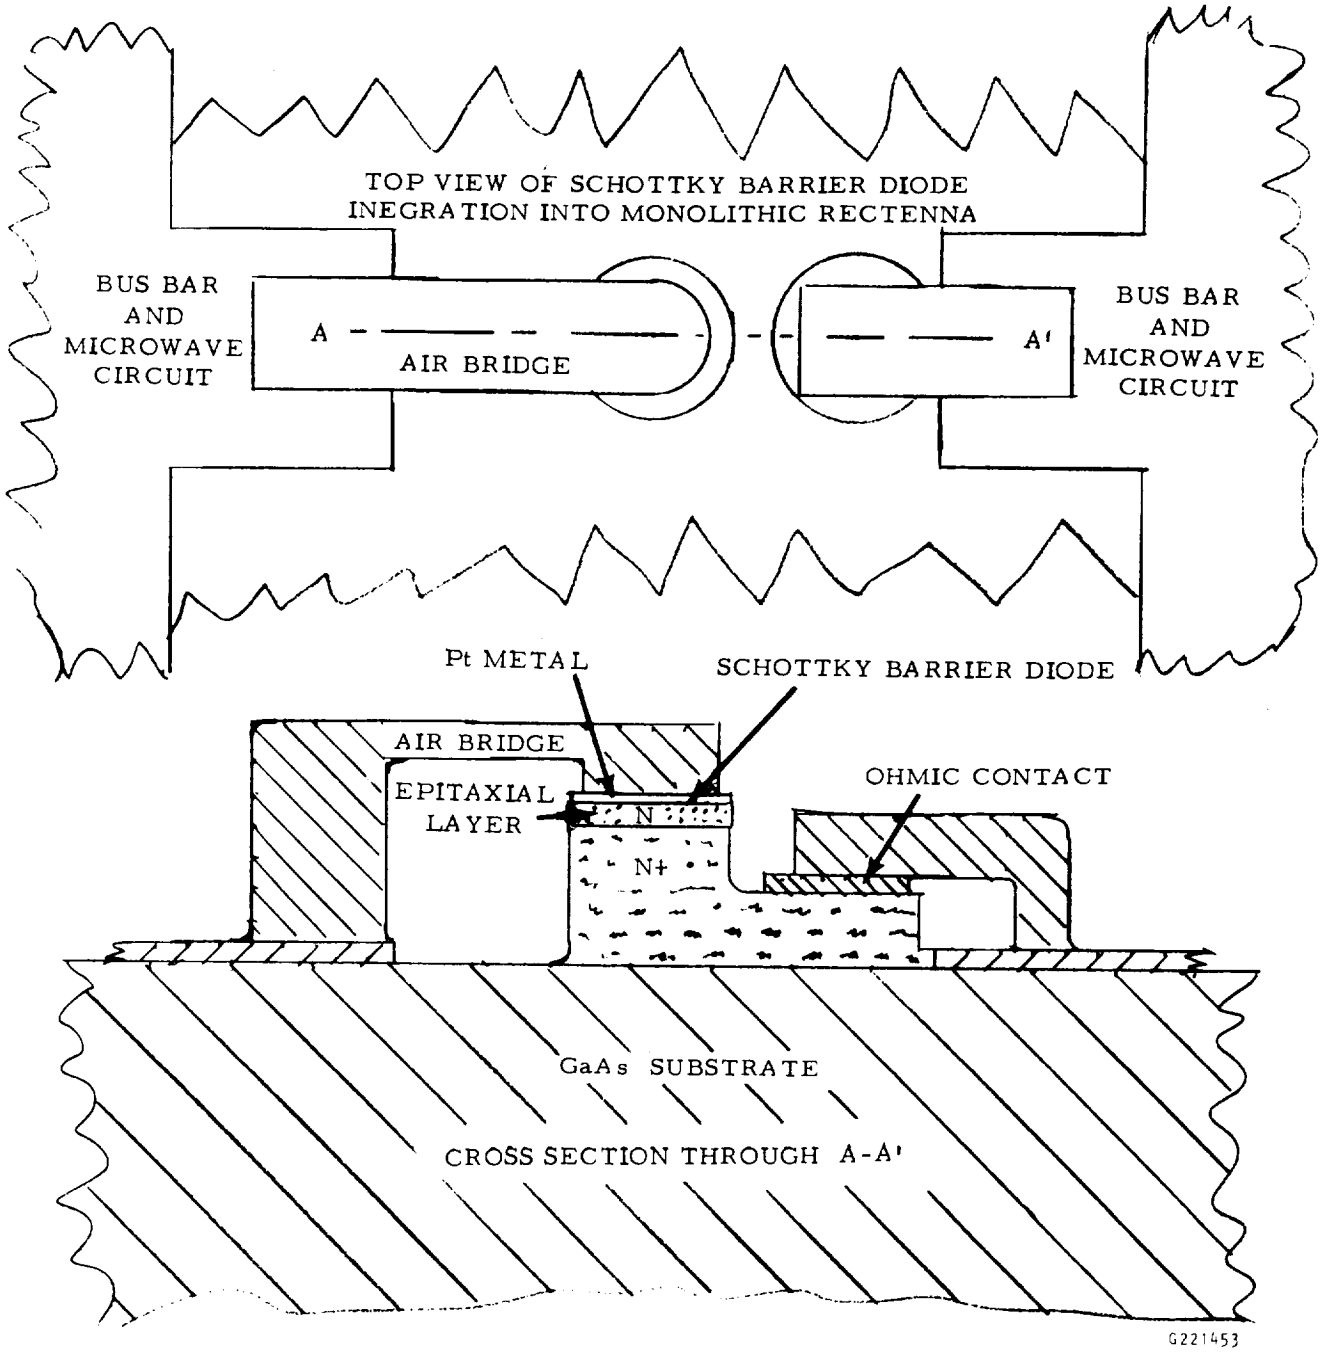


Figure 2-27. Diagram Illustrating the Schottky Barrier Diode Rectifier Portion of the GaAs Monolithic Structure for a Rectenna Element.

The contact with the top of the mesa diode is accomplished by a technique known as air bridging. Although other methods of contact could be used, and would be used in other approaches to the design of the diode, the air bridge has a unique advantage. Early in the development of the rectenna the ability of a diode short to disable the rectenna unless there was the equivalent of a fuse in series with it was recognized and fuses have been built into the packaged diodes since. In the monolithic rectenna, many diodes are operated in parallel across the DC bus. If a short occurs within one of the diodes, the short-circuit currents from the other diodes pass through the air bridge which will be very small in cross section and will act as a fuse. After the air bridge is burned through the rest of the rectenna elements return to normal operation.

From Figure 2-27 it is noted that the other side of the diode is connected to the other side of the microwave circuit through the N+ GaAs and an ohmic contact. The ohmic contact can be processed by applying "resist" to all the surface except the point at which the ohmic contact is to be made.

To reduce the resistance to current flow through the N+ material it is doped as much as possible to a level of 10^{18}, giving it a resistivity of 0.002 ohm cm. Although the path to the back contact is fairly long, the current has ample opportunity to spread out and this action coupled with the low resistivity makes the diode design approach acceptable.

Selecting the Initial Diode Design Parameters to Determine Internal Losses and Power Handling Capability

It is possible to initially select, largely on the basis of experience, design parameters of the diode from which it is possible to predict typical internal losses and the power handling capabilities of the diode. A final diode design would depend upon a number of reiterations that would probably be associated with the application of the rectenna and the environment in which it would be operated.

At the level with which we will deal with the design it is adequate to characterize the diode as an ideal rectifier with a capacitance in shunt with it, and a resistance in series with the combined diode and capacitance. The value of the capacitance varies with the potential across it, and it is typical to define this capacitance as that value it takes on when there is no voltage across it. This is called C_{to}, or the zero-bias capacitance.

The series resistance R_s is very important in determining the efficiency of the diode. In the conduction portion of the rectification cycle the DC current flows through it, while on the non-conducting portion the charging current to the capacitance C_{to} flows through it. The value of R_s depends upon the semiconductor material used, the doping density of the epitaxial layer, the thickness of the epitaxial layer, and the area of the Schottky barrier junction.

Another important parameter is that value of inverse voltage applied to the diode at which the diode starts to conduct in the reverse direction. This value of voltage is denoted V_b and its value is typically 2.5 times the DC output voltage of the rectifier, to allow for a peak inverse voltage also 2.5 times the DC output voltage. The parameter V_b determines the doping density of the epitaxial layer and its minimum thickness, and thus, in combination with the area of the junction, the series resistance R_s of the diode.

The first step in the design procedure was to select a value of C_{to} that is based upon retaining the microwave circuit impedance level of the 2.45 GHz design, and to scale the capacitance C_{to} by a factor equal to the ratio of the frequencies which is a factor of approximately 8. The C_{to} of the 2.45 MHz diode was 3 pf which implies a scaled value of 0.375 at 20 GHz.

As previously pointed out, another important parameter to specify initially is the reverse voltage breakdown, V_b, of the diode because this controls the doping density, the capacitance C_{to} per unit area of the junction, and the thickness of the epitaxial layer which along with the junction area controls the series resistance. It is assumed for an initial design that this voltage, V_b is 20 volts.

Given the reverse voltage breakdown of 20 volts, it is determined that the doping density should be 7×10^{16} atoms per cubic centimeter. (Figure 23, Chapter 5 of Reference 9.) For this doping density the zero bias capacitance will be about 70,000 pf/cm^2. (Figure 9, Chapter 3 of Reference 9.) The area of the Schottky barrier diode will then be 0.375/70,000 or 5.3×10^{-6} cm^2. This corresponds to the area of a circle with a diameter of 2.58×10^{-3} cm, or roughly 0.001 inch.

The thickness of the epitaxial layer may be obtained from the depletion layer which for a doping density of 7×10^{16} is 0.6 microns (Figure 25, Chapter 5 of Reference 9). Conservative design, however, would increase this to 1.0 micron thickness.

The resistivity of GaAs doped to 7×10^{16} is 0.08 ohm-cm. (Figure 22, Chapter 5, of Reference 9.) So for an epitaxial volume that is one micron thick (0.001 cm) and 0.00258 cm in diameter, the resistance R_s will be approximately 6 ohms. This resistance enters into the overall efficiency of the diode in complex ways but if the DC resistance level is in the range of 200 to 400 ohms, its impact on the overall efficiency will be a multiplying factor of about 0.9.

The comparable series resistance for silicon would be 30 ohms which would reduce the overall efficiency significantly. The situation will become even worse at higher frequencies because of the progressively smaller size of the junction area and no relief in the thickness of the epitaxial layer if the same breakdown voltage is to be maintained. It would therefore appear that the use of GaAs for high frequency rectennas is almost mandatory to retain a useable efficiency.

2.7.2.2 Dissipation Capabilities of the Diode and Its Power Handling Capability

The heat dissipation capability will now be examined with the aid of equation (2) in Section 2.6.5.2. Gallium arsenide with a heat conductivity of 0.64 watt/cm°C is a better heat conductor than is alumina so the first term in equation (2) become 2.0 for Gallium Arsenide. Now the expression (2) with X_2 much greater than X_1, as it is in the situation under discussion, is approximated by the term $2X_1$. X_1 for the 90° cone angle assumed for the heat flow is the same as the radius of the Schottky barrier junction which was 1.29×10^{-3} cm. Therefore the heat flow away from the junction, if the cooling is done only by heat flow to the backplane, is 0.0026 ΔT, where ΔT is the temperature difference between the diode and the back plate.

The determination of an expression for the approximate dissipation capability of the diode may now be used to approximately determine the DC output of the rectenna element in terms of the diode efficiency and ΔT. Although there are other losses in the rectenna element that should be taken into account in a more exact analysis, the losses in the diode are the predominant losses. The approximate expression becomes.

$$P_{dc} = \left(\frac{n}{1 - n}\right) \text{ (Power Dissipated in Diode)}$$

$$= \left(\frac{n}{1 - n}\right) (0.0026\ \Delta T$$

Where P_{dc} = DC power output from rectenna element

n = efficiency of diode

ΔT = temperature differential between diode and back plate

Figure 2-28 gives the contours of constant P_{dc} as a function of diode efficiency and ΔT.

From this figure it would appear that an expected DC power output in the range of 0.4 watts per diode element would be reasonable. What does this mean in terms of watts per square meter? On a strictly scaled basis the 200 elements per square meter in the 2.45 GHz array would scale the factor 8^2 to 12,800 elements. It is probable, however, that the elements will be much more densely packaged because of the high dielectric constant of the substrate. Thirty thousand elements would be more likely. Therefore, with a single rectenna power output of 0.4 watts, the power output per square meter would be 12.5 kilowatts.

This figure of 12.5 kilowatts assumes that the reflecting plane is conductively or covectively cooled in some manner. For an atmospheric application this is relatively easy to accomplish. However, for space applications

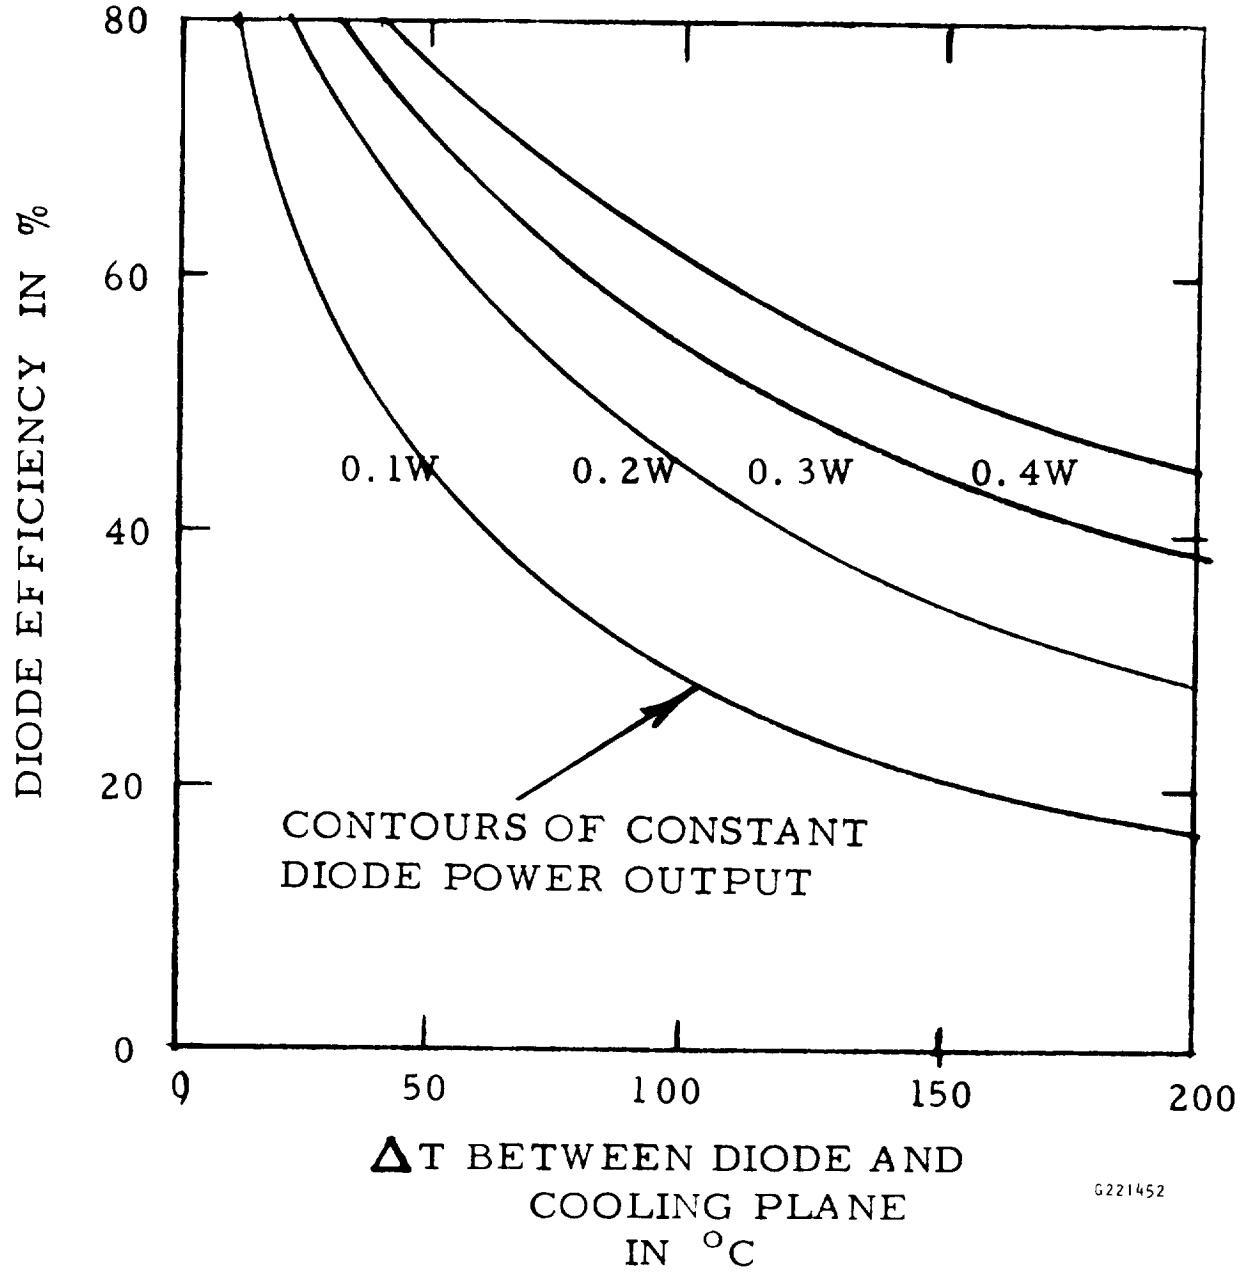

Figure 2-28. DC Power Output of Diode as Function of the Diode Efficiency and the Temperature Difference Between the Schottky Barrier of the Diode and the Reflecting Plane of the Rectenna Array. Assumptions are a GaAs Substrate, a Frequency of 20 GHz, and a Diode Spot Size of 0.00254 cm Diameter.

it may be necessary to rely upon heat radiation directly to space. If the reflecting plane is operated at 100°C, the maximum (black body) radiation to space from the back plane at a temperature of zero degrees Kelvin would be 1.09 kW. However, the front surface would probably be at nearly the same temperature, doubling the radiation to space. After making allowances for radiation into a higher ambient than 0°K and an emissivity of less than 1, radiated power in the range of 1 Kw/m^2 is more likely. This would seriously restrict the amount of DC power output from the rectenna. If the efficiency were 70%, the DC power output would be 2.33 Kw/m^2.

2.7.2.3 Output Voltage of the Rectenna Element

With a DC power output of 0.4 watts and a DC load resistance of 200 ohms, the DC output voltage would be 8.9 volts. The corresponding peak inverse voltage of 22.4 volts would exceed the reverse voltage breakdown of 20 volts established for the tentative initial design. However, with a limitation of 0.1 watt per diode which might well be the case for a radiation cooled rectenna, the DC voltage for a 200 ohm load would be only 4.5 volts.

2.7.2.4 Scaling to Higher Frequencies

Reasoning from the design sequence for the 20 GHz diode, it is reasonable to expect that the junction area will scale down directly with frequency, the internal resistance will scale up with frequency, and that the design dissipation capability of the diode will scale inversely as the square root of the frequency. However, the number of rectenna elements will scale up as the square of the frequency so that the number of diodes scales as the square of the frequency. The total dissipation of the diodes will then increase as the square root of the frequency. However, the series resistance is increasing to a significant value that will seriously impact the efficiency. Without a more detailed study and some experimental data for comparison purposes, the quantitative performance cannot be accurately predicted.

2.7.2.5 Microwave Circuit Design

The other part of the physical layout is the microwave circuit. It will be patterned after the technology discussed in Section 2.6.4.2 and Figure 2-26. It will be interdigitaled. Some study will have to be made on whether the interdigital microwave circuits are laid down on the substrate before or after the construction of the diodes, but this should not present a serious problem.

The minimum thickness of the films laid down as part of the microwave circuit is controlled by the skin thickness which is a function of the microwave frequency. At 20 GHz the skin depth in copper is 57 microns. A thickness double this or 114 microns would be adequate for microwave conduction even after allowing for current flow on both sides of the conductor. The corresponding thin film resistance (resistance to flow of microwave power) is

0.023 ohms per square. The conductors in the microwave circuit (per rectenna element) as scaled from 2.45 GHz are 0.3 cm long and 0.020 cm wide. There are about 15 squares in one of these conductors or 30 squares in the loop of two conductors. Because the current flows on both sides, the total microwave resistance is 0.69 ohms. If the conductors are of gold the resistance will be a little higher. Also the current will tend to accumulate on the inner surfaces of the conductors which will increase the resistance somewhat. But the values will be sufficiently low so that the rectenna element efficiency will not be seriously impacted.

The microwave conductors are also used as DC bus bars, to collect the rectified power. How thick will they need to be? The cross section of the bus bars and their length will determine the DC bus bar resistance and therefore bus bar losses. The resistance of the bus bars will be in series with the equivalent load resistor at the end of the row of diodes that are parallel together. If each rectenna element is to look into 200 ohms then the DC resistance across the bus bar will be 200 divided by the number of elements in parallel. The number in parallel on a 3 inch wafer could be typically 20, leading to a typical DC load resistance of 5 ohms. If it is desired to keep the bus bar losses to only 2% of the power output, then the equivalent resistance of the bus bar can be only 0.10 ohms. The loop length of the bus bar to service the 20 diodes, on the 3 inch wafer is 15 cm. If the bus bars average 0.04 cm in width, then it will be found that the thickness of a copper bus bar must be 0.003 cm, or 3000 microns, or 1.0 mil thick to keep the bus bar losses to 2%. This calculation reflects the reduced thickness needed because the full current is flowing in the bus bars only at the output end while no current is flowing at the input end, reflecting the fact that the diodes appear as generators evenly distributed along the length of the bus bars.

The 3000 micron thickness required for bus bar efficiency is 26 times the thickness needed to minimize microwave losses, and represents a challenge in the design and processing of the monolithic circuits. Of course, the bus bar thickness can be cut down by using fewer diodes in parallel, and by operating into a higher DC load resistance that in turn reflects the choice of a higher impedance level for the microwave circuit. But still the bus bar thickness will be much larger than that needed for the microwave circuit.

As explained in the summary in the introduction (Section 2.7.1) the necessity for heavy bus bars can be eliminated by connecting the elements in series, and indeed this has already been done in some of the early work on rectennas. From a monolithic device technology point of view this appears to be possible, and could have some additional advantages in eliminating the air bridge fuses if it is presumed that the failure mode of the diode is an internal short that would remain a short. Typical voltage outputs from 20 elements connected in series could range from 100 to 200 volts which would presumably be a generally convenient value of voltage to work with.

Also, as noted in the Introduction it may be difficult to maintain a high characteristic impedance of the low-pass filter sections at the input to the rectenna element. This situation will lead to modifications that will improve the dissipation capability of the diodes but at the expense of increasing the percentage of total power that is dissipated in the Schottky barrier. A combination of these considerations will force the rectenna power level upward to maintain efficiency.

2.7.3 Matching a Dipole that is Mounted on a Ceramic or Semiconductor Substrate

The previous sections have discussed both a monolithic rectenna with integration of the diode and microwave circuits and a hybrid rectenna that consists of an alumina substrate with silk screened circuits and separate beam lead diodes bonded to the circuits. In both of these approaches the necessity arises to match these structures to space so that the incoming microwave beam is effectively absorbed into the structure. This section discusses experimental efforts that were successful in matching an antenna on an alumina substrate to space. Because the dielectric constants of the semiconductor materials GaAs and Silicon are very close to that of alumina the results will be applicable to monolithic type rectennas.

Because it would be difficult to perform the experimental work at 20 GHz both because of test equipment considerations and because of the high precision required in laying out the physical parts of the experiment, the work was carried out at 2.45 GHz. However, the results can be readily scaled to any other frequency including those much higher than 20 GHz.

For these experimental measurements it was most desirable to use a Hewlett Packard network analyzer. The output of these analyzers, of course, is in the form of a coaxial output that is unbalanced with respect to ground while the rectenna dipole inputs are balanced with respect to ground. However, the rectenna circuit can be split in half by establishing a ground plane as illustrated in Figure 2-29. The center conductor of the HP network analyzer output is connected to one side of the dipole antenna while the outer conductor is connected to the ground plane. It is, of course, necessary to incorporate the reflecting plane of the rectenna into the set-up shown in Figure 2-29. The reflecting plane of the rectenna should not be confused with the ground plane of the measurement set up.

The varying input impedance of the radiating dipole as seen from the network analyzer terminals was obtained as a function of thickness of the ceramic substrate and the length of the dipole as shown in Figure 2-30. Conditions were found for a reflectionless match from a 100 ohm source. The 100 ohms corresponds to the 50 ohm impedance of the HP network analyzer source used in conjunction with the rectenna dipole element sliced in half with the use of the ground plane because the impedance level of the rectenna element is halved by this procedure. The match was obtained with an antenna length of

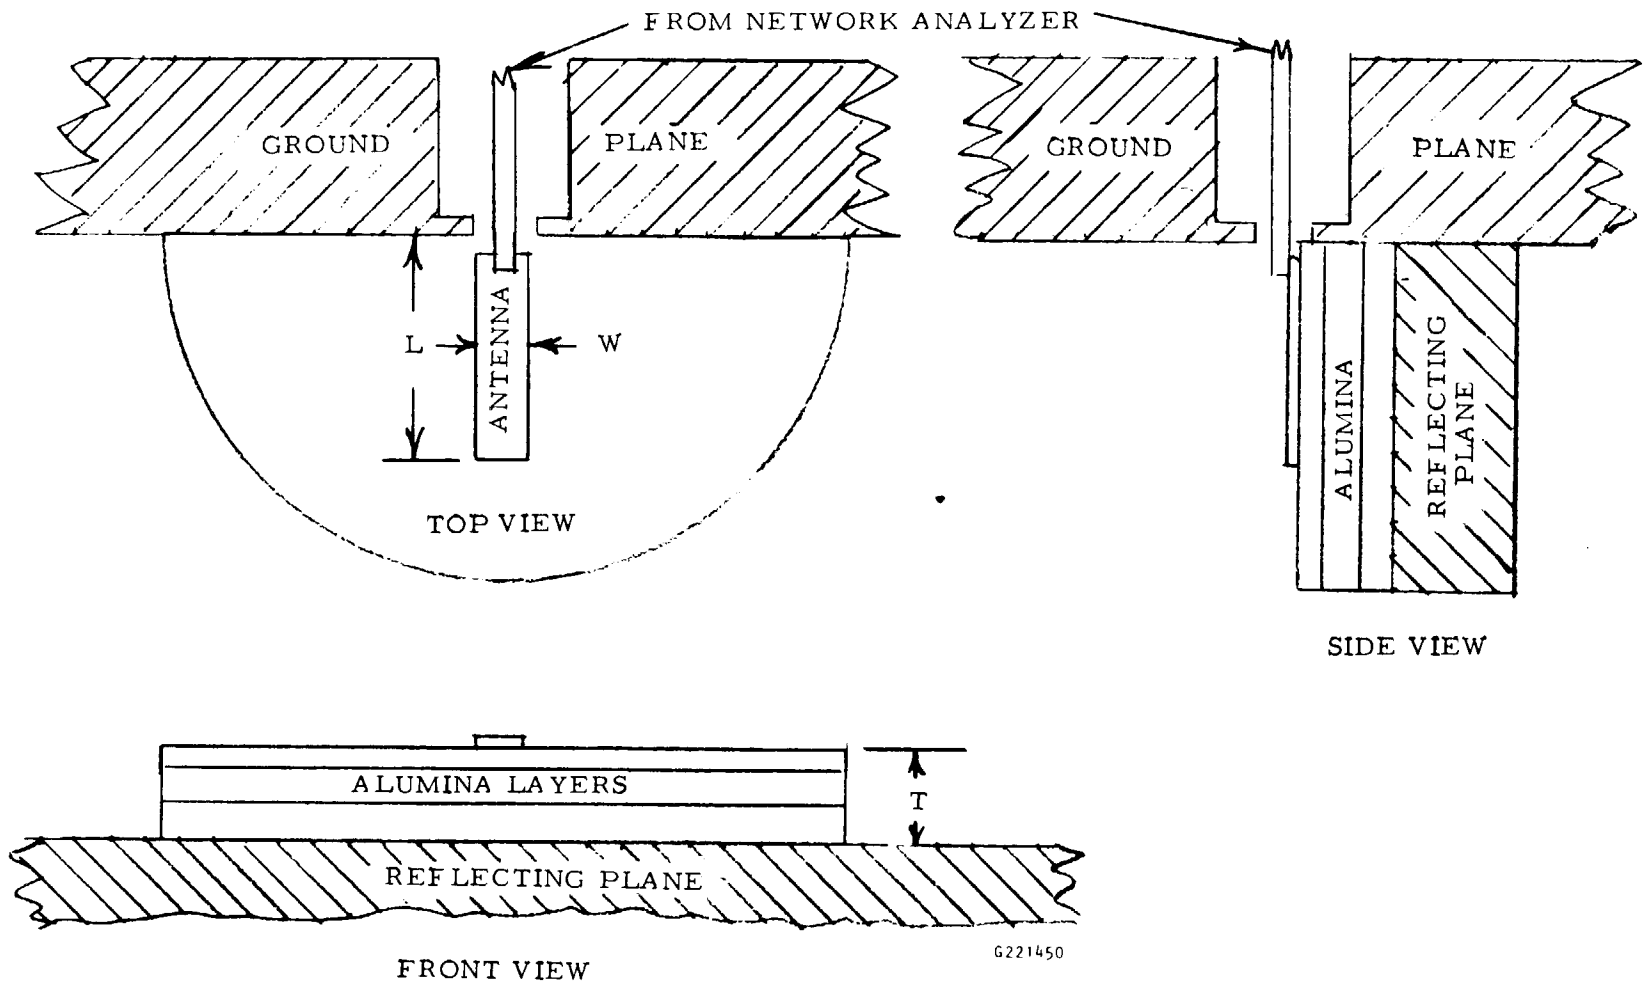

Figure 2-29. Test Arrangement for Matching a Rectenna Element Dipole that is Mounted on an Alumina Substrate to Space. The Rectenna Element is Split in Half by Means of a Ground Plane which Leaves the Characteristics of the Rectenna Element Unaffected Except for Halving the Characteristic Impedance. In this Manner, a Standard Network Analyzer can be Used to Make Measurements of the Match between the Element and Space.

OF POOR QUALITY

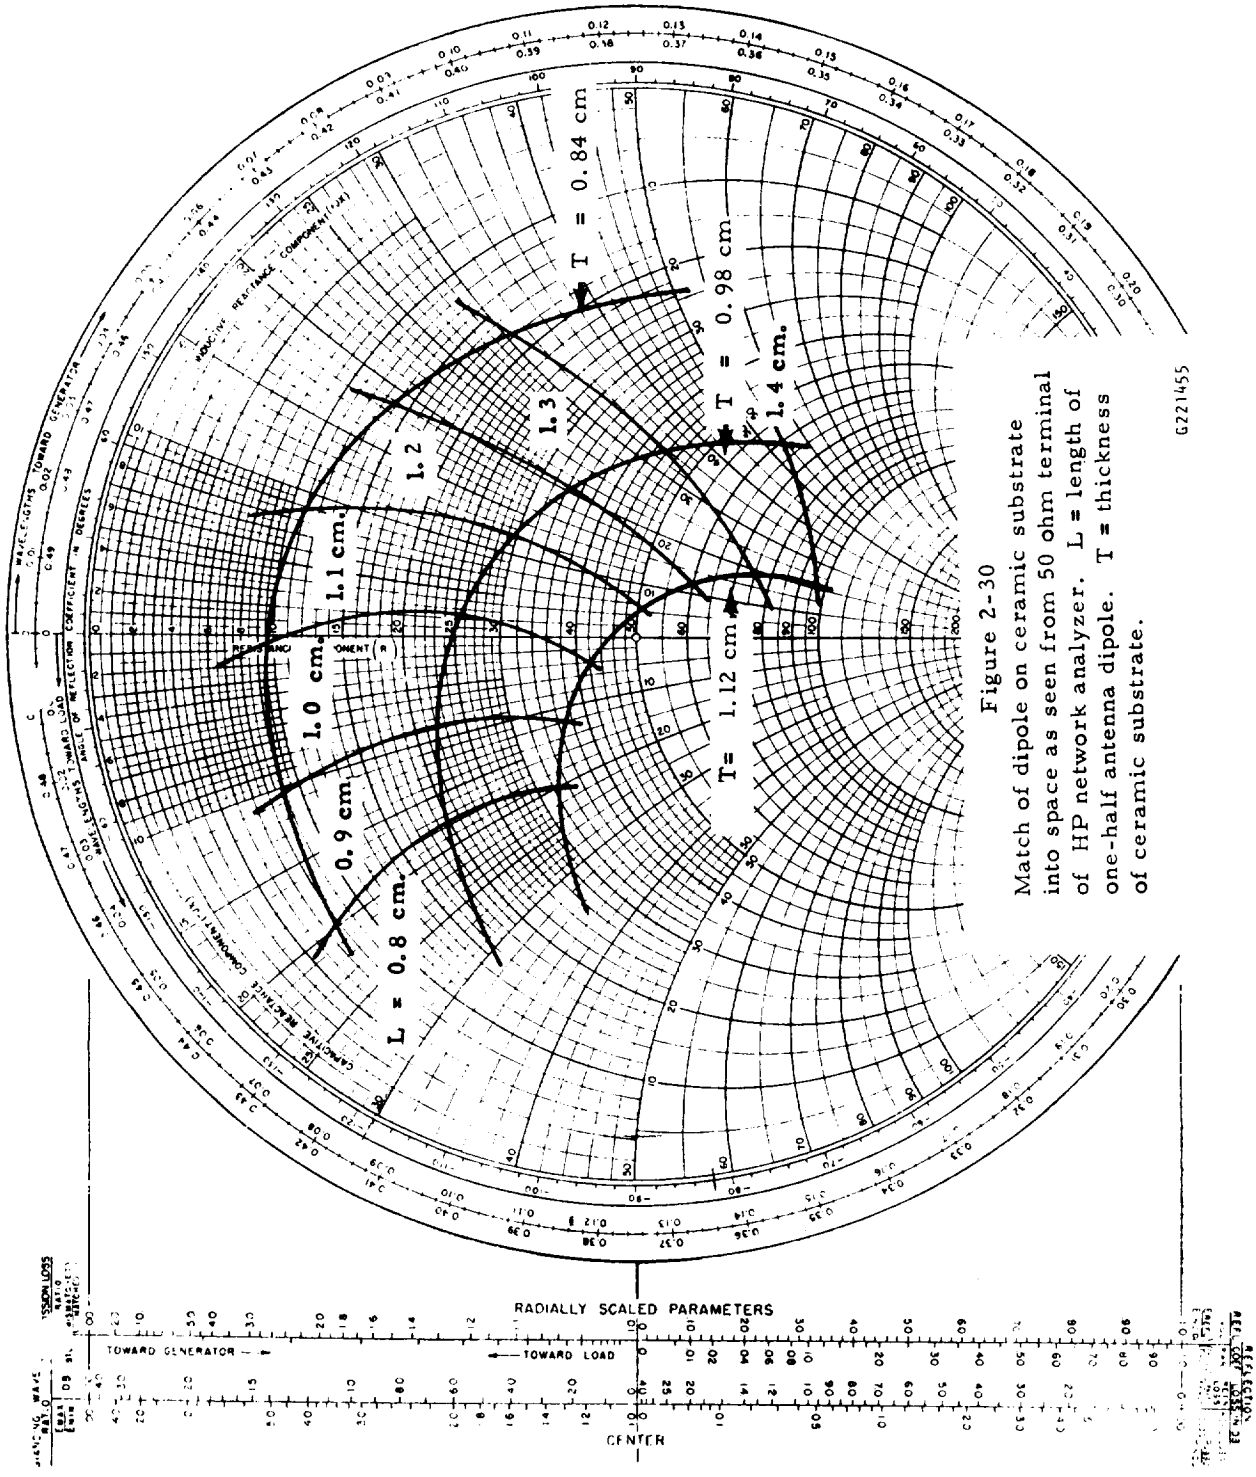

Figure 2-30

Match of dipole on ceramic substrate into space as seen from 50 ohm terminal of HP network analyzer. L = length of one-half antenna dipole. T = thickness of ceramic substrate.

1.05 cm and an alumina thickness of 1.12 cm. The length of the antenna at 2.45 GHz in the conventional thin-film, etched circuit rectenna described in Section 2.1 is 2.92 centimeters. The length is roughly shortened by a factor of 3, approximately the 1/2 power of the dielectric constant.

2.7.4 Measurements of Match, Power Output, and Operating Efficiency of a 2.45 GHz Rectenna Element Mounted on a Ceramic Substrate

Having obtained a match between space and an antenna dipole mounted on alumina substrate it was of interest to place a rectenna element with its dipole mounted on ceramic within a closed system so that measurements of match and overall efficiency could be made. A thin-film, etched-circuit rectenna element was used for this purpose. To prevent the ceramic material from modifying the low pass filters in the thin-film, etched-circuit format, this portion of the microwave circuit was elevated 0.100" above the ceramic. The antenna, shortened in length as required, was mounted directly on the ceramic.

It would be expected that the ceramic mounted dipole would have a cell area within the rectenna array considerably less than would a dipole separated from a reflecting plane with only air or vacuum in between. It would therefore need a test fixture with a smaller cross section to simulate the cell area. This was, indeed, found to be the case. Three differently configured sources of incident microwave power were used. The first was the standard expanded 4.5 x 4.5 inch fixture; the second was standard 4.5 x 2.25 inch waveguide, and the third was standard 3 x 1.5 inch waveguide. Waveguide openings had waveguide flanges so that there was a minimum of microwave leakage to space.

A best match of 4.8 dB (7.2 percent reflected power) was obtained with the 4 1/2 x 2 1/4 inch waveguide source. The resistive load was 300 ohms; the DC power output was 0.848 watt, and the element efficiency was 80.3 percent. For this performance the total length of the antenna dipole was 2.8 cm.

Before more work of this nature is done, it is recommended that the low pass networks and other portions of the microwave circuit also be placed on the ceramic substrate.

3.0 DISCUSSION OF RESULTS

A discussion of results is naturally divided into two parts. One part is that having to do with the results of the work on the thin-film, etched-circuit rectenna at 2.45 GHz. The other part is that having to do with the extension of rectenna technology to the frequency of 20 GHz and above.

3.1 Discussion of Results of the Program to Develop a 2.45 GHz Thin-Film Etched-Circuit

The broad intent of this program was to upgrade the rudimentary work on a thin-film, etched-circuit rectenna under a previous contract having to do with a rectenna for a microwave powered airship and to direct its further development toward use in space. The results of the program were highly successful in those aspects covered by the program. However, there were several aspects that were not covered.

The major achievement was the rather dramatic upgrading of the power handling capability of the thin-film rectenna for both space applications and for suitable terrestrial applications such as microwave powered aircraft. This upgrading in power handling capability resulted from several improvements. The first was an improvement in efficiency, from 70 to 85%. Because this increase in efficiency halved the inefficiency losses, it doubled the DC power output capability for a given rectenna operating temperature. Moreover, the change from mylar to Kapton substrate that caused the efficiency improvement also made it possible to operate the dielectric substrate safely at a temperature of 200°C where the GaAs diode can safely operate. Although difficult to quantify, it is expected that ability to operate at a higher temperature added another factor of 2 to the power handling capability of the rectenna in space or elsewhere.

It was possible to partially evaluate the power handling capability under incident microwave radiation up to one kilowatt of DC power output per square meter under conditions of convective air cooling at sea level air density. At this point, the high impedance design of the rectenna element limited further data taking. However, the diode temperature rise was still less than 100°C and the air flow velocity was nominally low. The implication is that the rectenna element should be redesigned to a much lower impedance level to accommodate higher levels of power density which might be desired for terrestrial applications and for which the rectennas is basically capable. In fact, going back to the impedance level of the rectenna design that was used so successfully in the 1975 tests on the Mojave desert appears to be desirable.

The scope of the contract did not include any testing in vacuum. However, from theoretical work based on the same radiative geometry (reported in reference 1) and then upgraded by the use of a ceramic package for the diode, it would appear that a DC power density of 400 w/m^2, twice that of the conservative

value previously assigned to a space application, would be reasonable. It is obvious that it is important to obtain data on the rectenna while it is being operated in a vacuum environment.

The rectenna that has been developed under this contract appears to basically meet requirements for aircraft use as far as efficiency, power-handling requirements, and life are concerned. There is, inevitably, some harmonic radiation from the rectenna which may limit its initial acceptance. And, recently, it has been observed that the current thin-film rectenna design has internal parametric oscillations at a few hundreds of MHz that modulate the 2.45 GHz signal reflected from the rectenna. Such sidebands in the reflected signal are intolerable. Current investigations indicate that this is not a general property of rectennas and that the phenomenon can probably be removed from the present design.

For space applications of the rectenna there are additional considerations having to do with the space environment that were not examined. The rectenna is impacted in space by various forms of radiation. The change to Kapton for the dielectric substrate eliminates deterioration from ultra violet radiation as a consideration, but the diode may be susceptible to other forms of radiation. If there is deterioration of the diode from such radiation, it could probably be minimized by adding shielding to the diode on a scale which would not add materially to the overall mass of the rectenna. The rectenna should be evaluated in an environment that closely simulates space in all respects, or be tested in the space environment itself.

There may also be the problem of leakage current flow through plasma between high voltage terminals of the rectenna when the rectenna is operated at relatively low altitudes. There is divided opinion as to whether or not that would be a problem with the current rectenna. However, if it is a problem in the current rectenna design, the leakage current could be minimized by adding an additional dielectric film over the etched copper circuits, much as is done with commercial flexible copper circuits which are bonded between two Kapton films. It is difficult to image a high voltage build up across terminals of the rectenna and causing arcs. Regardless of the polarity of the charge build-up, the diode serves as a means of allowing that charge to leak off in either the forward conduction cycle or by exceeding the breakdown voltage in the reverse direction.

There are a number of issues related to the fabrication and cost of the thin-film, etched-circuit rectenna. They relate to both the fabrication of the etched-circuit and to the diode.

For any large scale application the fabrication of the rectenna must be a continuous flow operation with the laminate coming in at one end and the finished etched rectenna coming out the other. The laminate must also be made continuously with the copper foil and dielectric substrate flowing into the

laminating machine from spools of the material. Initial continuous systems may be limited, for initial cost consideration, to a single rectenna row.

The Kapton F laminate itself requires a high temperature press which is non-standard equipment in most fabrication shops. What is needed is an adhesive that has a low dielectric loss but which will bond copper to Kapton H. In this context, the space application demands a dielectric substrate with minimal loss, but aircraft applications could tolerate nominal losses associated with Kapton itself and also nominal losses in the adhesive.

The diode that is currently being used is an exceptionally high quality diode in many aspects. The internal losses are low; it will operate at a relatively high temperature; and heat is conducted readily away through the plated heat sink. The diode has been evaluated on life test. If purchased to the proper set of specifications the diode will give satisfactory service for many years. The major issue with respect to the diode is its cost. Although it is a basically simple device, the very low demand for the diode has kept it at a high price. Downstream, at some point, there should be a new diode packaging technique which will make the diode easier to fabricate and also make it quite thin so that the rectenna can be rolled up tightly.

3.2 Discussion of the Results of the 20 GHz Rectenna Investigation

This portion of the study focussed upon investigating approaches to the design and fabrication of a rectenna at 20 GHz. However, the findings of the investigation were expected to be applicable to rectennas at considerable higher frequencies.

It appears that the investigation of a high frequency rectenna and preliminary findings on the best way to construct it may be timely. The recent development of the gyrotron, a new microwave tube that can continuously deliver several hundreds of kilowatts of power at these high frequencies, permits the generation of very sharp beams with a moderate sized aperture which could be mounted on ships or land vehicles. Thus, in principle at least, the high frequency rectenna and gyrotron expand the range of applications for free space power tranmission.

The investigation started out as a scale of the 2.45 GHz thin-film etched-circuit rectenna to 20 GHz. Various formats for the use of a thin dielectric film were examined in considerable detail. None, however, were without severe faults, so interest turned in the direction of using an alumina substrate and silk screened circuits - a technology in common use. Then the unavailability of suitable beam lead diodes, combined with the need for so many per unit area, and some concern about the difficulty of bonding the diodes to the circuits, motivated looking at the monolithic approach in which a semiconductor substrate is used and the diodes are built up on that substrate.

The monolithic approach was finally selected as the recommended approach for future development activity on high frequency rectennas. Further, GaAs was recommended over silicon as the substrate material because of its much better microwave properties, even though the quality of the substrate material needs upgrading, an activity that has now received priority because of the desire to use GaAs in other applications.

It was determined that a high frequency monolithic rectenna would require operation at a comparatively high power density to maintain an acceptable level of efficiency because of the Schottky barrier voltage becoming comparable to the output across the load and therefore representing a large loss. The power density for good efficiency will be in the 3 to 10 kilowatt per square meter range and the accompanying heat dissipation will be comparable, necessitating some form of convective cooling of the rectenna. This introduces a severe problem for space applications but one that can be tolerated for air borne applications where the higher power density may be wanted anyway.

Although the monolithic rectenna approach has been established as the direction in which to proceed with a high frequency rectenna development, it must be pointed out that the development will probably be a lengthy and costly one before production prototypes could become available. If such developments are started, there will undoubtedly be findings that will modify the initial design approach. For this reason, the initial monolithic rectenna development should be started as an exploratory venture. Total rectenna areas and associated power levels should be kept low to minimize the cost of test equipment, particularly the microwave generator which initially would be some other device than the gyrotron which is much too massive and expensive to use for laboratory work.

4.0 SUMMARY OF RESULTS

The scope of the activities carried out under this contract covered two activities whose objectives were distinctly different. The first of these objectives was the establishment of a thin-film, etched-circuit rectenna at 2.45 GHz that would be satisfactory for space operation. The second objective was investigating and establishing, if possible, suitable technologies for constructing rectennas at very high frequencies of 20 GHz and above.

A summary of the results of the work effort is logically divided according to these two different objectives.

4.1 Summary of Results to Improve the Thin-Film, Etched-Circuit Format of the Rectenna and to Adapt it to Space Use

1. In response to a need to determine why the early approach to a thin-film rectenna employing mylar was not satisfactory, special measurement tools were developed and used to determine precisely the dielectric constants and loss tangents of the mylar material and the loss properties of the adhesive material used to bond the mylar to the copper microwave circuits.

2. These measurement tools indicated that the published data on the dielectric constant and loss tangent for mylar were in error by a considerable factor and that our measurements were consistent with the poor behavior of the rectenna element. In the course of investigating the source for this published error, it was found that the correct values for mylar had been subsequently published in a relatively obscure report, thus corroborating our findings.

3. In the course of investigating more suitable materials for the dielectric film it was also found that Kapton had much better characteristics than those that had been published. This finding was based upon our experimental measurements and other information sources. It was decided to redesign the rectenna based upon the use of Kapton.

4. Experiments in bonding Kapton to copper were carried out to create the needed laminate material. Kapton does not bond directly to copper, so the industry has created a film material that uses Kapton as the core material with Teflon sealed to it. The teflon does bond to copper at suitably high temperatures. Our experiments determined that a one mil Kapton core with one half mil of teflon on both sides was a suitable film material.

5. The laminated material with copper on both faces was not available commercially and it was necessary to make the laminated material using special facilities at one of the Raytheon facilities.

6. Using the special laminated material, a rectenna element design was evolved and suitable masks for the etching process were made. The art work involved three successive reiterations, and took into account a rather drastic change in the design of the Schottky barrier diode.

7. A sequence of diode fabrication considerations as well as a trend toward a higher power density rectenna led to a change in packaging the diode from a glass to a ceramic pill package, and in increasing the size of the diode junction by a factor of three.

8. Measurements on the final design of the rectenna element that were made in a closed system, where accurate measurements of efficiency could be made, gave values of 85% with an estimated probable error of $\pm$1.5%. These efficiencies are only 5% less than the best achieved with the rigid, much heavier, and much more costly bar type rectenna construction. This 85% efficiency contrasts with the 70% efficiency of the mylar based element. Because any inefficiency in a space rectenna results in heat that has to be radiated to space, the improved design generates less than half as much heat for a given DC power output of the rectenna.

9. Based upon the design of the individual rectenna element, masks were made for rectenna sections containing 25 elements. Diodes were bonded to these sections. These sections were then mounted on a special fixture for evaluating their performance when immersed in an incident microwave beam of sufficiently large cross section to provide nearly uniform illumination of the rectenna section.

10. Nearly 120 watts (five watts per diode) were obtained from these sections at an estimated efficiency of 85%. The diode temperature rise for this power level was only 50°C.

11. For these tests, a new procedure utilizing the fluoroptic thermometer was evolved to determine the temperature of the diode and other parts of the rectenna element while it was being subjected to various levels of convective air cooling and incident microwave power. The fluoroptic thermometer permits non-invasive measurements of diode and circuit temperatures because it does not interact with the microwave field in any manner and because its thermal capacity and thermal conduction are negligible.

12. A very important achievement of the program was the introduction of a method of testing the efficiency and power handling capability of the rectenna element without resorting to the measurement of the microwave power input. This achievement arose from the fact that the fluoroptic thermometer makes it possible to determine the temperature of the diode, the critical factor in determining an upper limit on the elements' power handling capability, as a function of velocity of cooling air flowing over the surface of the balance of the rectenna element which serves as a cooling radiator for the diode as well as for heat generated elsewhere. Furthermore, the diode temperature for a given air flow can be observed as a function of the power dissipated within the diode resulting from the injection of carefully measured dc power. But when the diode is behaving as a microwave rectifier, diode inefficiency results in heat being generated in the same spot within the diode. This equivalence of heat sources allows the use of information obtained from observing temperature

rise with injection of DC power to determine power being dissipated within the diode when the rectenna element is absorbing microwave radiation and causing the diode temperature to increase. From this equivalence, the rectenna element efficiency can be closely approximated by the formula:

$$\text{Rectenna Element Efficiency} \approx \text{Diode Efficiency} = \frac{\text{DC Power Out}}{\text{DC Power Out} + \text{Diode Dissipation}}$$

The rectenna element efficiency approximates diode efficiency because the diode generates about 80% of the inefficiency and heat within the complete rectenna element. Further, the non-diode circuit losses are greatest in the region of the diode and tend to also raise the temperature of the rectenna element as measured at the diode.

13. The efficiency of individual rectenna elements measured with this technique closely checked those made in a closed system where the microwave power was carefully measured. The new method has the great advantage of allowing simultaneous measurements of efficiency and diode temperature rise while measurements of convective air flow are also being made under conditions that simulate, for example, those found in the application of the rectenna to a wing of an airplane. Such conditions would be difficult to simulate in a closed system for checking a rectenna.

14. Using this new test procedure, we were able to determine the dissipation power occurring within the diode as a function of the measured temperature rise on the case of the diode and of the air flow velocity at sea level pressure. Then, with a reasonable assumption for the efficiency of the diode and corresponding rectenna element, projections could be made of the DC power output density of the rectenna for acceptable diode temperature rise and convective cooling practices.

15. Under the assumption that it is the mass of air flow, or air velocity times density, that determines the amount of cooling, the results obtained at sea level can be transferred to high altitude where the air density is much less but the velocity of air flow may be much greater, for example, in the application to an airplane wing.

4.2 Summary of Results to Develop a Technology for Constructing Rectennas at Frequencies of 20 GHz and Above

1. An important result, after a thorough effort to adapt the thin-film, etched-circuit rectenna technology to a high frequency rectenna, was the conclusion that it would be very difficult to adapt the technology.

2. However, as part of this effort, the interdigital finger technique was introduced to allow lumped capacitances to be formed on one side of the film only. This technique was later applied to thick dielectric substrates.

3. The tentative move to the use of alumina ceramic as both a substrate for the circuit and as the dielectric filler between the foreplane and reflecting plane. In this conceptual arrangement the microwave circuit, with interdigital fingers for capacitors, would be silk screened onto the ceramic. The diodes were visualized as beam-lead devices that were compression bonded to the silk screened circuits.

4. A final move to a monolithic rectenna that used GaAs as a substrate for the microwave circuits and as a base for the integral Schottky barrier diodes.

5. The design of the diode itself, together with a reasonable estimate of its power handling capability as determined by its efficiency and ability of the substrate to conduct heat to the reflecting plane. A quantitative analysis of heat flow was made.

6. The estimate that the power handling capability in terms of DC power output density should be in the range of 3 to 10 kilowatts of DC power per square meter.

7. The development of an experimental approach to matching the rectenna element, when placed on a ceramic (or semiconductor) substrate, to space. It was possible to make the match by greatly reducing the dimensions of the half-wave dipole. The work was carried out at 2.45 GHz but can be scaled to the very high frequencies of interest.

8. The single dipole on its ceramic substrate, attached to the balance of a thin-film, etched-circuit rectenna element, was evaluated for efficiency in a closed system using waveguide and found to exhibit normal, high efficiency.

DenGyo Rectenna Harvests Lost Microwaves

By David Ponce on 12/20/11 • Leave a comment!

Available on demand Watch now

By David Ponce

Looks like people are still trying to harvest stray electromagnetic waves and convert these into usable energy. Some of you may remember the huge controversy we generated two years ago with news of RCA's Airnergy, a device that claimed to make electricity from WiFi signals. Most of you agreed this was bunk as there was just not enough power in these signals. Ok. But what about microwaves? Japanese company DenGyo has announced the Microwave Regenerative Converter, which is what they call a "rectenna". This stands for antenna and rectifier, smushed together, and not for anal antenna. The idea is that you'd place the device inside a microwave oven and any energy that doesn't go directly towards heating up your food would be converted back into electricity through this device, up to 100W. Since the water content of your food determines the oven's efficiency, the rectenna would be doing the most converting with old stale bread or some similar dry things.

If you follow the links, you'll be treated to all manner of mathematical formulas. We can't understand them, but we think this could work. Any engineers want to set us straight?

Acknowledgments

I would like to express my sincere gratitude to my supervisor, Professor Naoki Shinohara. I am so thankful to him for giving me an important opportunity to study my Ph.D. course in Shinohara Lab. of Research Institute for Sustainable Humanosphere (RISH) of Kyoto University. In this three years, he has provided continuous guidance, encouragement, useful advice for the present study. Specially, he is also concerned about my living as I am an international student studying in Japan. In addition, His enthusiasm for research and education will inspire me in my whole life. I have been extremely lucky to have a supervisor like him.

I am also grateful to Professor Osami Wada of Kyoto University for our fruitful discussions and his rigorous scholarship. I greatly appreciate his many helpful comments and suggestions as a reviewer of this thesis. I am very grateful to Professor Hiroshi Yamakawa of RISH of Kyoto University. I have to greatly thank him for reviewing this thesis and giving many useful comments and valuable advice. I also want to thank Associate Professor Hirotsugu Kojima of RISH of Kyoto University. I would like to give great thanks to him for affording enough time to discuss with me even he is very busy with his researches.

I must thank Associate Professor Tomohiko Mitani of RISH of Kyoto University. He provided us a convenient experiment environment and also gave me many valuable comments every time in the meeting of Shinohara Lab.. He has taught me many knowledge about microwave circuits and the usage of experiment equipment. I cannot thank him enough for his continuous support and constant interest in my study.

I am grateful to Professor Yoshiharu Omura, Associate Professor Yusuke Ebihara, and Assistant Professor Yoshikatsu Ueda for their great encouragement and helpful suggestions and advice on the present study. I greatly thank Dr. Takaki

Ishikawa, Dr. Naoki Hasegawa, Dr. Takayuki Matsumuro for their heartfelt discussions on my study and for kindly teaching me Japanese. I am very grateful to the countless others for their kind support including Dr. Yasumasa Ashida, Dr. Yoh Nagasaki, Dr. Kouhei Yamaguchi, Dr. Yohei Nakayama, Mr. Yuta Kubo, Mr. Ken Hatano, Mr. Akihito Nagahama and all of the space group members of RISH for many helpful discussions.

I wish to express my special gratitude to Ms. Yukiko Ueoka, secretary of Professor Shinohara, for her secretariat help and continuous careful support. I wish to thank Dr. Keiichiro Kashimura and Dr. Yao Yao for their kind support and encouragement.

Finally, I can hardly express my gratitude to my dear wife Hoho for her love, support, care and encouragement. I would also like to express my appreciation to my mother Xiurong and my older sister Min for their understanding and strong support for my Ph.D. course. I wish to thank my entire extended family for their support.

Abstract

Numerous studies have been carried out on the wireless power transmission (WPT) technologies, which transfers power to the electrical loads without man-made wires. As one mean of WPT, microwave power transmission (MPT) has attracted lots of attention due to its long-distance power transmission capability. A notable problem among these technologies is that the RF to DC conversion efficiency could be easily affected by the load resistance and the input power. Therefore, an impedance matching circuit becomes crucial to realize the wireless power transmission with high efficiency. Moreover, most of the impedance matching circuits in microwave circuits utilize distributed-constant circuits, whereas, the rectenna is a special distributed-constant circuit yielding a DC output. This present thesis aims at developing an ultra-wide load range rectenna for microwave power transmission and a resistance matching circuit from the viewpoint of DC, which is easy to design since it is unnecessary to consider high harmonics.

Different from the conventional DC-DC converters used for voltage conversion, in the present thesis, a resistance conversion DC-DC converter is proposed and validated in the following procedures:

Firstly, with aid of the simulator of advanced design system (ADS), a common pulse-width modulation (PWM) controlled boost converter is checked as an impedance matching circuit for rectifying circuit. For the validation a simulation model of RF-DC-DC circuit is built which consists of a simple single shunt rectifying circuit and the boost converter. The simulation results show that the overall efficiency of the RF-DC-DC circuit is almost constant over 70 % in the load range from 370 to 1300 Ω. Moreover, it is also found that the boost converter can prevent the reverse voltage applied on the rectifying diode from exceeding breakdown voltage and then the rectifying circuit can keep acting at the peak efficiency point. However, this PWM controlled boost converter can only convert

a wide load range into a narrow input resistance range which is insufficient for an impedance matching requirement of rectenna.

Next, according to the previous simulation results, an RF-DC-DC circuit is shown to be useful for impedance matching application. Therefore, an externally-powered RF-DC-DC circuit, consisting of a negative output rectifying circuit and a DC-DC converter, is designed. To choose a more suitable type of DC-DC converter, the input/output resistance relationships of three major DC-DC converter topologies (i.e. buck converter, boost converter and buck-boost converter) are investigated in continuous conduction mode (CCM) and discontinuous conduction mode (DCM), respectively. Only the DCM buck-boost converter is found to exhibit constant input resistance characteristic independent of the input voltage and the load resistance. Therefore, an inverting DCM buck-boost converter is adopted with an extra DC power supply for the control-pulse circuit, and the input resistance of the buck-boost converter is set to be close to the optimal load of the rectifying circuit. The experimental results show that the overall efficiency of this externally-powered RF-DC-DC circuit is approximately constant and over 60 %, despite the load resistance ranging from 100 to 5000 Ω.

However, the externally-powered RF-DC-DC circuit is difficult for the practical applications because of the requirement of an extra DC power supply. To solve this problem a self-powered RF-DC-DC circuit consisting of a positive output rectifying circuit and a non-inverting self-powered buck-boost converter is proposed. It can obtain a positive output voltage with a single positive input voltage. Furthermore, the input resistance of the buck-boost converter is designed to be equal to the optimal load of the rectifying circuit. The experimental results show that the overall efficiency of the self-powered RF-DC-DC circuit is constant and over 66 %, despite an ultra-wide load ranging from 200 to 10000 Ω.

Finally, several experiments are carried out on driving a DC motor using MPT with a compact designed power-receiving device which consists of a rectenna array (including some antennas and rectifiers) and an improved buck-boost converter. There exits four types of power-receiving devices combined by two different rectenna arrays and two different buck-boost converters. With these four power-receiving devices, some experiments are conducted by driving a dynamic load resistance device such as a DC motor with continuous-wave (CW) power transmission and pulsed-wave power transmission. In the CW case, the overall efficiency of the compact power-receiving device is above 50 % in a wide power

density ranging from 0.25 to 2.08 $\mathrm{mW/cm^2}$. In the pulsed-wave case, the overall efficiency is above 44 % in the duty ratio ranging from 0.2 to 1 for a power density of 0.98 $\mathrm{mW/cm^2}$. Moreover, at a fixed duty ratio of 0.5, the overall efficiency is almost constant at 59 % with the pulsed-wave frequency changing from 0.33 to 41.7 kHz.

Therefore, tested by both load resistances and a dynamic load resistance device, the proposed rectenna is found to be excellent in a relatively high efficiency for an ultra-wide load range. As a novel application of DC-DC converter, the proposed buck-boost converter, with constant input resistance characteristic, is also expected to be valuable for other WPT applications.

V_{DC}	dc output voltage
V_{DDmin}	minimum supply input
V_{DSS}	drain-source voltage
V_{FM}	peak forward voltage
V_{gate}	gate control-pulse voltage
V_{GS}	gate-source voltage
V_{h}	high frequency pulse voltage
V_{in}	input voltage
V_{j}	junction potential
V_{L}	inductor voltage
V_{ι}	low frequency pulse voltage
V_{rated}	rating voltage
V_{RRM}	repetitive peak reverse voltage
V_{m}	DC motor input voltage
V_{out}	output voltage
V_{SSmin}	minimum operating supply
Z_{out}	rectifier output impedance
Z_{opt}	rectifier optimal load
Z_{sw}	input impedance of control-pulse circuit

Chapter 1

Introduction

1.1 Wireless Power Transmission

Wireless power transmission (WPT) is the transmission of electrical energy from a power source to an electrical load without man-made conductors, which is useful in cases where interconnecting wires are inconvenient, hazardous, or impossible. Maxwell's equations, which were formulated in 1864, are essentially the first theoretical basis of WPT [1]. The concept of the Poynting vector elucidates the radio wave as representing the energy flux of an electromagnetic field. After Maxwell and Poynting, Nikola Tesla had a dream over a hundred years ago that all electricity would be provided without wires. He carried out the first WPT experiments via 150 kHz radio wave at the end of 19^{th} century [2]. However, his experiments ended in failure because they were far ahead of the high frequency technologies at that time. As the wireless communications and radar remote sensing technologies developing, William C. Brown developed a rectifying antenna named a "rectenna" and restarted WPT experiments with high-efficiency microwave technologies in 1960s [3]. The efficiency of the first rectenna developed by Brown was 50 % at an output of 4 WDC and 40 % at an output of 7 WDC, respectively [4]. With the rectenna, Brown's team had conducted many experiments on WPT such as the successful application of microwave power transmission (MPT) to a wired helicopter in 1964 and a free-flying helicopter in 1968 as shown in Fig. 1.1 [5].

Based on Brown's works, P. E. Glaser proposed a Space Solar Power Satellite (SSPS) system in 1968 [6], which is a huge satellite designed as an electric power

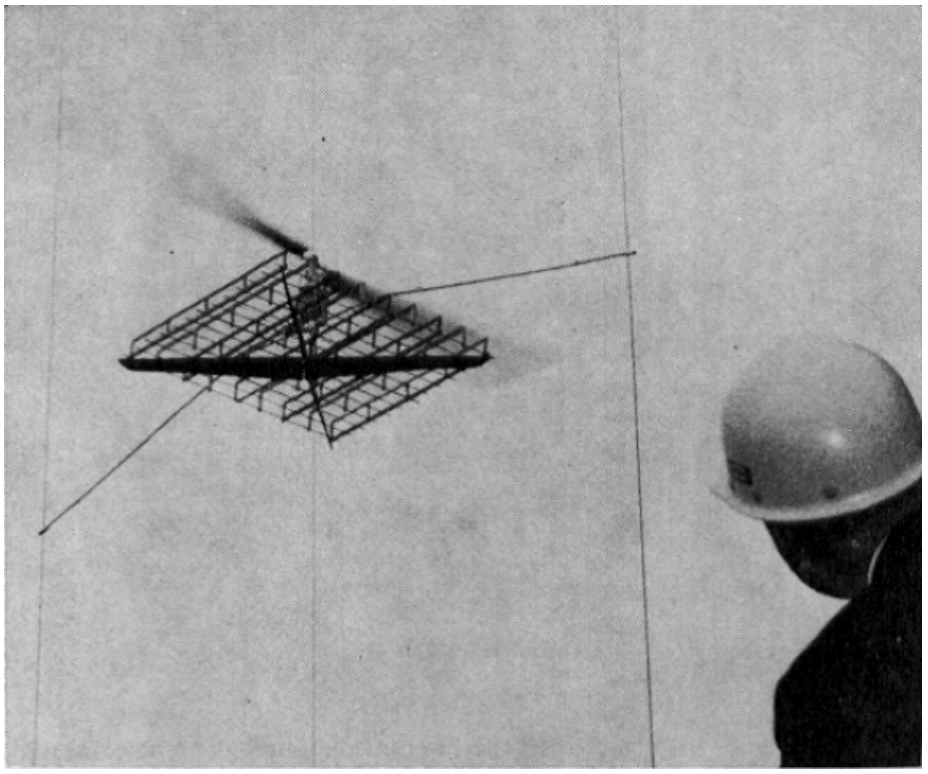

Figure 1.1: MPT experiment by W. C. Brown in 1964: the view of microwave-powered helicopter in flight at an altitude of 50 ft [5].

plant orbiting in the Geostationary Earth Orbit (GEO). Numerous Japanese scientists developed MPT technologies and researches throughout the 1980s [7]-[9]. Hiroshi Matsumoto's team carried out the first MPT experiment in space. The rocket experiment called MINIX (Microwave Ionosphere Nonlinear Interaction eXperiment) was conducted in 1983 as shown in Fig. 1.2, and ISY-METS (International Space Year - Microwave Energy Transmission in Space) was conducted in 1993 and so on.

The historical summary of WPT from Maxwell's times to nowadays is shown in Fig. 1.3 [10]. Over a hundred years development, WPT seems to be difficult for the commercial applications until recent years. A. Kurs's group, from MIT (Massachusetts Institute of Technology) of USA, proposed an efficient WPT via strongly coupled magnetic resonances at 9.9 MHz radio wave which was published on Science in 2007 [11]. They succeeded to transfer 60 watts with the efficiency of 40 % between two coils over distances in excess of 2 meters. Due to their success, it seems that resonant coupling WPT is more suitable for commercial needs. Therefore, there appears a worldwide upsurge of WPT researches in universities and companies.

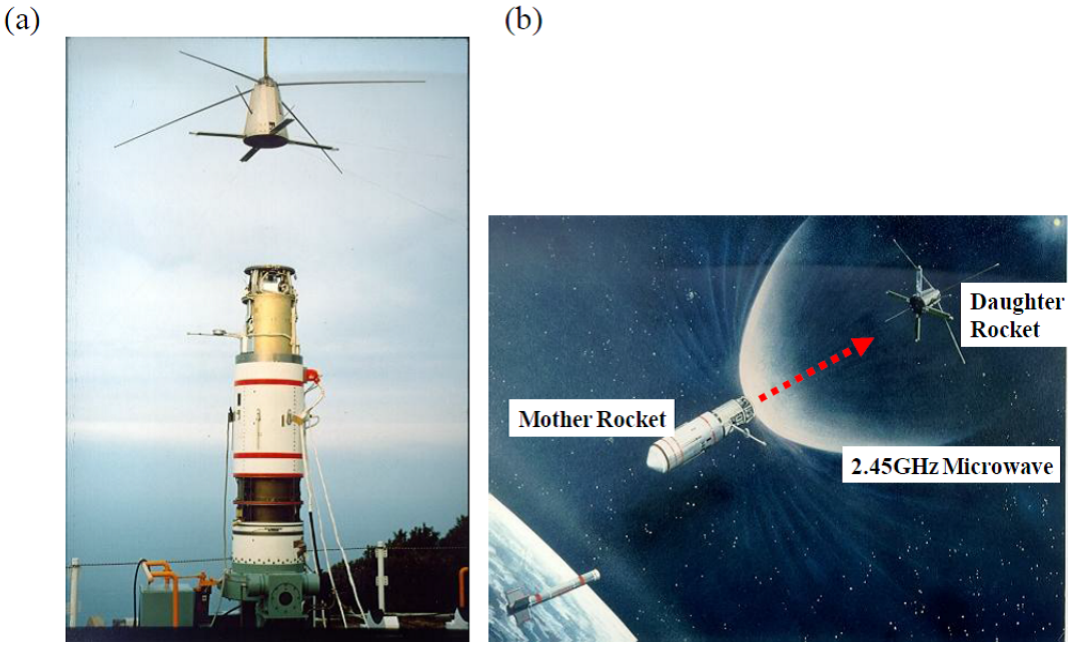

Figure 1.2: The first rocket experiment by H. Matsumoto in Japan in 1983, called the MINIX project. (a) Photo of mother and daughter rockets. (b) Photo of the experiment. These experiments were focused on the nonlinear interaction between intense microwaves and ionospheric plasmas and directed towards SSPS applications [8].

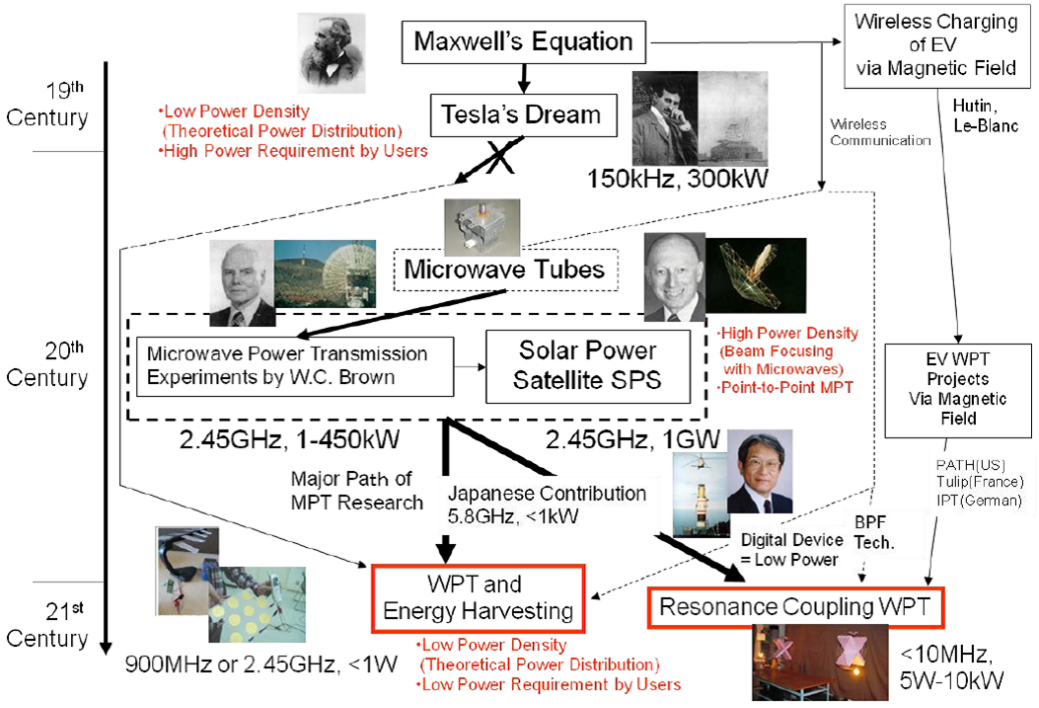

Figure 1.3: Historical summary of WPT from Maxwell's equation to RF harvesting technologies of recent years [10].

Table 1.1: Comparison of three WPT technologies [24].

	Radio wave or microwave	Resonance	Inductive coupling
Field	Electromagnetic (EM)	Resonance (Electric, Magnetic or EM)	Magnetic
Method	Antennas	Resonators	Coils
Efficiency	Low to high	High	High
Distance	Short to long	Medium	Short
Power	Low to high	High	High
Safety	EM	Under discussion (Evanescent)	Magnetic
Regulation	Radio wave or microwave	Under discussion	Under discussion

Nowadays, the common form of WPT is mainly carried out by three ways as follows: by radio waves or microwaves [12]-[15] based on wireless communication technologies and system design; by inductive coupling or be named as inductive power transmission [16]-[19]; by electric, magnetic or electromagnetic resonant coupling [20]-[23]. All of those WPT technologies are based on Maxwell's equations in theory but there are some differences in their applications. The characteristics of those WPT technologies are summarized in Table 1.1 [24].

1.2 Microwave Power Transmission

Microwave Power Transmission (MPT) is one type of WPT that mainly focuses on the frequency of 2.45 GHz, 5.8 GHz of ISM (Industry-Science-Medical) band. Based on the beam control technologies and high power transmission, the biggest advantage of MPT is that it offers the possibility of long-distance power transmission with a high efficiency [25]. Recently, with transmission power from micro-watt

level to kilo-watt level, the MPT technologies have been used in various applications. According to the distance of power transmission, applications of MPT can be roughly classified into space-to-space, space-to-ground and ground-to-ground power transmission. Examples of potential space-to-space applications include MPT for a Mars observation airplane [26] and wireless sensors in the spacecraft [27]. A well-known space-to-ground application is SSPS [28]-[31]. The SSPS consists of mainly three segments: solar energy collectors to convert the solar energy into DC (direct current) electricity; DC-to-microwave converters; and a large antenna array to beam down the microwave power to the ground. The first solar collector can be either photo-voltaic cells or solar thermal turbines. The second segment, DC-to-microwave converters, can be either a microwave tube system or a semiconductor system or the combination of both. The third segment is a gigantic antenna array. The SPS is designed as a huge solar power satellite in geostationary orbit, 36,000 km above the Earth's surface, where there is no cloud cover and no night throughout the year. Since microwave energy is almost not absorbed by air, cloud or rain, SSPS is possible to obtain approximately ten times the solar power than that on the ground. As a stable and CO_2-free green energy source, SSPS is expected to be a main power supply in the future during the late 20^{th} century. However, the development of SSPS has been delayed due to the large cost involved and the need to improve the underlying technologies.

Simultaneously, various ground-to-ground applications have been studied such as MPT for wireless LAN devices [32][33], ZigBee devices [34], sensors in car engine compartment [35], electric vehicles [36], a micro-robot in a pipe [37], small DC motors [38][39], implanted medical devices [40] and so on. Most of those MPT applications involve continuous-wave(CW) power transmission, with the exceptions of ZigBee and wireless LAN devices, which use an intermittent microwave to avoid interference between communication and power transmission [34]. Furthermore, some systems that use only ultra low power can run on energy harvested from ambient RF wave and microwave radiation [41]-[43]. Radio frequency energy exists around us such as TV signals, wireless radio networks, cell phone signals and wireless LAN signals. By using a rectifying circuit linked to a receiving antenna, this free flowing RF energy can be captured and converted into usable DC voltage for electronic applications.

1.3 Objectives

1.3.1 Structure of MPT System

However, because of the low overall efficiency of DC-RF-DC conversion and high cost involved, there are few commercial applications of MPT at present. Figure 1.4 shows a common MPT system, which usually includes a microwave generator, transmitting antennas, receiving antennas, rectifying circuits, a power management and a powered device. Here, an RF power transmission system transmits microwave incident on a receiving antenna (or array). After rectification and management, a DC power can afford to a powered device. In MPT system, the overall efficiency of DC-RF-DC conversion can be separated into three stages. The first stage is the DC-to-RF conversion that refers microwave generation and amplification. The second stage is the RF-to-RF transmission that means the antenna efficiency and the microwave transmission efficiency which are decided by the beam control of the antenna array, the transmission power and the number of antenna elements. The third stage is the RF-to-DC conversion that refers RF rectification and power management. The efficiency of the third stage is decided by the rectifying circuit and power management circuit. This thesis will mainly discuss the third stage.

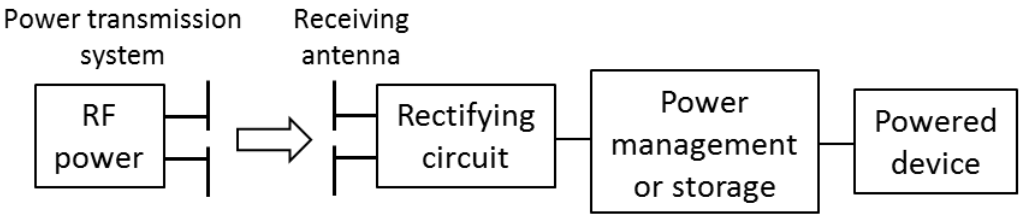

Figure 1.4: Block diagram of a MPT system. An RF power transmission system transmits microwave incident on a receiving antenna (array). After rectification and management, the DC power can afford to power an electrical device.

1.3.2 Overview of Rectenna Studies

The rectifying circuit , as a necessary component of a rectenna, is a very important element for the third stage of MPT system and significantly affects the overall efficiency of the whole MPT system. The single shunt rectifying circuit is the

most common style of rectifying circuit as referred to in Appendix A. The RF-to-DC conversion efficiency of a rectenna depends on the input power and the connected load [44]. As shown in Fig. 1.5, the efficiency of a rectenna is mainly affected by the following three factors. First, the V_{j} (junction potential) effect: The efficiency is low in the low-power region because the voltage applied across the diode is less than or comparable to the forward drop voltage of the diode. Second, the higher harmonics effect: The efficiency increases as the power increases and levels off with the generation of strong higher order harmonics which reduces the proportion of energy that gets converted to DC. Third, the B_{V} (breakdown voltage) effect: The efficiency sharply decreases as the voltage applied across the diode exceeds the breakdown voltage of the diode. It means a rectenna exhibits a maximum efficiency for an optimal output load and lower efficiency for other loads. A maximum efficiency level corresponds to tradeoffs among those three factors of threshold voltage, harmonic generation, and reverse breakdown effects. In most researches on MPT, the load characteristics of the device being powered are matched with the optimal load for the rectenna. Many researches of rectennas at different frequencies have been reported in the literature. This thesis only focuses on the MPT using 2.45 GHz microwave. Table 1.2 lists the overview of relatively high-efficiency rectennas or rectifiers for 2.45 GHz. Until now, the MPT technologies have been developed over fifty years. Most researchers have focused primarily on improving the peak efficiency of rectenna which has reached up to 90 % in recent years [45]. This high efficiency is very close to the efficiency of power transmission by wires. Therefore, it is time to consider a rectenna as a power source for our living.

The efficiency as shown in Table 1.2 is the peak efficiency at a suitable load resistance which is referred as optimal load. However, for the different devices with different load characteristics, it is necessary to use different rectennas with different optimal loads. In other words, the relationship between rectennas and users is 1:1 mode. Furthermore, devices such as a battery, ZigBee sensor nodes and DC motors exhibit variable load characteristics that depend on the operating conditions. These devices will work at very low efficiency or even can not work when they are changed from one operating condition to another because of impedance mismatch. For example, it has been reported that by matching the optimal load of a rectenna array with the load of a DC motor, MPT was successfully used to drive the motor at 3000 rpm, with an efficiency from the antenna array to the motor input port of 50 % [38]. However, if the receiving power of rectenna

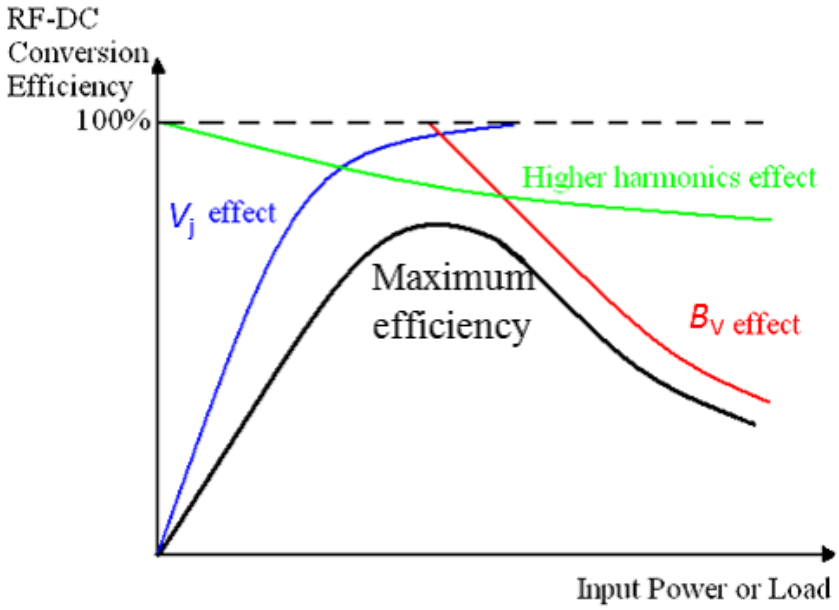

Figure 1.5: Efficiency characteristics of a general rectenna. The efficiency strongly depends on the input power or the load resistance [44].

array is changed because of some obstacles in the microwave transmission route, the efficiency would decrease due to impedance mismatch. Then the rotational speed of the DC motor can not maintain at 3000 rpm. Likewise, an airplane of MILAX (with a rectenna array) droved by a DC motor could not fly as far enough in the experiment [39]. This thesis proposes a flexible rectenna which can exhibit a high efficiency for different load characteristics of users. As shown in Fig. 1.6, the relationship between the flexible rectenna and users is 1:N mode. In this case, the flexible rectenna just seems to be a DC power source for various electronic applications.

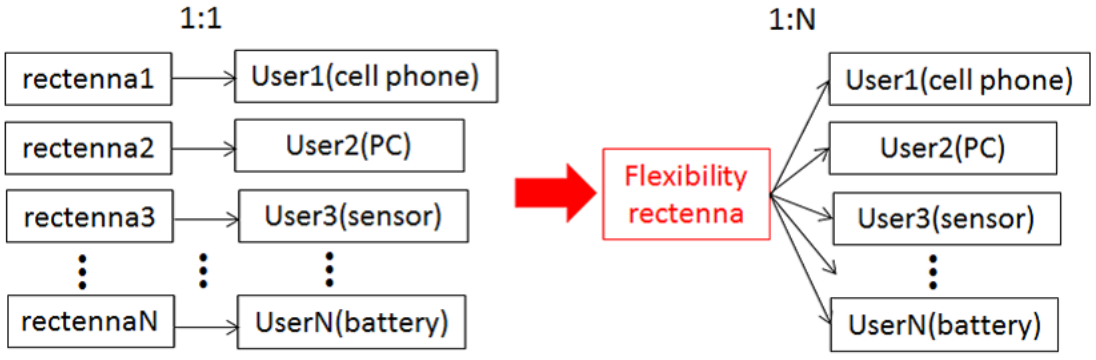

Figure 1.6: Comparison of a general rectenna and a flexible rectenna. A general rectenna for users is 1:1 mode. A flexible rectenna for users is 1:N mode.

In fact, the efficiency depends on the connected load resistance that is also a problem in other forms of WPT systems such as inductive coupling [18] and

Table 1.2: Overview of high-efficiency rectennas or rectifiers for 2.45 GHz microwave with input power levels from mW to W.

Reference	Year	Input power	HF diode	Peak efficiency

resonance power transmission [22]. The resistance conversion DC-DC converter proposed in this thesis can also be used for impedance matching in other forms of WPT system.

1.4 Thesis Outline

This thesis consists of 6 chapters which mainly focus on the designing and experiment of both rectifying circuits and a resistance conversion DC-DC converter, and the application of MPT for driving a DC motor with a dynamic resistance characteristic. The thesis is organized as follows:

Chapter 1 introduces the development of WPT and the objectives of this thesis.

Chapter 2 utilizes a common pulse-width modulation (PWM) controlled boost converter to play an impedance matching role for a rectifying circuit in the simulation using advanced design system (ADS) simulator. We firstly give an overview of efficiency improvement methods of rectennas and a comparison of impedance matching methods in WPT studies. As a DC-DC converter improves the efficiency of the rectenna from the viewpoint of the DC output, it is easy to design and is independent of the operating frequency. Therefore, a simulation model of an RF-DC-DC circuit which consists of a rectifying circuit and a common boost converter is built. The simulation results indicate that the boost converter can prevent the reverse voltage applied on the rectifying diode from exceeding the breakdown voltage and then the rectifying circuit can keep acting at the peak efficiency point. However, this common boost converter just compresses a wide load range into a narrow load range which is not enough for an impedance matching requirement of the rectenna.

Chapter 3 analyzes the input/output resistance conversion relationships of three basic DC-DC converter topologies in continuous conduction mode (CCM) and discontinuous conduction mode (DCM). Among those six DC-DC converters, the input resistance of the DCM buck-boost converter is independent of the input voltage and the load resistance. Therefore, we design an externally-powered RF-DC-DC circuit which consists of a negative output voltage rectifying circuit and an inverting DCM buck-boost converter. Where the input resistance of the buck-boost converter is close to the optimal load of the rectifying circuit and the buck-boost converter requires an extra DC power source. Finally, the experiment on the externally-powered RF-DC-DC circuit is conducted.

Chapter 4 designs a self-powered RF-DC-DC circuit consisting of a positive output voltage rectifying circuit and a non-inverting DCM buck-boost converter. We firstly design a positive output voltage rectifying circuit with a relatively high peak efficiency. Then the DCM buck-boost converter in Chapter 3 is improved to be a non-inverting self-powered DCM buck-boost converter. Furthermore, the input resistance of the improved buck-boost converter is designed to be equal to the optimal load of the rectifying circuit. Finally, the experiment on the improved buck-boost converter and the self-powered RF-DC-DC circuit are conducted.

Chapter 5 conducts experiments on driving a low-power DC motor with continuous-wave (CW) power transmission and pulsed-wave power transmission. A compact power-receiving device, consisting of a rectenna array and a simplified

buck-boost converter, is used for driving a dynamic resistance characteristic of a DC motor in MPT experiments. Firstly, we design a patch antenna as the power receiving antenna. Then we design two small rectifying circuits with different optimal load resistances. Moreover, two types of improved buck-boost converters, with the control-pulse circuit supplied by the input voltage or the output voltage, are also designed. With the combination of those antennas, two rectifying circuits and two buck-boost converters, there are four combinations of power-receiving devices. Using these four power-receiving devices, MPT experiments on driving a low-power DC motor in both CW and pulsed-wave are conducted.

Finally, Chapter 6 gives a summary and the contributions of this thesis and some directions for future work of MPT area.

Chapter 2

DC-DC Converter for Impedance Matching Application

2.1 Introduction

This chapter firstly gives an overview of efficiency improvement methods and summarizes the impedance matching applications in WPT researches. As a DC-DC converter deals with the DC output of the rectenna, it is easy to design and it plays a resistance conversion role independent of the operating frequency of the rectenna. Therefore, a common PWM controlled boost converter used for impedance matching application in rectifying circuit is investigated. We build a simulation model of an RF-DC-DC circuit which consists of a single shunt rectifying circuit and a PWM controlled boost converter using the simulator of ADS. Through the harmonic balance (HB) analyzing in ADS, the overall efficiency of the RF-DC-DC circuit can keep constant in a wide load range. More importantly, the reason for the constant overall efficiency of the RF-DC-DC circuit is clearly explained.

2.2 Overview of Impedance Matching Methods

The output of the receiving side of WPT is not directly suited to a power supply for circuits because of variations in power and voltage over the load resistance. Accordingly, a power management circuit, which should be able to adapt its input to

the receiving side of WPT and its output to the load, is usually required. Therefore, in order to obtain a necessary DC voltage with high conversion efficiency, there are mainly three solutions reported in the literature. The first method is an active control method which focuses on the active element of the rectifier such as diodes and MOSFET in applications of the RF energy harvesting with an ultra-low RF power input. For example, Gate controlled diodes (GCD) which can achieve the near zero turn-on voltage [51] and Self-V_{th}-Cancellation (SVC) CMOS where the threshold voltage of the MOSFET is cancelled by applying gate bias voltage generated from the output voltage of the rectifier itself [52]. This method intends to improve the V_j effect as shown in Fig. 1.5. The second method proposes a resistance compression networks (RCNs) in the rectifying circuit to reduce the sensitivity of the rectifying circuit versus variations of loads or input powers [53]-[56]. This method can compress a wide load range into a narrow load range in some degree, and the RCNs heavily depends on the operating frequency of the rectifying circuit. The third method uses a DC-DC converter connected to the output of the rectifying circuit for resistance conversion [22][23][43], which focuses on improving the B_V effect as shown in Fig. 1.5. The previous two methods implement solutions at the microwave circuit itself so that their effects are limited by the operating frequency of the rectenna. Their biggest advantage is that the overall efficiency almost do not decrease. The third method adds a DC-DC converter to the DC output of the rectifying circuit which implements solutions on the DC circuit so that it is independent of the operating frequency of the rectifying circuit but the overall efficiency would decrease because of the loss of the DC-DC converter.

Table 2.1 gives a comparison among examples of DC-DC converters, RCNs used in WPT system. Reference [22] used a common buck converter in continuous conduction mode (CCM) for impedance matching in magnetic resonant coupling system. The resistance relationships between the input side and the load resistance of three DC-DC converter topologies, such as buck converter, boost converter and buck-boost converter, were discussed. However, the summarized resistance relationships in [22] did not divide into the continuous conduction mode case and the discontinuous conduction mode (DCM) case. Similarly, in magnetic resonant coupling system, reference [23] utilized a microcontroller in the boost-buck converter to obtain a constant input resistance converter. Therefore, the system of [23] could maintain a constant efficiency in a wider load range than the one of [22]. In [43], it presented a microcontroller-based boost converter with online power stage efficiency optimization and maximum power point tracking in sub-milliwatt levels of

RF power transmission. It also realized an efficient application of harvesting RF power from a nearby cellular tower with the input power range from 10 μW to 1 mW. In [56], the design of the rectifier was based on the concept of dual-band RCNs as the impedance matching network of the circuit. The 915 MHz/2.45 GHz rectifiers exhibit a low sensitivity at different loads and input powers. Reference [57] summarized some rectennas in different incident power levels and in different frequency, where the rectenna obtained a peak efficiency of 57 % with the power density of 25-200 μW/cm^2 at 2.45 GHz. However, the efficiency was heavily dependent on the incident power and the load resistance since the rectenna did not use any impedance matching circuit. This work proposes an RF-DC-DC circuit consisting of a rectifying circuit and a DCM buck-boost converter. The overall efficiency of the RF-DC-DC circuit exhibits independent of the load and a low sensitivity at different input power variations, which is far superior than other studies. A rectifying circuit connected to a DC-DC converter is firstly referred to

as an RF-DC-DC circuit in this work.

According to the examples reported in Table 2.1, it includes distributed-constant circuits and lumped-constant circuits according to different operating frequencies. Magnetic resonant coupling circuits and DC-DC converters are lumped-constant circuits. Rectifying circuits and RCNs are distributed-constant circuits. Therefore, the impedance matching methods reported in Table 2.1 can be segregated into following three major divisions. First, the main circuit is a distributed-constant circuit and the impedance matching circuit is also a distributed-constant circuit such as references [53]-[56]. In this method, the impedance matching circuit heavily depends on the operating frequency used in the main circuit. Second, the main circuit is a lumped-constant circuit and the impedance matching circuit is also a lumped-constant circuit such as references [22][23]. Third, the main circuit is a distributed-constant circuit while the impedance matching circuit is a lumped-constant circuit such as references [43] and this work. In the later two methods, the impedance matching circuit is a lumped-constant circuit which is independent of the operating frequency used in the main circuit.

2.3 Simulation of Rectifying Circuit

The rectenna is very important for converting RF power into DC power. A rectenna usually contains a receiving antenna, a low pass filter, a rectifying element, a DC pass filter and a load resistance [13][44]. The receiving antenna collects microwave incident power, and the low pass filter matches the antenna impedance to the impedance of the rectifying circuit and rejects higher order harmonics from radiating through the antenna. A high frequency diode placed in shunt across the transmission line is commonly used as a rectifying element. The DC pass filter shorts the RF energy and passes the DC power. Two topologies of DC pass filters, such as a λ /4 line plus a capacitor and a $\lambda/4$ line plus some open stubs, are discussed and compared in [58][59].

This section simulates a simple quarter-wave single shunt rectifier using Advanced Design System (ADS) software of Agilent. Figure 2.1 shows the simulated schematic circuit of the rectifier. TL2, TL3, TL4 are matching circuits. A 100 pF capacitor (C2) is used as a DC block which passes the microwave from input and blocks the DC from the output. The DC pass filter consists of a $\lambda/4$ line (TL1) and

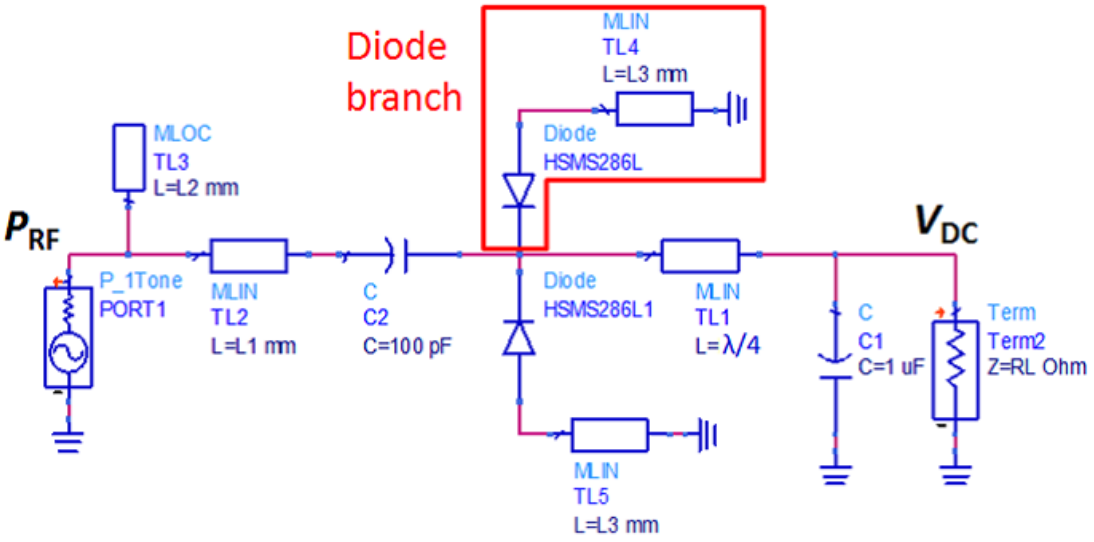

Figure 2.1: Circuit diagram of a simple quarter-wave single shunt rectifier.

Table 2.2: SPICE parameters of the HSMS2860 diode.

Parameter	Value	Unit
B_{V}	7	V
C_{j0}	0.18	pF
E_{g}	0.69	eV
I_{BV}	1E-5	A
I_{s}	5E-8	A
N	1.08

P_{B}(VJ)	0.65	V
P_{T}(XTI)	2	
M	0.5	

a 1 μF capacitor (C1) which smoothes the DC voltage and reutilizes harmonics energy. The characteristic impedance of all lines is 50 Ω and the fundamental frequency of the input microwave is 2.45 GHz. The two symmetrical diode branches are inserted in the circuit. The RF-DC conversion efficiency is defined only by the diode rectifying efficiency excluding the reflection rate in some literature. Here, the RF-DC conversion efficiency $\eta_{\mathrm{rf-dc}}$ is defined as following, which includes the

reflection.

$$\eta_{\mathrm{rf-dc}} = \frac{V_{\mathrm{DC}}^2}{P_{\mathrm{RF}} R_{\mathrm{L}}} \times 100\,\%, \tag{2.1}$$

where P_{RF}, V_{DC}, R_{L}, as shown in Fig. 2.1, are the input RF power, the DC output voltage and the load resistance, respectively.

As stated in Chapter 1.3.2, the RF-DC conversion efficiency mainly depends on the rectifying diodes. Therefore, it is important to select a suitable rectifying diode. Three diodes in different packages such as HSMS2860, HSMS2865 and HSMS286L of Avago HSMS286x series diode [60] are compared in the simulation. Table 2.2 shows the SPICE parameters of HSMS2860 and Fig. 2.2 shows the packages of three diodes. Using this three diodes in one diode branch or two diode branches, there are total 5 different rectifiers as shown in Table 2.3. These five rectifiers are simulated with the same input power and the comparison of maximum efficiency is shown in Fig. 2.3. The red point shows the maximum efficiency of five rectifiers on the matching state at the optimal load. The efficiency is increasing from 1D to 6D because the total diode loss is decreasing. The reason is that lower series resistance of parallel arranged diodes results in decreasing of diode's normal resistance losses. Therefore, the rectifier with two HSMS286L diode branches is selected in the simulation.

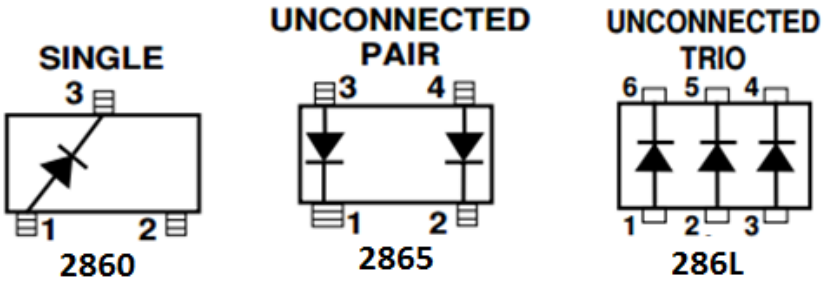

Figure 2.2: Top view of three rectifying diodes.

Then, using Harmonic Balance (HB) analysis of ADS, the rectifying circuit shown in Fig. 2.1 is simulated with the input power of 100 mW. Figure 2.4 shows the simulation results. The maximum RF-DC conversion efficiency is 83.4 % at an optimal load of 95 Ω and the reflection, the diode loss are 0.8 %, 14.7 %, respectively. At the range of load resistance from 50 to 125 Ω, the efficiency is over 70 % but it is strictly decreasing as the load resistance is greater than the optimal load. This is because the diode loss sharply increases as the reverse voltage applied on the diode is over the breakdown voltage. It is clearly seen from the Fig. 2.5 that the maximum voltage applied on the diode is greater than 7 V when the

2.4 DC-DC Converter Simulation Using ADS

2.4.1 Common DC-DC Converter

Common DC-DC converters are electronic devices usually used whenever we want to change DC electrical power efficiently from one voltage level to another. They are employed in many applications such as computers, office equipments, spacecraft power systems and telecommunications equipments [62]. The basic components of the DC-DC converter can be rearranged to form a buck converter, a boost converter, or a buck-boost converter. The buck converter has a linear control characteristic, and the output voltage is less than or equal to the input voltage. The boost converter is capable of producing an output voltage with a magnitude that is greater than that of the input voltage. The buck-boost converter can either increase or decrease the magnitude of the voltage, but the polarity is inverted. So, with a negative input voltage, the buck-boost converter can produce a positive output voltage of any magnitude.

Most DC converters use MOSFET devices as switching devices because of their very low on-resistance and zero gate-current. When the gate of the MOSFET is off, practically speaking, there is no current, and when the MOSFET is on, there is almost no voltage drop across the drain and the source. Hence, the ideal MOSFET dissipates no power, and the ideal DC-DC converter exhibits 100 % efficiency. In practice, using actual MOSFETs, diodes, and capacitors, DC-DC converter efficiencies of 80 % to 95 % are typically obtained [63]. Additionally, MOSFET probably operates at a high switching frequency which brings about the smaller and lighter transformers, inductors and capacitors. Generally, the converter is used to manage the output voltage with pulse-width modulation (PWM) control [64] or pulse-frequency modulation (PFM) control [65] or PWM/PFM switchable control which uses PFM for low load impedance and automatically switches to PWM control for large load impedance [66].

2.4.2 PWM Controlled Boost Converter

A boost converter is widely applied in energy harvesting systems since the power is very low in an ambient RF environment [61]. In this chapter, a feedback PWM controlled boost converter is used and the schematic circuit is shown in Fig. 2.6.

Table 2.4: Simulation parameters of a PWM controlled boost converter: V_{in} is the input voltage, f_{sw} is the switching frequency of PWM controller.

Parameter	Value	Unit
V_{in}	2.8	V
f_{sw}	1.8	MHz
L	10	μH
C	10	μF
R_1	1	kΩ
R_2	0.5	kΩ

The voltage difference between the feedback node (V_{fb}) and the reference (V_{ref}) is called the error voltage (V_{error}). The PWM wave, generated by comparing the error voltage to the sawtooth wave (V_{saw}), controls the gate of the MOSFET. Table 2.4 shows the simulation parameters. An MBR0520L diode which has a low junction potential voltage of 0.38 V and a high breakdown voltage of 20 V is used. The circuit is simulated by HB analysis of ADS and Fig. 2.7 shows the efficiency, MOSFET loss (P_{mos}), diode loss (P_{d}) versus the load resistance. The efficiency is over 84 % as the load is varying from 370 to 1300 Ω. The maximum efficiency is 89.1 % with the P_{mos} of 5.9 % and the P_{d} of 5 %.

Here, the input resistance of the DC-DC converter (R_{in}) is defined as Eq. (2.2) where the V_{in}, I_{inave} are the input voltage and the average of input current, respectively. Figure 2.8 shows the simulated results of R_{in} which are compressed in the range of 80 to 105 Ω with the load range from 370 to 1300 Ω.

$$R_{\text{in}} = \frac{V_{\text{in}}}{I_{\text{inave}}}. \tag{2.2}$$

2.5 RF-DC-DC Circuit

The RF-DC-DC circuit is a combination of RF-DC rectifier and the boost converter as mentioned above. Fig. 2.9 shows the block diagram of the RF-DC-DC circuit where the boost converter is connected to the RF-DC rectifier. Therefore, the

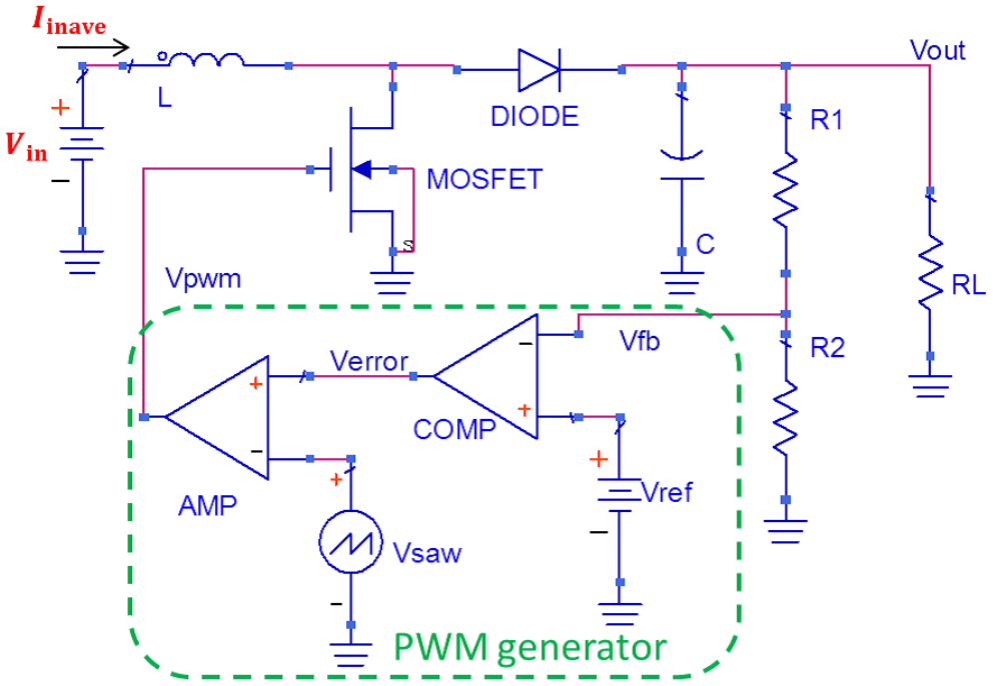

Figure 2.6: Circuit diagram of the simulated DC-DC converter: a PWM controlled boost converter.

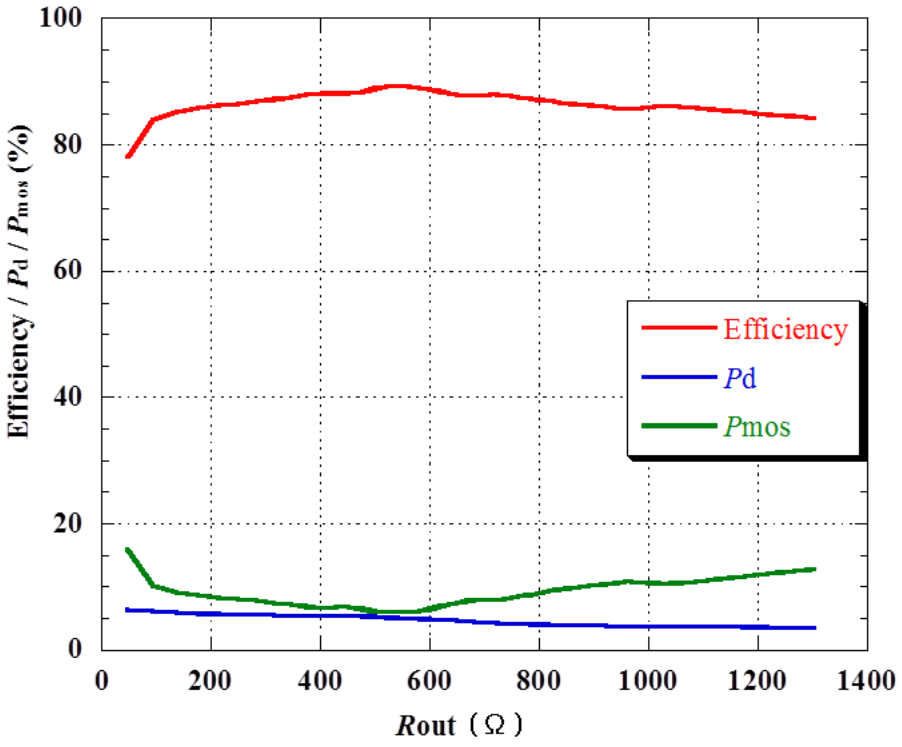

Figure 2.7: Simulation results of the boost converter such as Efficiency, MOSFET loss (P_{mos}), diode loss (P_{d}) vs. load resistance.

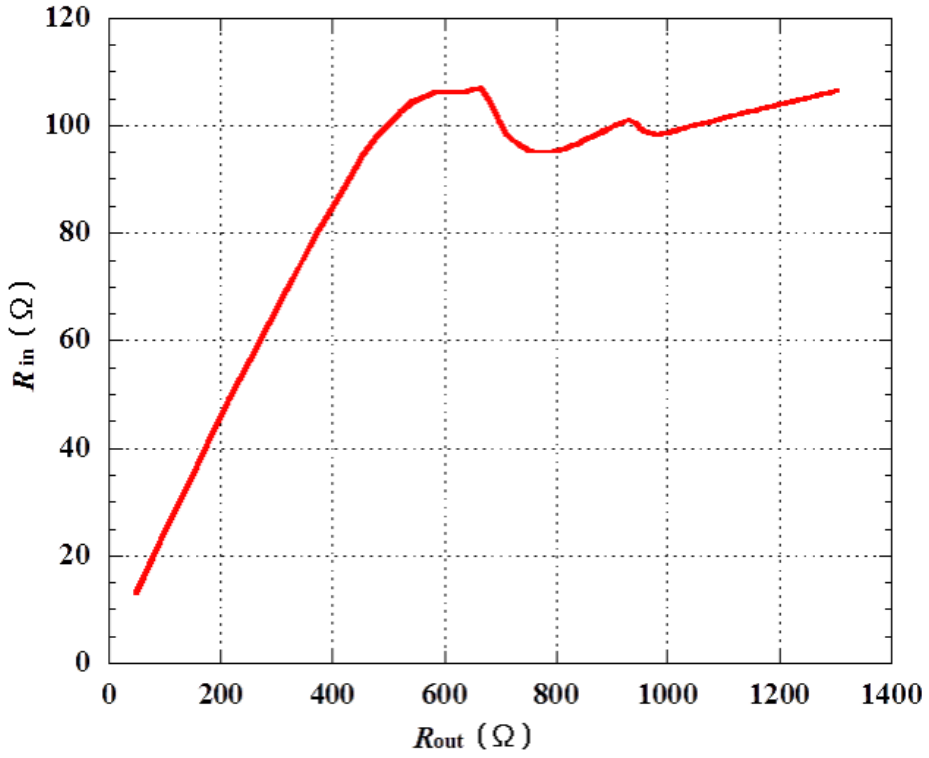

Figure 2.8: Simulation results of the boost converter such as the input resistance (R_{in}) vs. load resistance.

overall efficiency of the RF-DC-DC circuit η_{all} should satisfy following equation.

$$\eta_{\text{all}} = \eta_{\text{rf-dc}} \cdot \eta_{\text{dc-dc}}, \tag{2.3}$$

where $\eta_{\text{dc-dc}}$ is the efficiency of the boost converter.

The relationships between efficiency and load are shown in Table 2.5. As the input resistance R_{in} of the boost converter is matching with the output impedance of rectifier, the overall efficiency of the combined RF-DC-DC circuit is expected to be over 67 %.

Using HB analysis in ADS at two fundamental frequencies of 2.45 GHz and 1.8 MHz to simulate the RF-DC-DC circuit which is shown in Fig. 2.10. The input microwave power is also 100 mW which is the same as the RF-DC rectifier. Figure 2.11 shows the efficiency comparison of the RF-DC-DC circuit and the RF-DC rectifier. Comparing to a narrow range of 50 to 125 Ω of the RF-DC rectifier, the overall efficiency of the RF-DC-DC circuit is almost constant greater than 70 % at the load range of 370 to 1300 Ω. Figure 2.12 shows the impedance comparison which indicates that the Z_{out} of the RF-DC-DC circuit is almost the

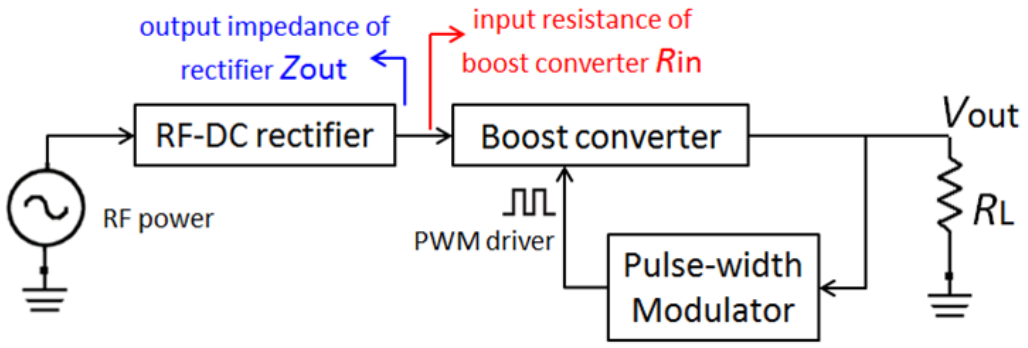

Figure 2.9: Block diagram of the RF-DC-DC circuit: the boost converter is connected to the RF-DC rectifier.

Table 2.5: Efficiency and load relationships of the RF-DC rectifier and boost converter.

	R_{out}	R_{in}	Efficiency
RF-DC rectifier	70-105 Ω		80-83.4 %
boost converter	370-1300 Ω	80-105 Ω	84-89 %
RF-DC-DC circuit	370-1300 Ω		predicted value 67 %

same as the R_{in} of the boost converter. Therefore, the simulation results of the RF-DC-DC circuit agree well with that of the two circuits simulated separately. A comparison of the maximum reverse voltage on the rectifying diode (V_{d}) of the two circuits is shown in Fig. 2.13. It is clear that V_{d} of the RF-DC-DC circuit is constant under 7 V (breakdown voltage) while V_{d} of the RF-DC rectifier is over 7 V when the load resistance is bigger than the optimal load. This results mean that the boost converter limits the maximum reverse voltage of the rectifying diode to prevent the conversion efficiency of the RF-DC rectifier from sharply decreasing.

Finally, the output voltage of the RF-DC-DC circuit is increasing as the load increases which is shown in Fig. 2.14. Here, the output voltage is different with the constant output voltage of the conventional PWM controlled boost converter. According to Figs. 2.13 and 2.14, a constant overall efficiency of the RF-DC-DC circuit can be explained as follows. In the RF-DC-DC circuit, the output voltage of the rectifier (when it is connected with the converter) is almost constant even though the load is changed, which leads to the maximum voltage applied on the

diode being constant and under the breakdown voltage. As a result, the efficiency of the rectifier (when it is connected with the converter) is almost constant which leads to a constant overall efficiency of the RF-DC-DC circuit even though the load is changed. In contrast, the output voltage of the rectifier (when it is not connected with the converter) is increasing as the load is increased, which leads to the maximum voltage applied on the diode increasing up to over the breakdown voltage and the increase of diode losses. Consequently, the efficiency of the rectifier (when it is not connected with the converter) decreases at a high load resistance.

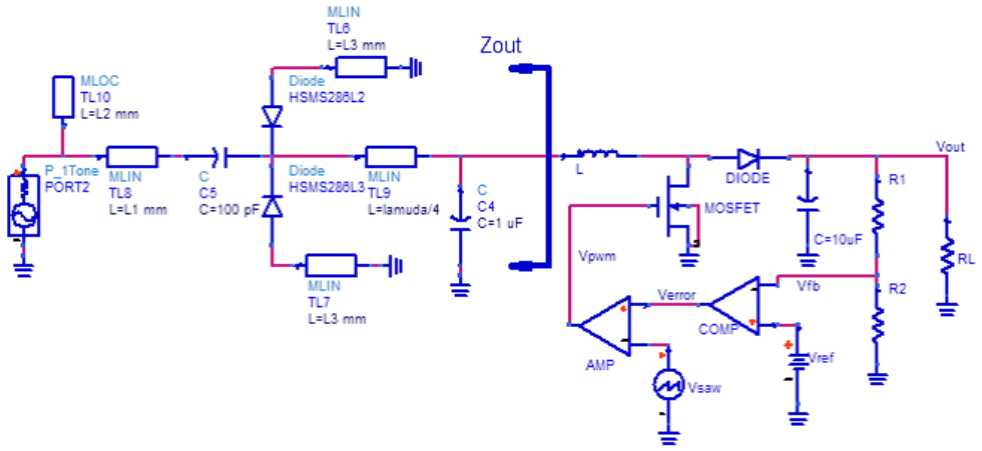

Figure 2.10: Circuit diagram of the RF-DC-DC. Simulate it with two fundamental frequencies of 2.45 GHz and 1.8 MHz using HB analysis in ADS.

2.6 Summary

Firstly, we give an overview of efficiency improvement methods in rectenna researches and a comparison of impedance matching methods in WPT studies. The DC-DC converter addresses the DC output of the rectifying circuit and improves the B_v effect in the efficiency-load characteristics. More importantly, the DC-DC converter as an impedance matching application which is independent of the operating frequency of the rectenna. Therefore, a PWM controlled boost converter is used to improve the efficiency-load characteristics of the rectifying circuit. Using HB analysis of ADS, we build a model of RF-DC-DC circuit which consists of the single shunt rectifying circuit and the PWM controlled boost converter. The RF-DC-DC circuit obtains a steady high overall efficiency (over 70 %) at the load

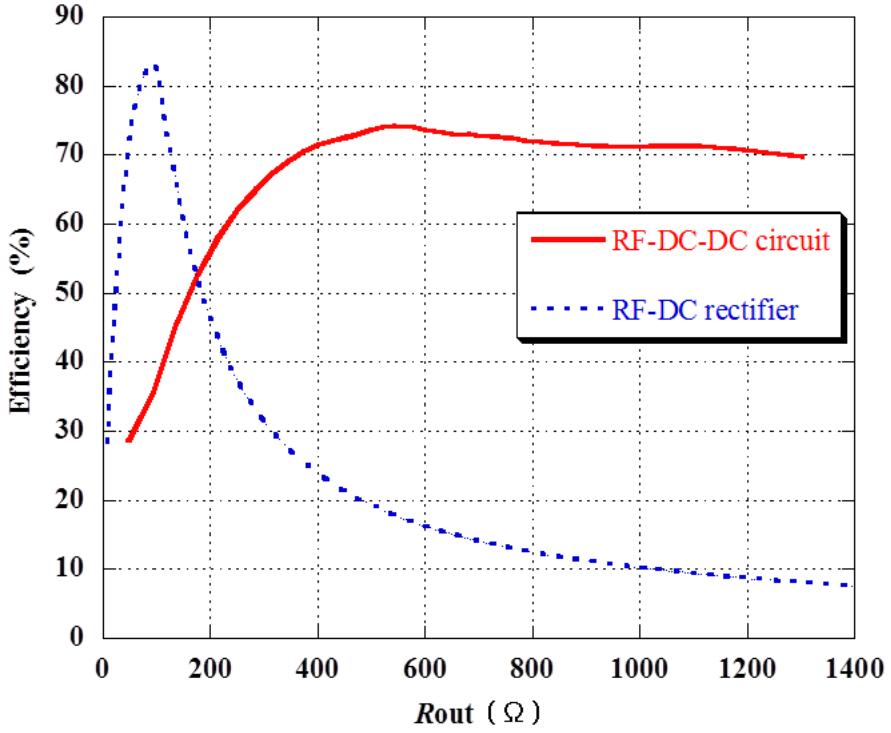

Figure 2.11: Efficiency comparison of the RF-DC-DC circuit and general rectifier.

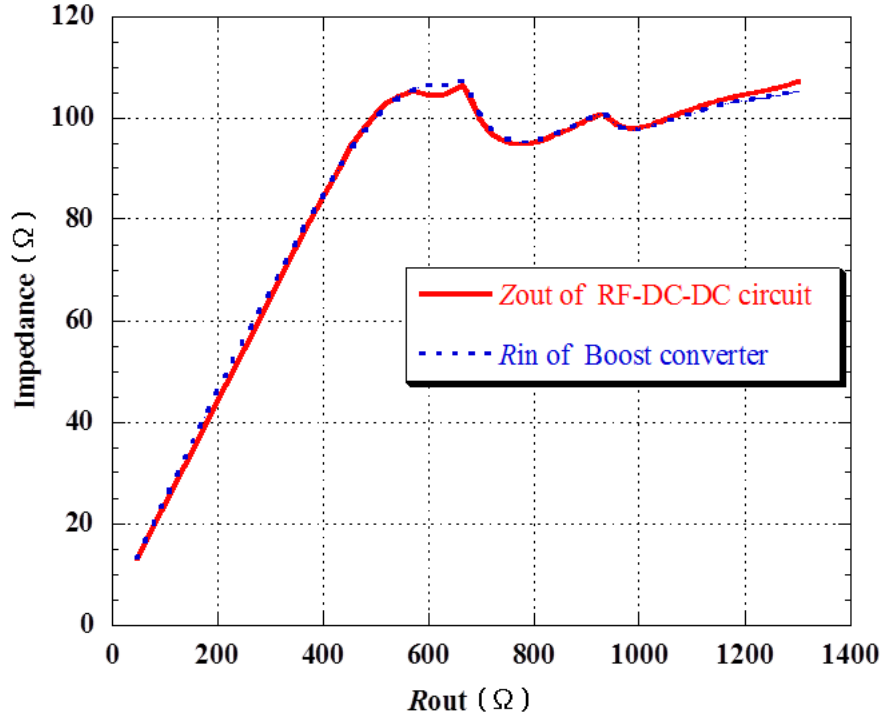

Figure 2.12: Impedance comparison: Z_{out} of the RF-DC-DC circuit is almost the same as R_{in} of the boost converter.

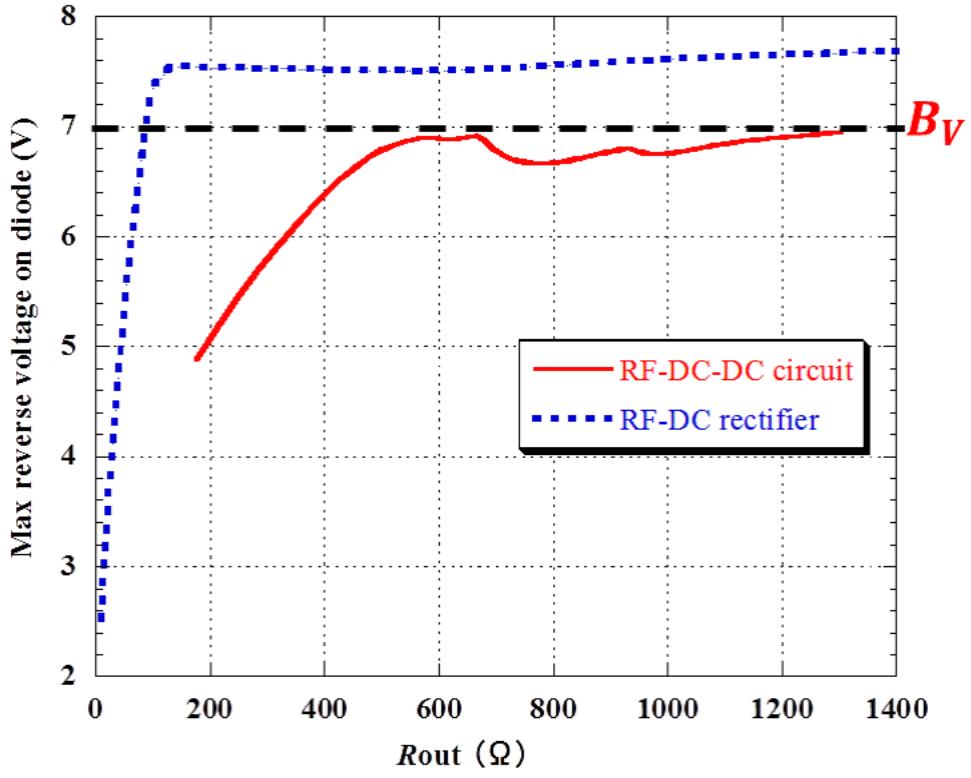

Figure 2.13: Maximum reverse voltage on the rectifying diode (MaxV_d) comparison: MaxV_d of the RF-DC-DC circuit is under breakdown voltage (7 V).

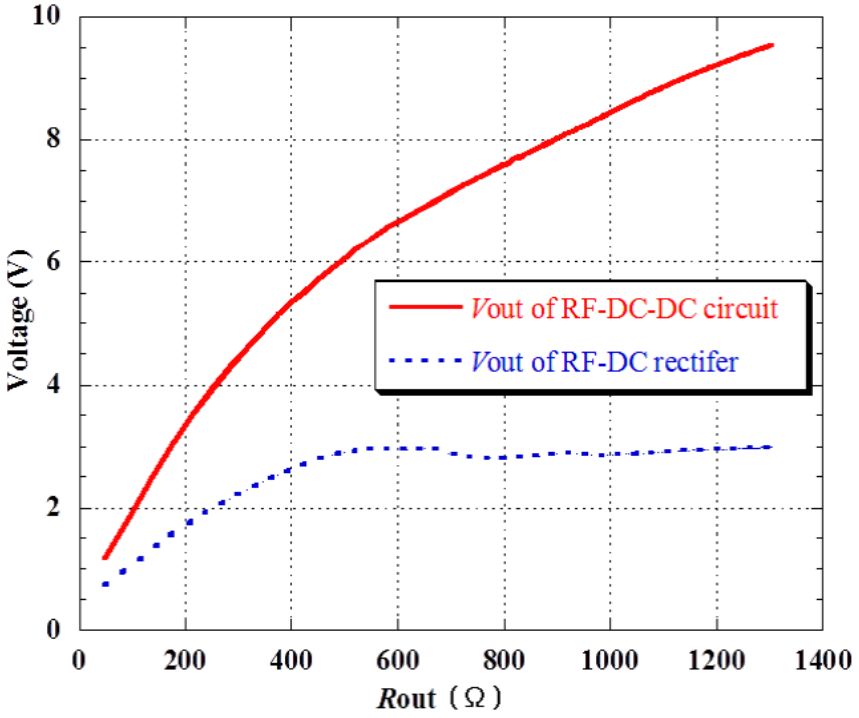

Figure 2.14: Output voltage of the RF-DC-DC circuit and the voltage at the output port of RF-DC rectifier.

range of 370 to 1300 Ω, where the load range is wider than the RF-DC rectifier at the same efficiency level. Additionally, that the boost converter is connected to the RF-DC rectifier can limit the maximum reverse voltage applied on the rectifying diode under breakdown voltage at this load range. The simulation results clearly explain the reason why a DC-DC converter has an effect on impedance matching for RF-DC rectifier. Therefore, an RF-DC-DC circuit is verified to be available for improving efficiency-load relationships of the rectenna in this chapter. However, the simulated PWM controlled boost converter just compresses a wide output load range into a narrow input resistance range in some degree. It is insufficiency for impedance matching for a flexible rectenna. Therefore, based on the simulation results of this chapter, a much more effective DC-DC converter is proposed and discussed in the next chapter.

Chapter 3

Externally-powered RF-DC-DC Circuit

3.1 Introduction

Last chapter demonstrates that a DC-DC converter is useful for impedance matching of a rectifying circuit based on simulation. In this chapter, to select a suitable DC-DC converter for impedance matching of the rectenna, the three basic topologies DC-DC converters such as buck converter, boost converter, buck-boost converter in CCM and DCM are discussed. The CCM is defined by continuous inductor current which is greater than zero over the entire switching period. The DCM is defined by discontinuous inductor current which equals to zero during a portion of the switching period. Hence, the energy stored in the inductor is zero at the beginning and at the end of each switching period. The CCM is preferred for high efficiency and good utilization of semiconductor switches and passive components. The DCM may be used in applications with special control requirements because the dynamic order of the converter is reduced. It is uncommon to mix these two operating modes because of different control algorithms [67].

Both CCM and DCM are discussed for three basic topologies DC-DC converters in this chapter. Unlike the usual discussion on DC-DC converter, this chapter will analysis the relationships between input resistance and load resistance instead of input/output voltages. Comparing those DC-DC converters, an inverting buck-boost converter in DCM, which exhibits constant input resistance,

is selected. The control-pulse circuit of this buck-boost converter requires an extra DC power source. Additionally, to match the polarity of the input voltage and the output voltage, a negative output voltage rectifier is designed. Then, an externally-powered RF-DC-DC circuit consisting of the rectifier and the buck-boost converter is proposed. Finally, experiments on the externally-powered RF-DC-DC converter are conducted.

3.2 DC-DC Converter in CCM and DCM

3.2.1 DC-DC Converter in CCM

A DC-DC converter operating in CCM or DCM depends on the characteristics of the inductor current. In the case of the CCM, the inductor current is continuous and never falls to zero. Figure 3.1 shows the operating waveform of the inductor (I_{L}) in CCM at the steady condition. The I_{LP} is the peak inductor current and I_{LV} is the minimum inductor current which is greater than zero. Figure 3.2 shows the schematic circuits of three basic topologies DC-DC converters which consist of capacitors, an inductor, an N-channel MOSFET (N-MOS), and a diode. T_{on}, T_{off}, T are the on-state time, off-state time and the period, respectively. D is the duty-on ratio of the control-pulse. Then it yields:

$$D = \frac{T_{\mathrm{on}}}{T} = \frac{T_{\mathrm{on}}}{T_{\mathrm{on}} + T_{\mathrm{off}}}. \tag{3.1}$$

As we know, the relationship between the inductance L, the inductor voltage (V_{L}) and the inductor current (I_{L}) satisfies the following formula:

$$V_{\mathrm{L}} = L\frac{\Delta I_{\mathrm{L}}}{\Delta t}. \tag{3.2}$$

Moreover, ΔI_{Lon}, ΔI_{Loff} are the current variation of the inductor at on-state and off-state, respectively. As the overall current variation of the inductor should be zero when the converter operates at steady-state. Then it means:

$$\Delta I_{\mathrm{Lon}} + \Delta I_{\mathrm{Loff}} = 0. \tag{3.3}$$

A). Buck converter

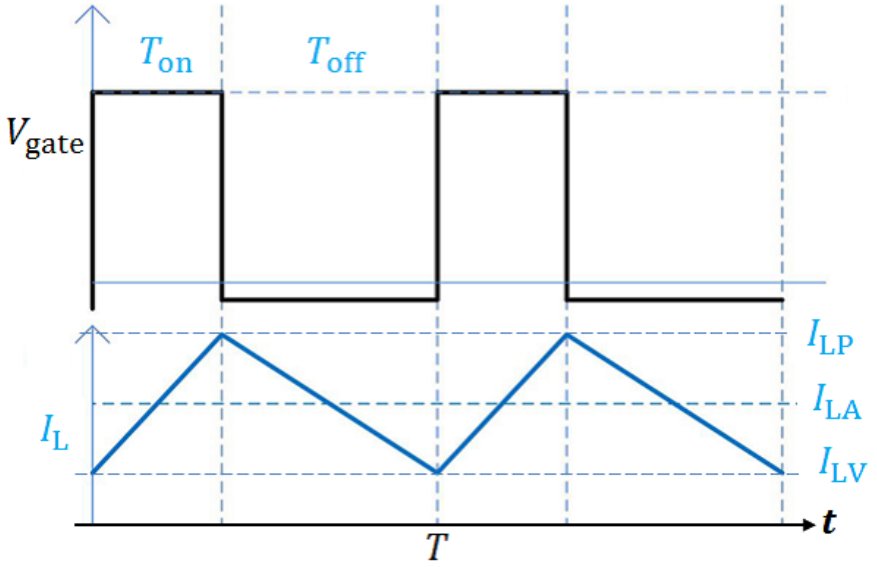

Figure 3.1: Operating waveforms of the inductor current (I_L) and gate control voltage (V_{gate}) for a DC-DC converter in CCM.

As can be seen from the Fig. 3.2(a), when the gate voltage V_{gate} is at high level, N-MOS lets the current flow through drain to source then the current flows through the inductor to the load. At this on-state, the inductor current is increasing to the peak value I_{LP} and no current flows through the diode since it is reverse-biased by the voltage. Then the inductor voltage at on-state (V_{Lon}) can be written as:

$$V_{Lon} = V_{in} - V_o. \tag{3.4}$$

Using Eqs. (3.2) and (3.4), the current variation of the inductor ΔI_{Lon} can be calculated as:

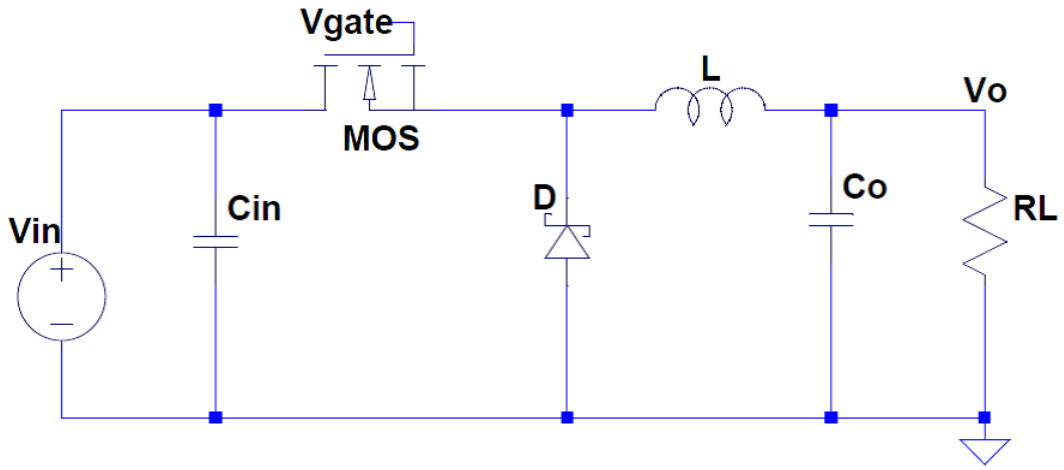
$$\Delta I_{Lon} = \frac{V_{in} - V_o}{L} DT. \tag{3.5}$$

When the gate voltage V_{gate} is at low level (or zero), N-MOS does not let the current flow through drain to source, then the current stored in the inductor flows through the load and diode. At this off-state, the inductor current is decreasing to the valley value I_{LV} and the current flows through diode as it is forward-biased. Then the inductor voltage at off-state (V_{Loff}) can be written as:

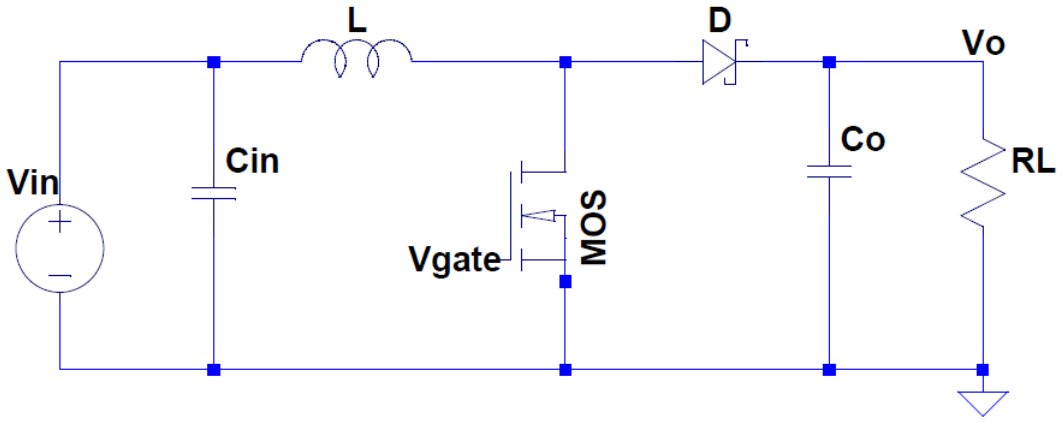
$$V_{Loff} = -V_o. \tag{3.6}$$

Similarly, using Eqs. (3.2) and (3.6), the current variation of the inductor ΔI_{Loff} can be calculated as:

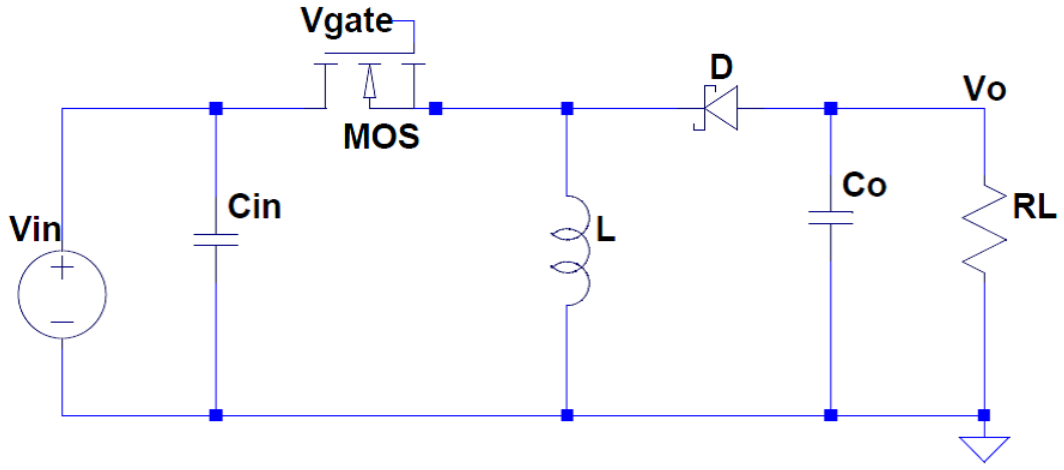
$$\Delta I_{Loff} = -\frac{V_o}{L}(1 - D)T. \tag{3.7}$$



(a)



(b)



(c)

Figure 3.2: Circuit diagram of three basic topologies DC-DC converters. (a) Buck converter. (b) Boost converter. (c) Buck-boost converter.

Based on Eqs. (3.3), (3.5) and (3.7), it yields:

$$V_{\mathrm{o}} = DV_{\mathrm{in}}. \tag{3.8}$$

R_{in} is the average input resistance of the converter and R_{L} is the load resistance. P_{in}, P_{o} are the input power and output power, respectively. Then:

$$P_{\mathrm{in}} = \frac{V_{\mathrm{in}}^2}{R_{\mathrm{in}}}, \tag{3.9}$$

$$P_{\mathrm{o}} = \frac{V_{\mathrm{o}}^2}{R_{\mathrm{L}}}. \tag{3.10}$$

Assuming it is an ideal converter, the input power P_{in} should equal the output power P_{o}. Then it means:

$$\frac{V_{\mathrm{in}}^2}{R_{\mathrm{in}}} = \frac{V_{\mathrm{o}}^2}{R_{\mathrm{L}}}. \tag{3.11}$$

According to Eqs. (3.8) and (3.11), R_{in} can be written as:

$$R_{\mathrm{in}} = \frac{1}{D^2} R_{\mathrm{L}}. \tag{3.12}$$

As $D < 1$, then, $R_{\mathrm{in}} > R_{\mathrm{L}}$ for the buck converter.

B). Boost converter

Similarly, as shown in Fig. 3.2(b), the current flows through the inductor to the ground then the diode and load are shorted at on-state. The inductor current is increasing linearly to the peak value I_{LP}. At off-state, the current flows through the inductor and diode to the load. Then, the inductor current is decreasing to the valley value I_{LV}. This yields following equations.

$$V_{\mathrm{o}} = \frac{1}{1-D} V_{\mathrm{in}}, \tag{3.13}$$

$$R_{\mathrm{in}} = (1-D)^2 R_{\mathrm{L}}. \tag{3.14}$$

Hence, as for boost converter, $R_{\mathrm{in}} < R_{\mathrm{L}}$.

C). Buck-boost converter

As shown in Fig. 3.2(c), the current flows through the inductor to the ground at on-state. The inductor current is increasing linearly to the peak value I_{LP}. At off-state, the current flows through the inductor to the load and diode. Then,

the inductor current is decreasing to the valley value I_{LV}. The polarity of the output voltage V_{o} is negative because the converter inverts the polarity of input and output voltages. This gives following equations.

$$V_{\mathrm{o}} = -\frac{D}{1-D}V_{\mathrm{in}}, \tag{3.15}$$

$$R_{\mathrm{in}} = (\frac{1}{D} - 1)^2 R_{\mathrm{L}}. \tag{3.16}$$

Hence, as for buck-boost converter, $0 < R_{\mathrm{in}} < \infty$. It can be smaller than R_{L} or bigger than R_{L}.

Therefore, we summarize the relationships of input/output resistances and input/output voltages for these three basic topologies DC-DC converters in CCM in Table 3.1.

Table 3.1: Input/output resistance and voltage relationships of three basic topologies DC-DC converters in CCM.

Topology	Voltage	Resistance	Variation of R_{in}
buck	$V_{\mathrm{o}} = DV_{\mathrm{in}}$	$R_{\mathrm{in}} = \frac{1}{D^2}R_{\mathrm{L}}$	$R_{\mathrm{L}} < R_{\mathrm{in}} < \infty$
boost	$V_{\mathrm{o}} = \frac{1}{1-D}V_{\mathrm{in}}$	$R_{\mathrm{in}} = (1-D)^2 R_{\mathrm{L}}$	$0 < R_{\mathrm{in}} < R_{\mathrm{L}}$
buck-boost	$V_{\mathrm{o}} = -\frac{D}{1-D}V_{\mathrm{in}}$	$R_{\mathrm{in}} = (\frac{1}{D} - 1)^2 R_{\mathrm{L}}$	$0 < R_{\mathrm{in}} < \infty$

3.2.2 DC-DC Converter in DCM

In some cases, the amount of energy required by the load is small enough to be transferred in a time not the whole commutation period. In this case, the DC-DC converter operates in DCM, where the current through the inductor falls to zero during a part of the period. Figure 3.3 shows the operating waveform of the inductor (I_{L}) in DCM at the steady condition. There are three states according to three time intervals. 0 - $t1$ is the on-state that the inductor current is increasing linearly; $t1$ - $t2$ is the off-state that the inductor current is decreasing linearly; $t2$ - T is the zero-state that the inductor current is zero. Those time intervals satisfy

following equations:

$$t1 = DT, \tag{3.17}$$

$$t2 - t1 = \delta T. \tag{3.18}$$

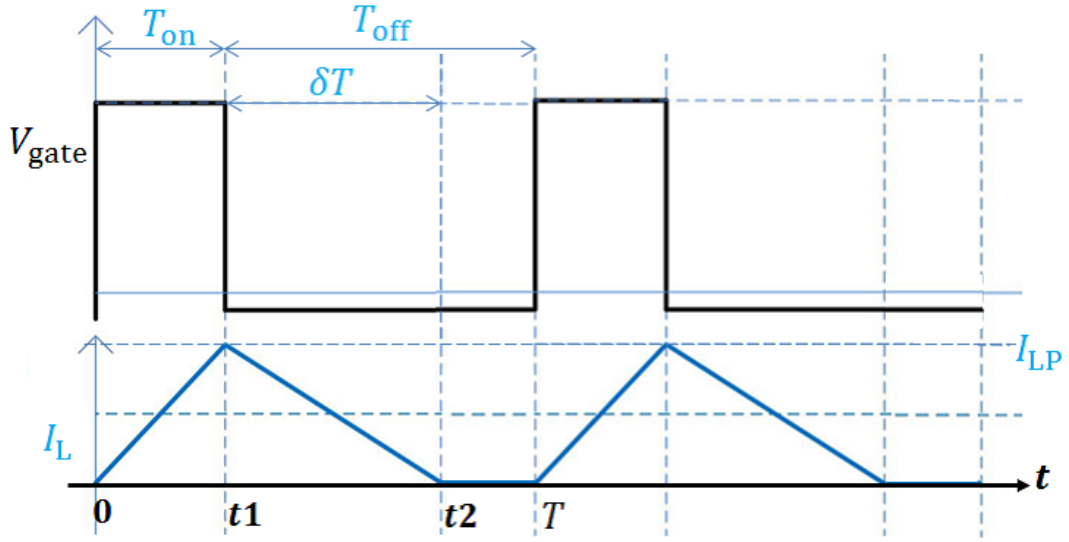


Figure 3.3: Operating waveforms of the inductor current (I_L) and gate control voltage (V_{gate}) for a DC-DC converter in DCM.

The only difference with the CCM is that the inductor is completely discharged at the end of the commutation cycle. Although slight, the difference has a strong effect on the output voltage equation and the input resistance equation.

A). Buck-boost converter

Referring to the Fig. 3.2(c), the current flows through the N-MOS to the inductor at on-state which makes the input voltage (V_{in}) appear across the inductor. The inductor current is increasing from 0 to the peak value I_{LP}. Considering Eqs. (3.2) and (3.17), inductor current variation at on-state ΔI_{Lon} can be written as following:

$$\Delta I_{Lon} = \frac{DT}{L} V_{in}. \tag{3.19}$$

At the off-state, the current flows through the inductor to the load and diode until the inductor current falls to zero through δT period. Assuming zero voltage drop across the diode, the output voltage (V_o) appears across the inductor. Then the inductor current variation at off-state ΔI_{Lon} is given by:

$$\Delta I_{Loff} = \frac{\delta T}{L} V_o. \tag{3.20}$$

Applying Eqs. (3.19) and (3.20) to Eq. (3.3) leads to the following:

$$\delta = -D\frac{V_{\text{in}}}{V_{\text{o}}}. \tag{3.21}$$

At the zero-state, the inductor current maintains zero and there is no current flowing to the load which seems that the converter falls into sleeping interval.

As analyzed above, no current flows to the diode and load during the on-state. The output current (I_{o}) is equal to the average of the diode current. During the off-state, the diode current is equal to the inductor current. Therefore, I_{o} can be written as following:

$$I_{\text{o}} = \delta\frac{I_{\text{LP}}}{2}. \tag{3.22}$$

Based on Eqs. (3.19), (3.21) and (3.22), V_{o} is obtained as following:

$$V_{\text{o}} = -\frac{D^2T}{2LI_{\text{o}}}V_{\text{in}}^2. \tag{3.23}$$

Compared to Eq. (3.15), the relationships of the input/output voltage for DCM are much more complicated than that in CCM.

Additionally, considering $P_{\text{o}} = |V_{\text{o}}I_{\text{o}}|$, Eq. (3.23) can be rewritten as following:

$$P_{\text{o}} = \frac{D^2T}{2L}V_{\text{in}}^2. \tag{3.24}$$

Assuming it is an ideal DC-DC converter, then $P_{\text{in}} = P_{\text{o}}$ is formed. Combining Eqs. (3.9) and (3.24), it is obvious that:

$$R_{\text{in}} = \frac{2L}{D^2T}. \tag{3.25}$$

If f_{sw} is the frequency of the V_{gate}, then, $f_{\text{sw}} = \frac{1}{T}$. Hence, Eq. (3.25) can be rewritten as following:

$$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}. \tag{3.26}$$

As seen from Eq. (3.26), the input resistance R_{in} is independent of the input voltage V_{in} and the load resistance R_{L} with respect to the buck-boost converter in DCM. The input resistance R_{in} is only decided by the inductance L, switching frequency f_{sw} and the duty-on ratio D.

B). Buck converter

For the same reason, the variation of the inductor current should be zero among the on-state and off-state. Then δ can be given by following:

$$\delta = D\frac{V_{\text{in}} - V_{\text{o}}}{V_{\text{o}}}. \tag{3.27}$$

The current always flows through the inductor and load both at on-state and off-state as shown in Fig. 3.2(a). Therefore, the output current I_{o} should be equal to the average of the inductor current I_{L}.

$$I_{\text{o}} = \frac{1}{2}(D + \delta)I_{\text{LP}}. \tag{3.28}$$

Applying Eqs. (3.5) and (3.27) to Eq. (3.28) leads to the following:

$$V_{\text{o}} = \frac{1}{\frac{2LI_{\text{o}}}{D^2T} + V_{\text{in}}}V_{\text{in}}^2. \tag{3.29}$$

Similarly, Eq. (3.29) can be rewritten as

$$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}\frac{1}{1 - \frac{V_{\text{o}}}{V_{\text{in}}}}. \tag{3.30}$$

Therefore, the input resistance R_{in} is complicated and depended on the proportion of output and input voltages.

C). Boost converter

Similarly, as for boost converter, the V_{o} and R_{in} also can be expressed as following:

$$V_{\text{o}} = (\frac{D^2T}{2LI_{\text{o}}}V_{\text{in}} + 1)V_{\text{in}}, \tag{3.31}$$

$$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}(1 - \frac{V_{\text{in}}}{V_{\text{o}}}). \tag{3.32}$$

Finally, we summarize the relationships of the input/output resistances and input/output voltages for these three basic topologies DC-DC converters in DCM as shown in Table 3.2. Referring to the Table 3.1, R_{in} of three topologies DC-DC converters in CCM are all relative to the load resistance R_{L}. In the DCM case, R_{in} of buck and boost converters are both relative to the proportion of V_{in} and V_{o}. However, the R_{in} of the buck-boost converter is independent of V_{in}, V_{o} and R_{L}. If the inductance L, switching frequency f_{sw}, duty-on ratio D are decided, the R_{in} of the buck-boost converter can be calculated and it will be constant. Therefore,

Table 3.2: Input/output resistance and voltage relationships of three basic topologies DC-DC converters in DCM.

Topology	Voltage	Resistance	Variation of R_{in}
buck	$V_{\text{o}} = \frac{1}{\frac{2LI_{\text{o}}}{D^2T}+V_{\text{in}}}V_{\text{in}}^2$	$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}\frac{1}{1-\frac{V_{\text{o}}}{V_{\text{in}}}}$	depends on $\frac{V_{\text{o}}}{V_{\text{in}}}$
boost	$V_{\text{o}} = (\frac{D^2T}{2LI_{\text{o}}}V_{\text{in}}+1)V_{\text{in}}$	$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}(1-\frac{V_{\text{in}}}{V_{\text{o}}})$	depends on $\frac{V_{\text{o}}}{V_{\text{in}}}$
buck-boost	$V_{\text{o}} = -\frac{D^2T}{2LI_{\text{o}}}V_{\text{in}}^2$	$R_{\text{in}} = \frac{2Lf_{\text{sw}}}{D^2}$	independent of V_{in} and R_{L}

a buck-boost converter operated in DCM is chosen for impedance matching in the rectenna circuit.

3.3 Externally-powered DCM Buck-boost Converter

3.3.1 Input Resistance R_{in}

The buck-boost converter in DCM exhibits constant input resistance despite the load resistance as mentioned above. However, it inverts the polarity of input and output voltages. Therefore, we design an inverting DCM buck-boost converter which inputs a negative voltage to get a positive output voltage. The proposed inverting DCM buck-boost converter is shown in Fig. 3.4(a) where the control-pulse circuit consists of a 5 V power source, a low-frequency (LH) oscillator, a high-frequency (LH) oscillator and a MOSFET gate driver. The LF and HF oscillators respectively generate the LF, HF pulse waves which are combined into the gate control pulse V_{gate}. Through the gate driver, the V_{gate} controls the N-MOS's gate on or off. Here, the input port of the converter is expected to be connected to the output of the rectenna (or rectifier). Figure 3.4(b) shows the operating waveform of the proposed converter where I_{in}, I_{L}, I_{D} are input current, inductor current, diode current, respectively, and V_{gate}, V_{h}, V_{ι} are gate control pulse wave, HF pulse wave, LF pulse wave, respectively. An additional 5 V power source powers the LF oscillator and gate driver, and the HF oscillator is powered

by the LF oscillator. It means that the V_{gate} is as same as the V_{h} when the V_{ι} is on while the V_{gate} is off when the V_{ι} is off. As seen from the waveform, there is no current flowing though the circuit at the off-state of the LF oscillator. It seems that the LF oscillator compels the circuit to be sleep state at an interval then the current becomes discontinuous.

The operating condition can be classified into two states such as a work-state and a sleep-state. The work-state is when the LH pulse is on. At work-state, there are three operating states as same as mentioned in Chapter 3.2.2. The sleep-state is when the LH pulse is off. At sleep-state, there is no current flowing through the circuit. As shown in Fig. 3.4(b), the input current is equal to the inductor current only at the on-state. If I_{inave} is the average input current, then:

$$I_{\text{inave}} = \frac{I_{\text{LP}} D_{\text{h}} D_{\iota}}{2}, \tag{3.33}$$

where D_{h}, D_{ι} are the high, low frequency pulse duty-on ratio. Referring to Eq. (3.19), the peak inductor current I_{LP} can be written as following:

$$I_{\text{LP}} = \frac{V_{\text{in}} D_{\text{h}} T_{\text{h}}}{L}, \tag{3.34}$$

where the T_{h} is the period of the HF pulse. Furthermore, input power P_{in} satisfies the following equation:

$$P_{\text{in}} = V_{\text{in}} I_{\text{inave}}. \tag{3.35}$$

Combining Eqs. (3.9), (3.33), (3.34) and (3.35), the input resistance R_{in} is given as follows:

$$R_{\text{in}} = \frac{2L}{D_{\text{h}}^2 D_{\iota} T_{\text{h}}}. \tag{3.36}$$

Let f_{h} represent the frequency of the HF pulse, applying $T_{\text{h}} = \frac{1}{f_{\text{h}}}$ to Eq. (3.36) leads to the following:

$$R_{\text{in}} = \frac{2L f_{\text{h}}}{D_{\text{h}}^2 D_{\iota}}. \tag{3.37}$$

Hence, the R_{in} of the proposed inverting DCM buck-boost converter is decided by the inductance L , low, high frequency pulse duty-on ratio D_{ι}, D_{h} and the high frequency f_{h}.

Table 3.3: Components of the proposed inverting DCM buck-boost converter.

Component	Maker	Part NO.	Description
High-frequency oscillator	Linear Technology	LTC6900	$I_{SS} = 0.5$ mA ($f = 3$ MHz); $V_{SSmin} = 2.7$ V
Low-frequency oscillator	Linear Technology	LTC6992	I_{SS}= 115 μA ($f = 100$ Hz); $V_{SSmin} = 2.25$ V
N-MOS	Fairchild	FDS6298	$V_{DSS} = 30$ V; $R_{DS(on)} = 12$ mΩ ($V_{GS} = 4.5$ V)
Schottky Diode	Toshiba	CRS01	$V_{RRM} = 30$ V; V_{FM}= 0.36 V
MOSFET Driver	Microchip	TC1427	$V_{DDmin} = 4.5$ V
Inductor	Panasonic	ELC18B102L	$L = 1$ mH; $R_{dc} = 0.39$ Ω; I_{dc} = 1.1 A
Capacitor	Rubycon	Electrolytic Capacitors	$C_{in} = 47$ μF ($V_{rated} = 10$ V); $C_o = 100$ μF ($V_{rated} = 50$ V)

3.3.2 Simulation and Experimental Results

In this buck-boost converter, set $L = 1$ mH, $D_h = 0.5$, $D_\iota = 0.6$, and $f_h = 10$ kHz, so that the input resistance of the converter R_{in} becomes 133 Ω, as calculated using Eq. (3.37). Table 3.3 lists the components used in the buck-boost converter, and Fig. 3.5 shows a photograph of the buck-boost converter, which uses dielectric substrate as a printed circuit board (PCB).

In order to verify the theory as mentioned above, we simulate the converter by LTspice and conduct an experiment on it. The structure of the experiment circuit is shown in Fig. 3.6, where a negative voltage supplied by a DC power source is the input voltage. A +5 V power source supplies the power for the control-pulse circuit. An ammeter and a voltmeter measure the input current and the output voltage, respectively. We measure the efficiency and the input resistance of the converter with an input voltage from 0.8 to 5 V, where the input power is from 5 to 187 mW. Figure 3.7 shows the simulation and experimental results for input

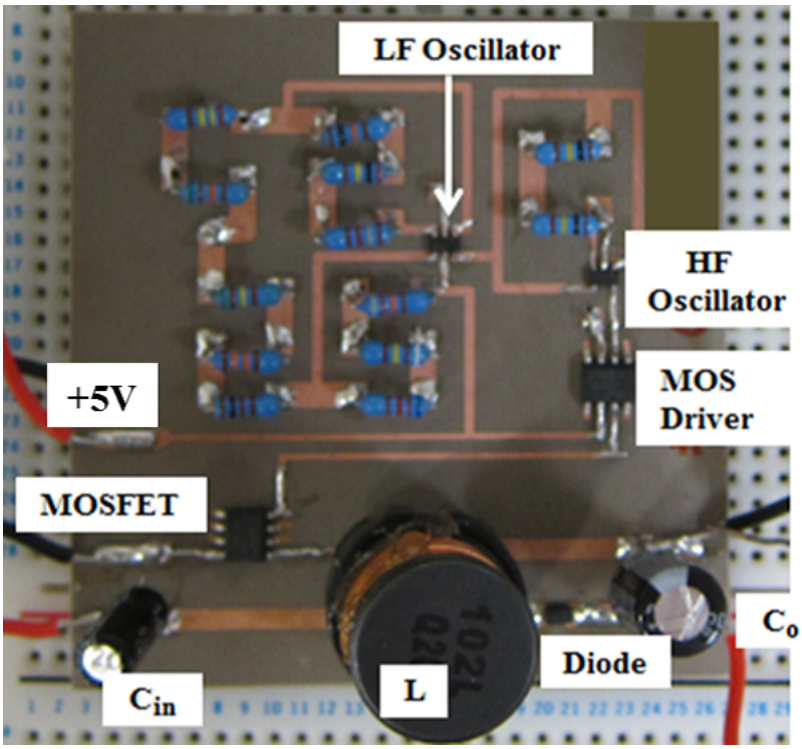

Figure 3.5: Photograph of the inverting DCM buck-boost converter.

resistance R_{in} versus the load resistance R_L from 100 to 5000 Ω for the input voltage of 1.2 and 3 V. According to Fig. 3.7, the simulation results almost agree well with the theory of 133 Ω. The experimental R_{in} is near the calculated value of 133 Ω, but it is slightly lower for a low load resistance when the R_L is smaller than 400 Ω. This is because the inductor current becomes continuous at the beginning of the switching-on period of the MOSFET at a low load resistance. However, the equation of the input resistance (Eq. (3.37)) is calculated as a discontinuous conduction mode. Thus, the measured input current is slightly larger than the calculated value. Consequently, the input resistance is smaller than the calculated value. Figure 3.8 shows the R_{in} versus the input power from 2 to 187 mW for the load resistance of 1000 Ω. According to Fig. 3.8, the experimental R_{in} almost agrees with the simulation results, and it is varying in the range of 123 to 133 Ω as the input power is changing from 5 to 187 mW. Therefore, according to Figs. 3.7 and 3.8, as expected, the designed buck-boost converter has constant input resistance despite the load resistance and the input power.

Furthermore, the efficiency of the converter is also measured. Here, the efficiency does not include the power dissipated by the control circuit. Similarly, Figure 3.9 shows the measured efficiency of the converter for load resistances from 100 to 5000 Ω for the input voltage of 1.2 and 3 V, where the input power are 12

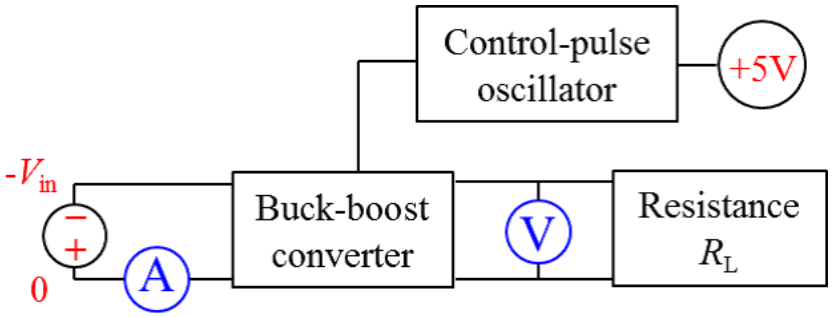

Figure 3.6: Measurement setup of the externally-powered buck-boost converter. An extra +5 V power source is required.

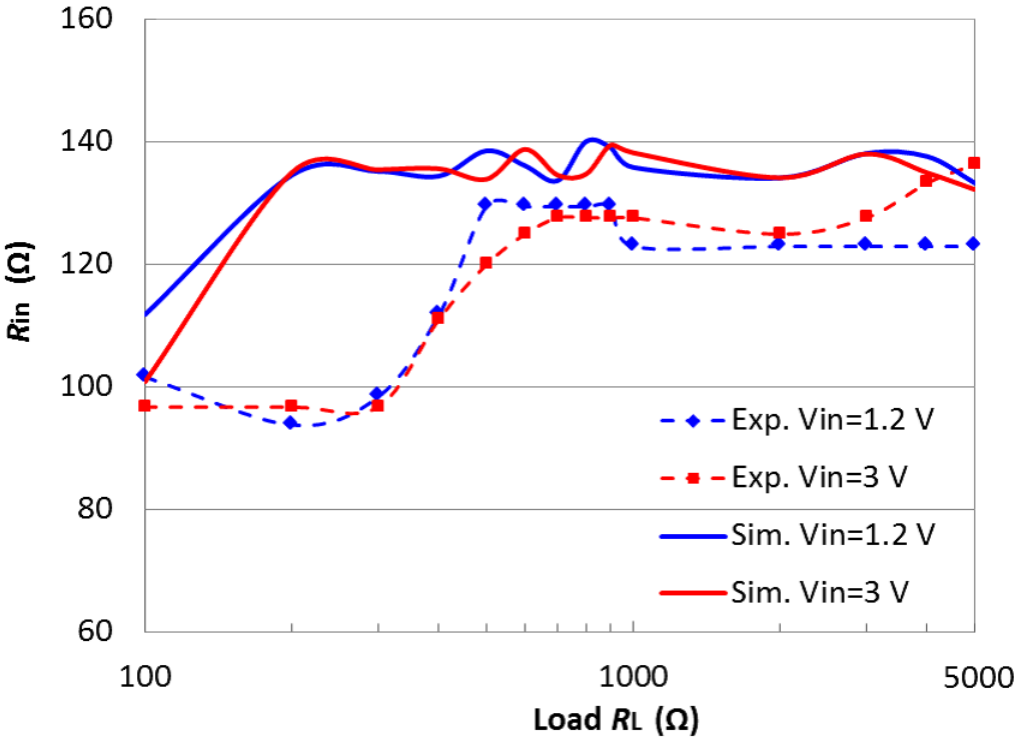

Figure 3.7: Simulation and experimental results of the input resistance R_{in} vs. load resistance for an input voltage of 1.2 or 3 V.

and 70 mW, respectively. The efficiency is almost greater than 80 % for a wide range of loads from 200 to 5000 Ω at the input voltage of 3 V. The efficiency is a little low at load resistance of 100 Ω because the load resistance is smaller than the input resistance and the input voltage is reduced by the converter. At this moment, the converter works as a buck converter, where the output voltage is lower than the input voltage. The efficiency decreases under a large load resistance because the output current is shunted by the output capacitor. The current flowing through the output capacitor will increase as the load resistance is increased. Figure 3.10 shows the measured efficiency of the converter for input power from

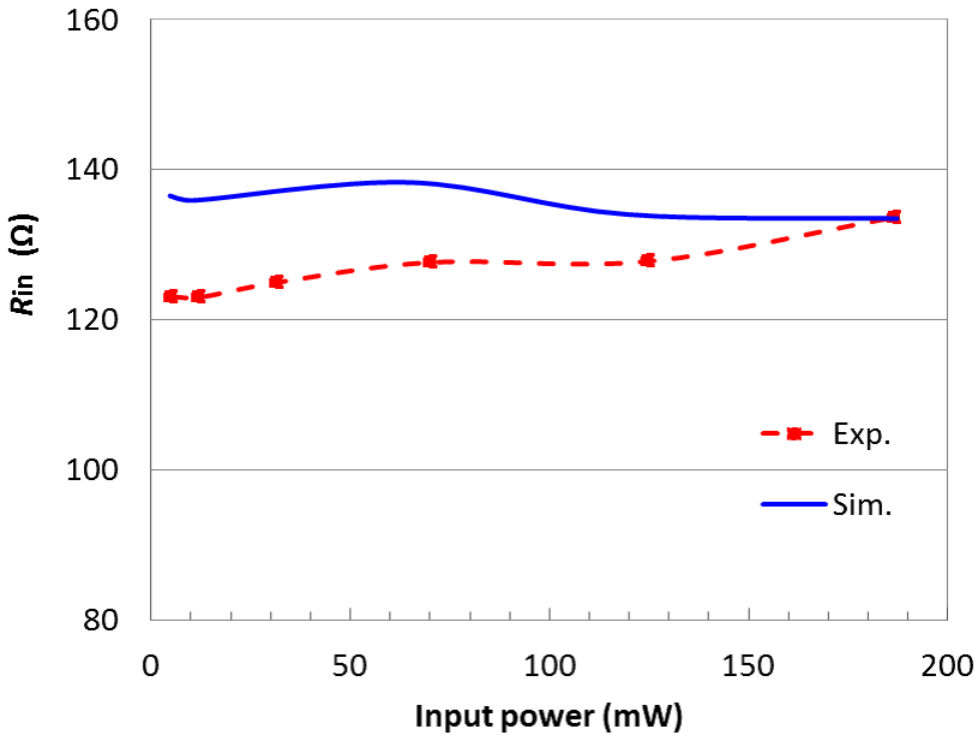

Figure 3.8: Simulation and experimental results of the input resistance R_{in} vs. input power for a fixed load resistance of 1000 Ω.

5 to 187 mW for a fixed load resistance of 1000 Ω. The efficiency is increasing lightly as the input power is increasing. In this case, the measured efficiency is greater than 85 % for this wide range of input powers. Additionally, since ideal capacitors and wires are used in the simulation, the measured efficiency is almost 5 % lower than the simulation results which both can be seen from Figs. 3.9 and 3.10.

3.4 Rectifying Circuit with Negative Output Voltage

As mentioned in Chapter 2.3, there are two types of dc pass filters such as a $\lambda/4$ line plus a capacitor [58] and a $\lambda/4$ line plus some open stubs in single shunt rectifier. The authors obtained a higher experimental efficiency using open stubs instead of capacitor [59]. We also utilize a $\lambda/4$ line plus four open stubs as a dc pass filter as shown in Fig. 3.11(a). The impedance of the dc pass filter Z_{dc}, opposite to the class-F^{-1} mode [68], presents zero for even harmonics and

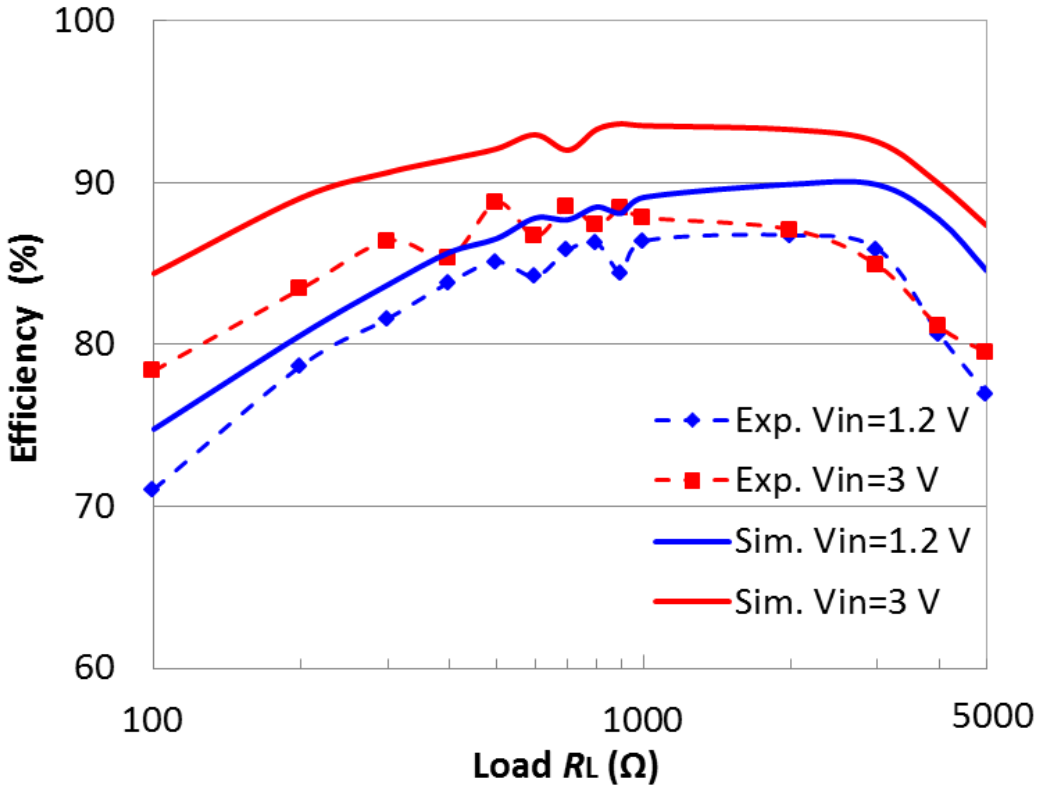

Figure 3.9: Simulation and experimental results of the efficiency vs. load resistance for an input voltage of 1.2 or 3 V.

infinity for odd harmonics. In other words, all even harmonics are terminated in short circuits and all odd harmonics are terminated in open circuits. The set of harmonic terminations is the same as for a class-F amplifier [69], thus this rectifier is referred to as a class-F rectifier. In fact, the impedance of the dc pass filter, consisted of a $\lambda/4$ line and a capacitor in shunt, also presents a class-F characteristic which is analyzed in [59]. Due to the parasitic components of a real capacitor, the combination of a $\lambda/4$ line and a capacitor can not satisfy the demand of the dc pass filter characteristic for high harmonica frequencies.

The designed buck-boost converter inverts the polarity of the input voltage and the output voltage, which is described in Chapter 3.3. Hence, unlike other rectifiers, we reverse the polarity of the diode in order to obtain a negative output voltage from the rectifier. There is a little discussion and comparison about the diode topologies in single, two-diode package and two anti-parallel diodes in [57] which indicates that two-diode rectifier would result in higher efficiency for high power levels. Additionally, the rectifier using two-diode parallel HSMS2865 or three-diode parallel HSMS286L obtained a higher efficiency in simulation results

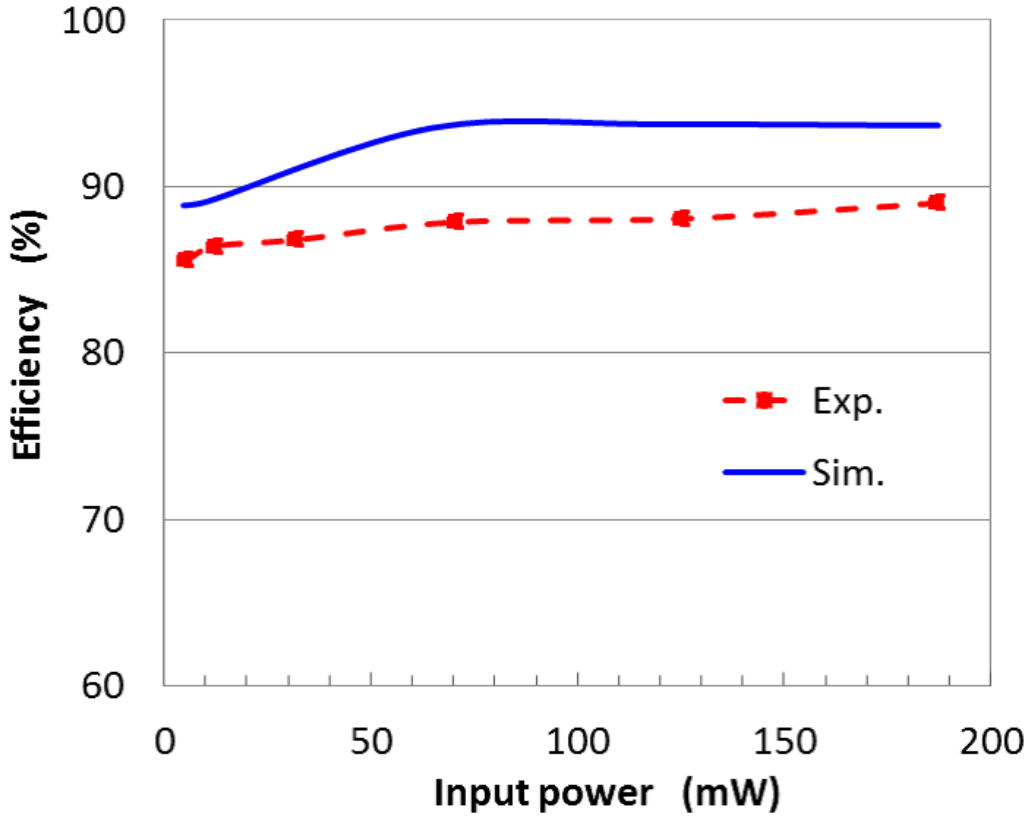

Figure 3.10: Simulation and experimental results of the efficiency vs. input power for a fixed load resistance of 1000 Ω.

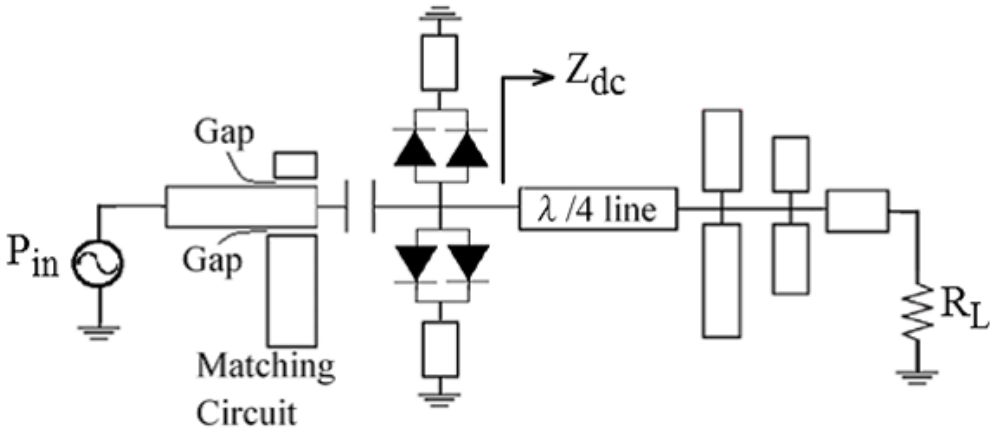
in Chapter 2.3. However, as seen from Fig. 2.2, the physical size of HSMS2865 (4 pins) and HSMS286L (6 pins) are too wide to limit the characteristic impedance of the connected microstrip line. Therefore, considering the physical size and the parallel diodes, we choose two HSMS286F as a rectifying diode. HSMS286F diode, consisting of two HSMS2860 diodes mounted into a single surface mount package, has 3 pins because of a common cathode pin. Table 3.4 lists the components used in the rectifier and Fig. 3.11(b) shows the photograph of the designed rectifier.

We first simulate the rectifying circuit using ADS2011. We optimize the whole rectifying circuit to gain the highest efficiency not just considering the impedance matching with the diodes but also reducing the dissipation power of diodes in the simulation. Then, we fabricate it and test it with 2.45 GHz microwave power. The simulation and experimental results of the rectifier circuit are shown in Fig. 3.12.

Figure 3.12(a) shows the RF-DC conversion efficiency versus load resistances ranging from 50 to 1000 Ω, which represents a typical efficiency characteristic of



(a)

Figure 3.11: Proposed negative output voltage rectifier. (a) Structure. (b) Photograph.

the rectifying circuit. The two solid curves are simulation results and the dot curve is the experimental results. Sim.1 gets the maximum simulation efficiency of 82.5 % at the input power of 69 mW. However, the maximum experimental efficiency is 79.2 % at input power of 82 mW as shown in Exp. curve. Then, when we set the input power as 82 mW in simulation, the maximum efficiency of 81.8 % is obtained (Sim.2 curve). The detailed results of these three curves are summarized in Table 3.5. We obtain the maximum efficiency of 79.2 % at an optimal load of 160 Ω. In particular, the measured efficiency difference between an optimal load of 160 and 1000 Ω is approximately 53 %, which clearly indicates that the efficiency of the rectifier depends on the load resistance.

Figure 3.12(b) shows the simulation and experimental efficiency versus the

Table 3.4: Components of the negative output voltage rectifier.

Component	Maker	Part NO.	Description
DC block capacitor	Murata	GRM1882C1-H331JA01D	$C = 330$ pF; $V_{\text{rated}} = 50$ V
HF diode	Avago	HSMS286F	Refer to Table 2.2
Dielectric substrate	Nippon pillar	NPC-F260	$\varepsilon_{\text{r}} = 2.53$; $\tan\delta = 0.0018$; $t = 18$ μm; H = 0.8 mm

Table 3.5: Comparison of simulation and experimental results of the rectifier.

	Input power	Efficiency	Reflection	Optimal load
Sim.1	69 mW	82.5 %	1.6 %	135 Ω
Exp.	82 mW	79.2 %	4.9 %	160 Ω
Sim.2	82 mW	81.8 %	3.4 %	110 Ω

input power ranging from 20 to 170 mW at the load of 150 Ω. The efficiency is changing with the input power while the maximum difference in efficiency is only 10 % for this range of input powers. In simulation, the maximum efficiency is obtained at the input power of 60 mW, while the efficiency drops rapidly with the input power exceeding 60 mW because the reverse voltage is over the breakdown voltage of the diode. However, in experiment, the efficiency gets much higher even though the input power increases far over 60 mW. A similar phenomena can be seen from Fig. 3.12(a), the experimental efficiency is higher than the simulation one when the load resistance exceeds the optimal load. This is because the real breakdown voltage is higher than the value (7 V) given by the SPICE parameters. A high precision HF diode model is required in ADS simulation.

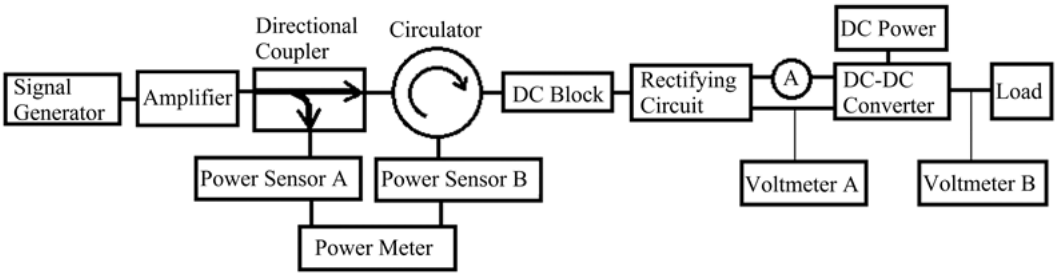
Table 3.6: Efficiency and load relationships of the rectifier and buck-boost converter in experimental results.

	R_L	R_{in}	Efficiency
RF-DC rectifier	130 Ω		78 %
buck-boost converter	400-5000 Ω	130 Ω	80 %
RF-DC-DC circuit	400-5000 Ω		predicted value 62 %

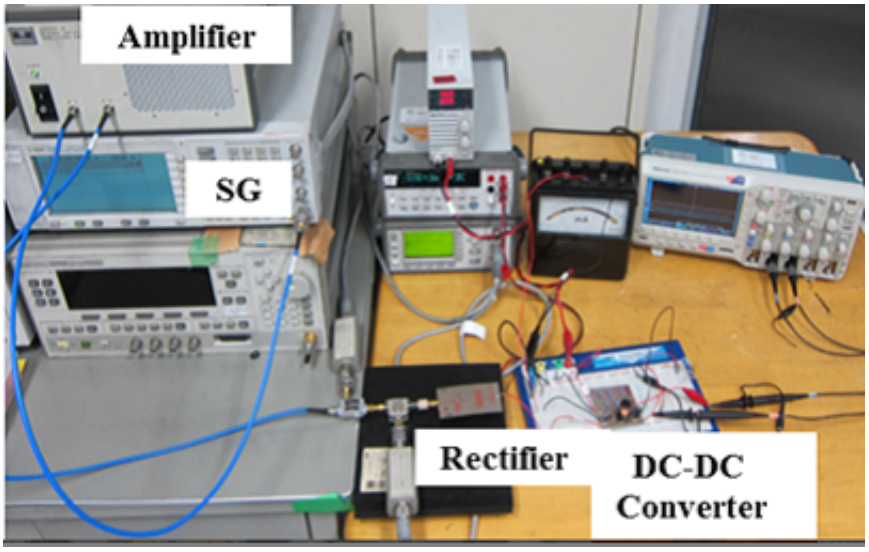
3.5 Experiment on Externally-powered RF-DC-DC Circuit

The experiment on the RF-DC-DC circuit consisted of the rectifier and the buck-boost converter designed above is conducted. Figure 3.13(a) is the experimental architecture for measuring the efficiency of the RF-DC-DC circuit and Fig. 3.13(b) is the experiment photograph. The microwave power is first regulated by the RF-DC rectifier, and the DC output voltage of the RF-DC rectifier is again regulated by the buck-boost converter. The input resistance of the DC-DC converter seen from the left side is also the output impedance of the rectifier. Summarize the efficiency and load relation of the rectifier and the buck-boost converter designed above in Table 3.6. The designed R_{in} of the converter is 133 Ω which is slightly different with the optimal load (160 Ω) of the rectifier, while the efficiency of the rectifier at 133 Ω is only 1.2 percentage points lower than that at the optimal load. Thus, as expected, the buck-boost converter can track the maximum efficiency of the rectifier and the overall efficiency of the RF-DC-DC circuit is expected to be steady and over 62 %.

Following Fig. 3.13(a), we use a 2.45 GHz microwave power generated from a signal generator. Power sensor A measures the input power of the rectifier. Through the circulator, power sensor B measures the reflection power at the input point of the DC block. Here, we use a DC block to prevent the DC voltage from passing through the rectifier, which also can prevent the positive output pole of the rectifier from being grounded, because the positive input pole of the buck-boost converter is not allowed to become grounded. Referring to Fig. 3.4, if the



(a)



(b)

Figure 3.13: Experimental setup for measuring the efficiency of the RF-DC-DC circuit. (a) Block diagram. (b) Experiment photograph.

positive input pole of the converter is grounded, the MOSFET will be shorted and the converter can not act as a buck-boost converter. An ammeter is used to measure the input current of the converter, and voltmeters A and B are used to measure the output voltage of the rectifier and the output voltage of the converter, respectively. We use DC power for the control circuit to supply voltage to the LF oscillator and the gate driver in the experiment. Before reporting the experimental results, the tracking efficiency η_{track} is defined as follows:

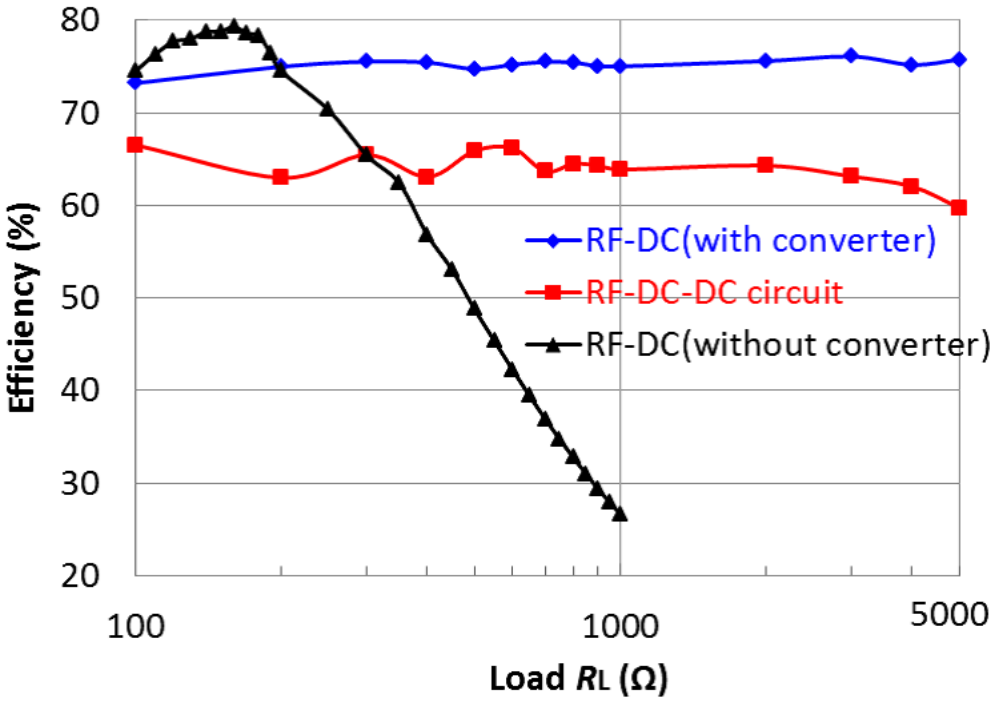
$$\eta_{\text{track}} = \frac{\eta'_{\text{rf-dc}}}{\eta_{\text{max(rf-dc)}}} \times 100\,\%, \tag{3.38}$$

where $\eta'_{\mathrm{rf-dc}}$ is the conversion efficiency of the RF-DC rectifying circuit when it is connected to the buck-boost converter, and $\eta_{\mathrm{max(rf-dc)}}$ is the maximum conversion efficiency of the RF-DC rectifying circuit at the optimal load without a buck-boost converter.

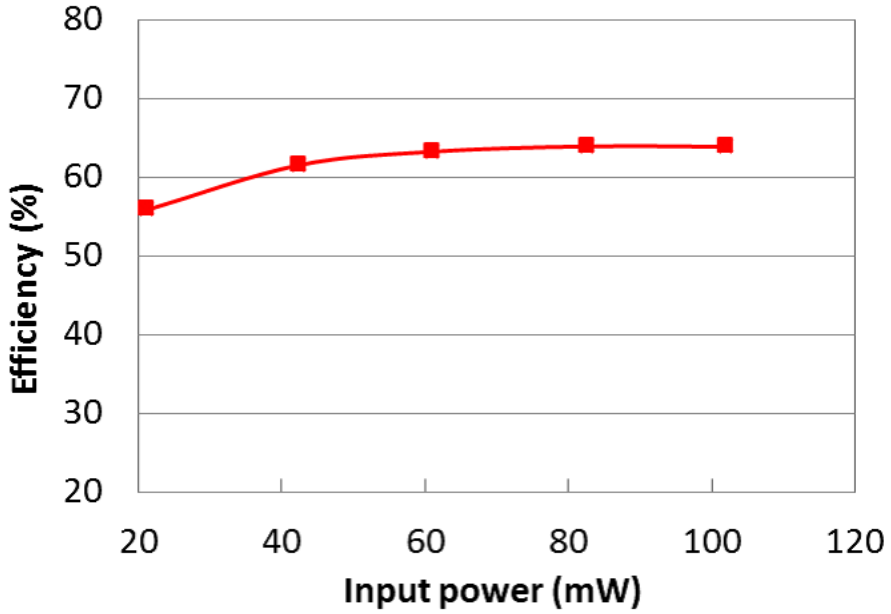
Figure 3.14 shows the measured efficiency versus the load resistance from 100 to 5000 Ω and an input power from 20 to 100 mW. Figure 3.14(a) compares the efficiency of the RF-DC-DC circuit with the rectifying circuit described in Chapter 3.4 under the input power of 82 mW. The blue curve, RF-DC (with converter), is the efficiency of only the rectifying circuit when it is connected to the buck-boost converter. The black curve, RF-DC (without converter), is the efficiency of the rectifying circuit alone when it is not connected to the buck-boost converter. The black curve decreases dramatically when the load exceeds the optimal load and the efficiency is only 26 % at the load of 1000 Ω. In comparison, the conversion efficiency of the rectifying circuit connected with the converter is almost steady at 75 %, which is near the maximum power point of the rectifying circuit, even though the load resistance is changed from 100 to 5000 Ω. Furthermore, as expected, the overall efficiency of the RF-DC-DC circuit is over 60 % in a wide range of load resistances from 100 to 5000 Ω, as indicated by the red curve. Compared to the rectifying circuit without a converter, the overall efficiency is lower than that when the load is below 300 Ω. However, the overall efficiency is much higher than that when the load exceeds 300 Ω. Under the large load resistance, the overall efficiency decreases slightly because the efficiency of the buck-boost converter decreases as the load increases.

Figure 3.14(b) shows the overall efficiency versus the input power changing from 20 to 100 mW at the load resistance of 1000 Ω. Note that the variation of the overall efficiency is small and the overall efficiency is over 55 % in this power range.

Additionally, we also check the tracking efficiency and the input resistance R_{in} of the buck-boost converter when it is utilized in the RF-DC-DC circuit as shown in Fig. 3.15. Figure 3.15(a) shows that the tracking efficiency η_{track} remains over 92 % over the entire range of loads from 100 to 5000 Ω and the input resistance R_{in} is approximately near to the designed value of 133 Ω. The coherent variation trend of two curves can be seen from Fig. 3.15(a). This is because the $\eta'_{\mathrm{rf-dc}}$ is increasing when the R_{in} is close to 133 Ω, which leads to η_{track} increasing according to Eq. (3.38). Similarly, Fig. 3.15(b) presents η_{track} and R_{in} with input power ranging



(a)



(b)

Figure 3.14: Measured overall efficiency of the RF-DC-DC circuit. (a) Efficiency comparison of the RF-DC-DC circuit and the general rectifier for a constant input power of 82 mW. (b) Overall efficiency vs. input power for a constant load of 1000 Ω.

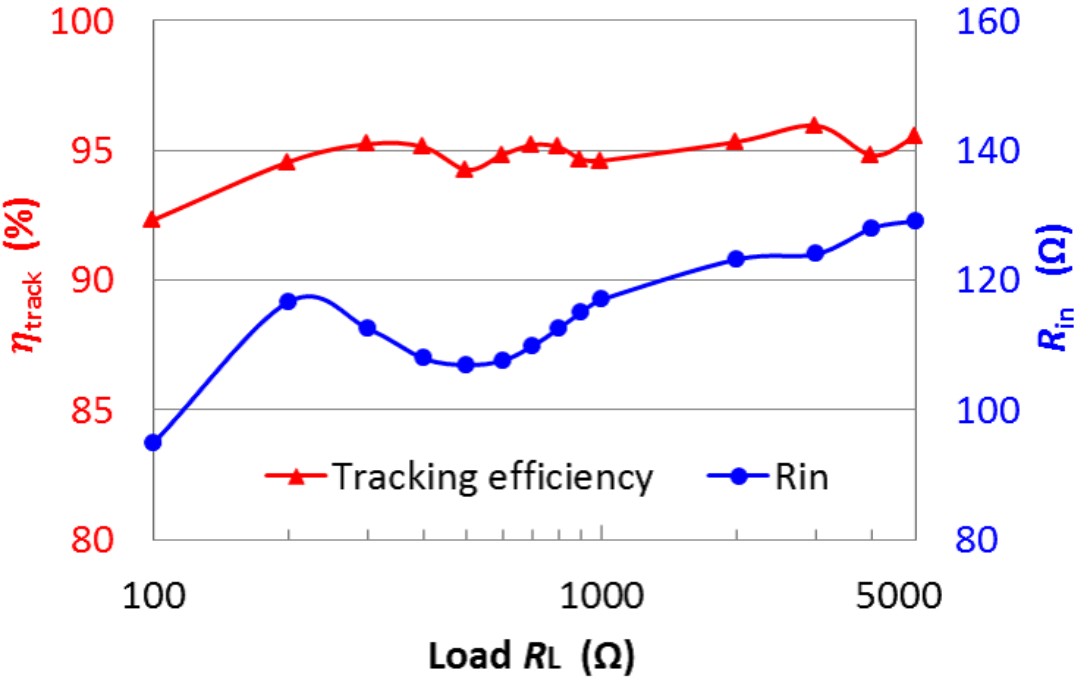
from 20 to 100 mW at the load resistance of 1000 Ω. Note that the tracking efficiency is slightly increasing as the input power increases. The reason is as follows. The input resistance of the converter is close to the optimal load of the rectifier as the input power is increased, which leads to increase in the efficiency of the rectifier ($\eta'_{\mathrm{rf-dc}}$). However, the maximum difference of the tracking efficiency is about 2 percentage points in this power range.

Figure 3.16 compares the output voltage versus load resistance at the input power of 82 mW. The red curve is the output voltage of the RF-DC-DC circuit, which is increasing as the load resistance increases. The black curve is the output voltage of the rectifier when it is not connected to the converter. Compared to it, the blue curve is the output voltage of the rectifier when it is connected to the converter, where the voltage is almost steady at 2.7 V. Note that the RF-DC-DC circuit obtains a higher output voltage than the usual rectifier at a same load resistance. Here, the relation of three voltage curves agree well with the simulation results reported in Fig. 2.14.

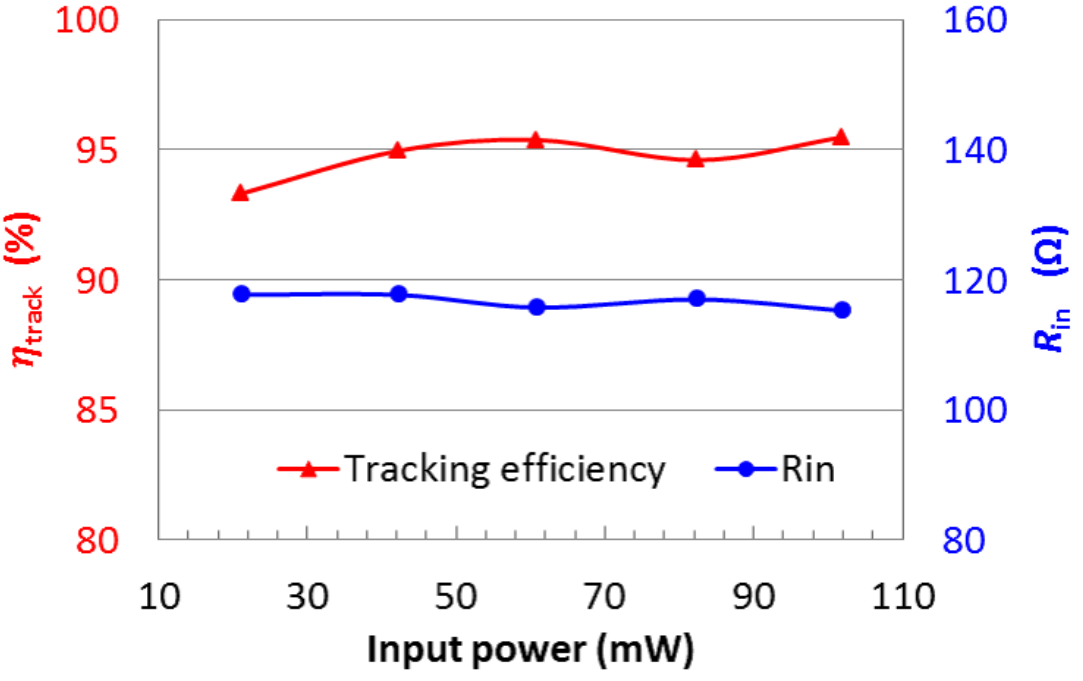
3.6 Summary

This chapter, firstly, from a new viewpoint, the input/output voltages and input/output resistances relationships of three basic topologies DC-DC converters are discussed. Unlike conventional application, the DC-DC converter is used in resistance conversion instead of voltage conversion. Based on the discussion results, a DCM inverting buck-boost converter, whose input resistance is independent of the load resistance or input power, is chosen for impedance matching in rectenna.

Secondly, we design a DCM inverting buck-boost converter which requires an extra DC power source for powering the control-pulse circuit. The buck-boost converter inputs a negative voltage to obtain a positive output voltage. More importantly, the input resistance of the buck-boost converter match the optimal load of the rectifying circuit to track the maximum efficiency point of the rectifying circuit. As expected, the measured input resistance of the buck-boost converter is approximately 133 Ω, despite the changes of the load resistance and input power. The measured efficiency of the converter exceeds 80 % for a wide range of loads or input powers. Next, we design a rectifying circuit with negative output voltage and peak experimental efficiency of 79.2 %.



(a)



(b)

Figure 3.15: Measured tracking efficiency and input resistance R_{in}. (a) Tracking efficiency and R_{in} vs. load resistance. (b) Tracking efficiency and R_{in} vs. input power.

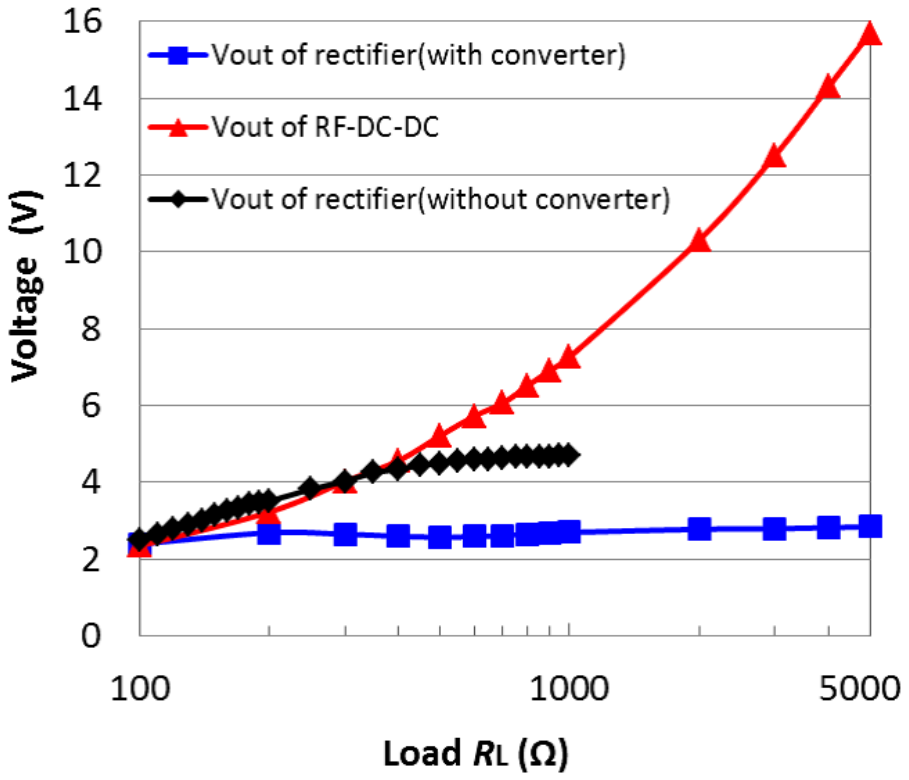


Figure 3.16: Measured output voltage vs. load resistance for a constant input power of 82 mW.

Finally, we verify that the proposed converter successfully tracks the maximum efficiency of the rectifying circuit. The conversion efficiency of the rectifier is approximately steady at 75 %, despite the load resistance varying from 100 to 5000 Ω for an input microwave power of 82 mW. This means that the maximum power tracking efficiency is over 94 %, compared to the maximum efficiency of 79.2 % at the optimal load. Additionally, the overall efficiency of the RF-DC-DC circuit is approximately steady over 60 %, despite the load resistance changing from 100 to 5000 Ω. According to the experimental results, the proposed RF-DC-DC circuit is an effective MPPT method to rectennas.

However, one big disadvantage is that the proposed buck-boost converter requires an additional DC power source for the control-pulse circuit which makes it hard for practical application. Additionally, owing to the loss of the buck-boost converter, the overall efficiency of the RF-DC-DC circuit is much lower than the maximum efficiency of the general rectifying circuit. Therefore, it is necessary to improve the efficiencies both of the rectifying circuit and the converter. Next chapter will give a solution about the problems above.

Chapter 4

Self-powered RF-DC-DC Circuit

4.1 Introduction

Based on the simulation and experiment results of previous discussions, a buck-boost converter in DCM is practicable for impedance matching in rectifying circuit. However, some critical issues such as the lower overall efficiency of the RF-DC-DC circuit and the requirement of an additional DC power source are need to be solved. Therefore, this chapter will solve the issues as mentioned above to improve the RF-DC-DC circuit. To improve the overall efficiency, we design a rectifying circuit with high peak efficiency. Furthermore, the input resistance of the buck-boost converter completely agrees with the optimal load of the rectifying circuit, which increases the tracking efficiency leading to a higher overall efficiency. To remove the additional DC power source, a non-inverting DCM buck-boost converter, whose control-pulse circuit is powered by the output of the rectifying circuit, is proposed. Similarly, an experiment on RF-DC-DC circuit is conducted to verify the advantages of the improved RF-DC-DC circuit.

4.2 High-efficiency Rectifying Circuit

As shown in Fig. 4.1, we also use a class-F rectifier with output filter consisted of a $\lambda/4$ line and four open stubs in this chapter. Compared with the rectifier in Chapter 3.4, the rectifier designed in this chapter has some differences as follows. First, with respect to the input filter, two open stubs are applied for impedance

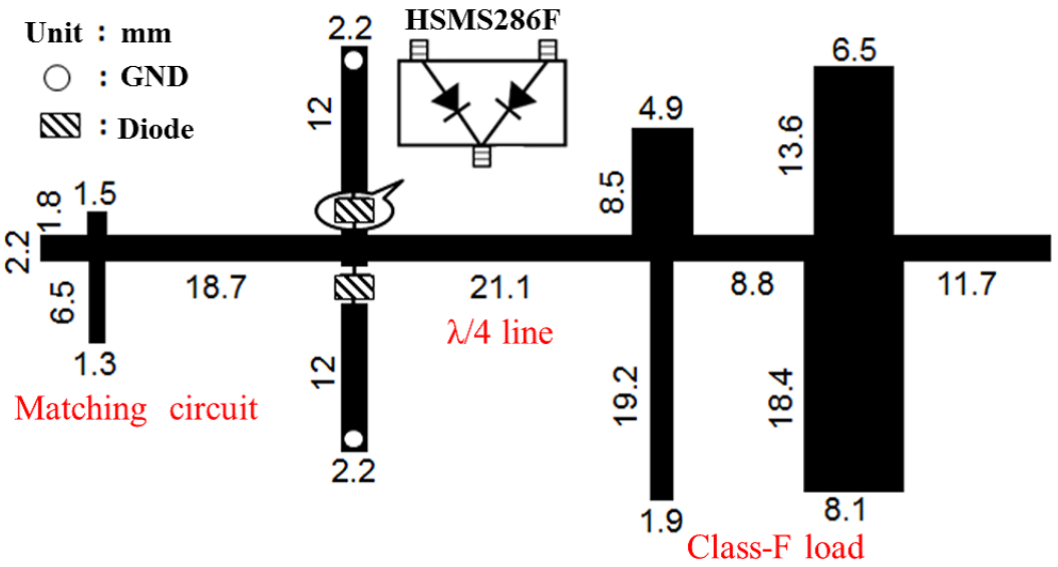
Table 4.1: Efficiency and output voltage with different input powers for a fixed load of 190 Ω.

Input power (mW)	40	60	80	100
Efficiency (%)	80.2	81.9	82.5	81.4
Output voltage (V)	2.46	3.06	3.54	3.93

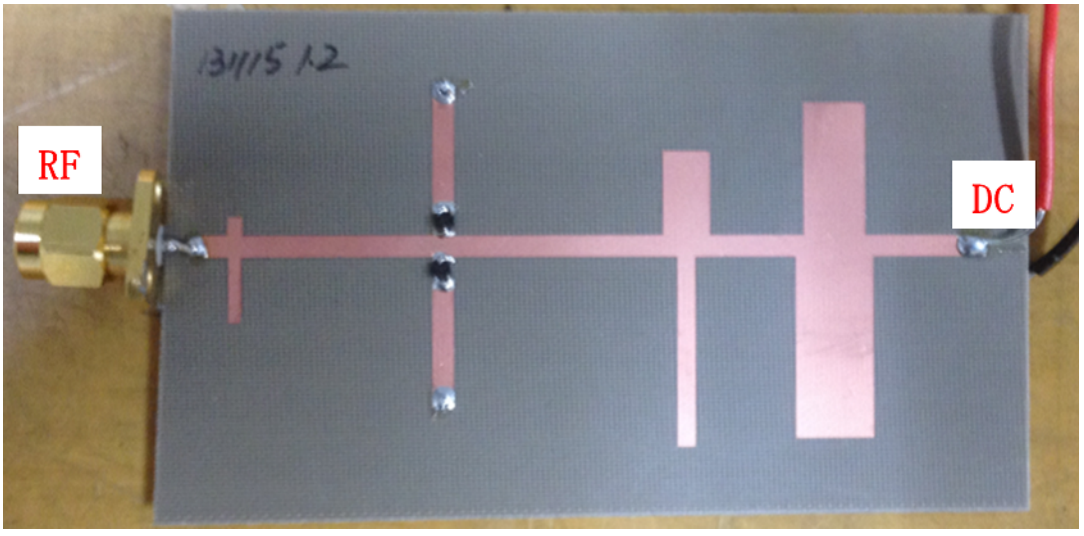
matching at the input port. Second, the DC blocking capacitor is removed because the equivalent series resistance of the capacitor causes some losses. Instead of a DC blocking capacitor in the rectifying circuit, a DC blocking element is used in the experimental equipment to block DC voltage from diodes. Third, the same rectifying diode of HSMS286F is used but the polarity of the diode is inverted to obtain a positive output voltage as usual. In simulation, we optimize the dimensions of each microstrip line to make a trade-off between reflection, diode loss, high harmonic loss and the efficiency until obtaining a high efficiency. Figure 4.1(a) shows the layout circuit and the size of the designed rectifier. We use the same dielectric substrate of NPC-F260 whose parameters are listed in Table 3.4. Figure 4.1(b) shows the photograph of the fabricated rectifier and the whole size of the circuit is approximately as same as the circuit in Chapter 3.4.

Similarly, the efficiency of the rectifying circuit is confirmed and the results are shown in Fig. 4.2. Figure 4.2(a) shows the experimental results of the efficiency versus the load resistance from 100 to 400 Ω for different input powers such as 40, 60, 80, 100 mW. It is obvious that the efficiency is varying with the load resistance. As seen from the figure, the optimal load is approximately steady at 190 Ω even slight smaller as the input power is increasing. At the load of 190 Ω, the peak efficiency and output voltage of each input power level are presented in Table 4.1. In these input power ranges, the peak efficiency is changing from 80.2 % to 82.5 %, where the variation is small. In addition, For a higher input power, the efficiency curve rises early and also drops rapidly with the increase of load resistance. This is because the higher input power gets a higher output voltage which causes the voltage applied on the diode exceeding the breakdown voltage.

Figure 4.2(b) shows the simulation and experimental results of the efficiency versus the input power varying from 20 to 120 mW when the load resistance is

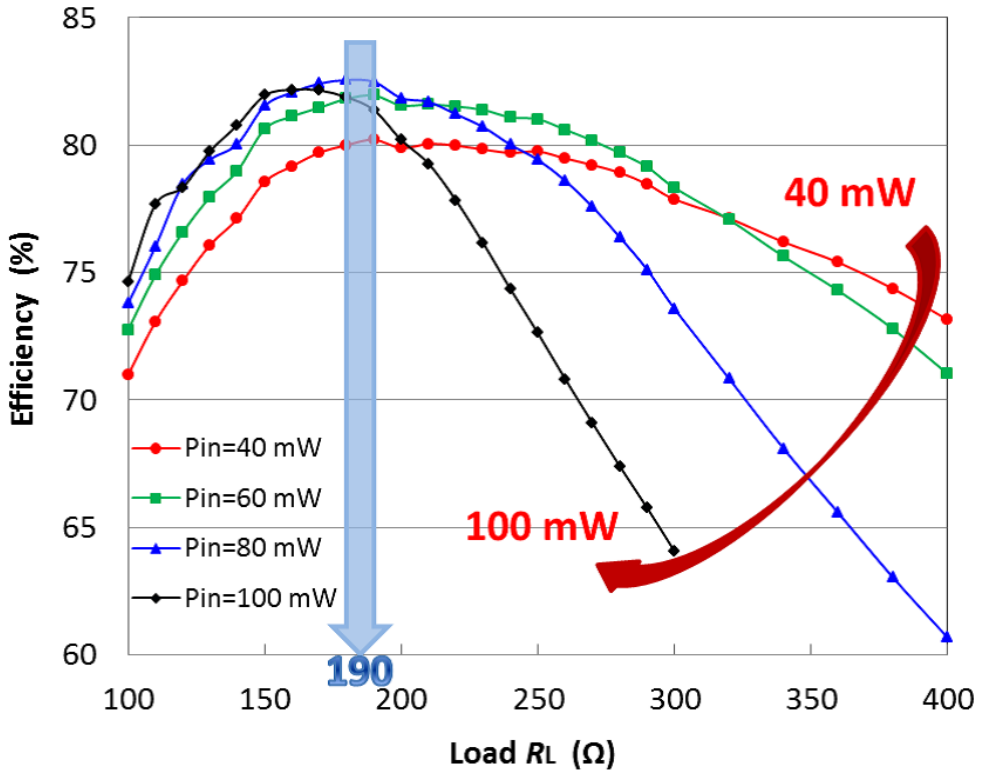


(a)

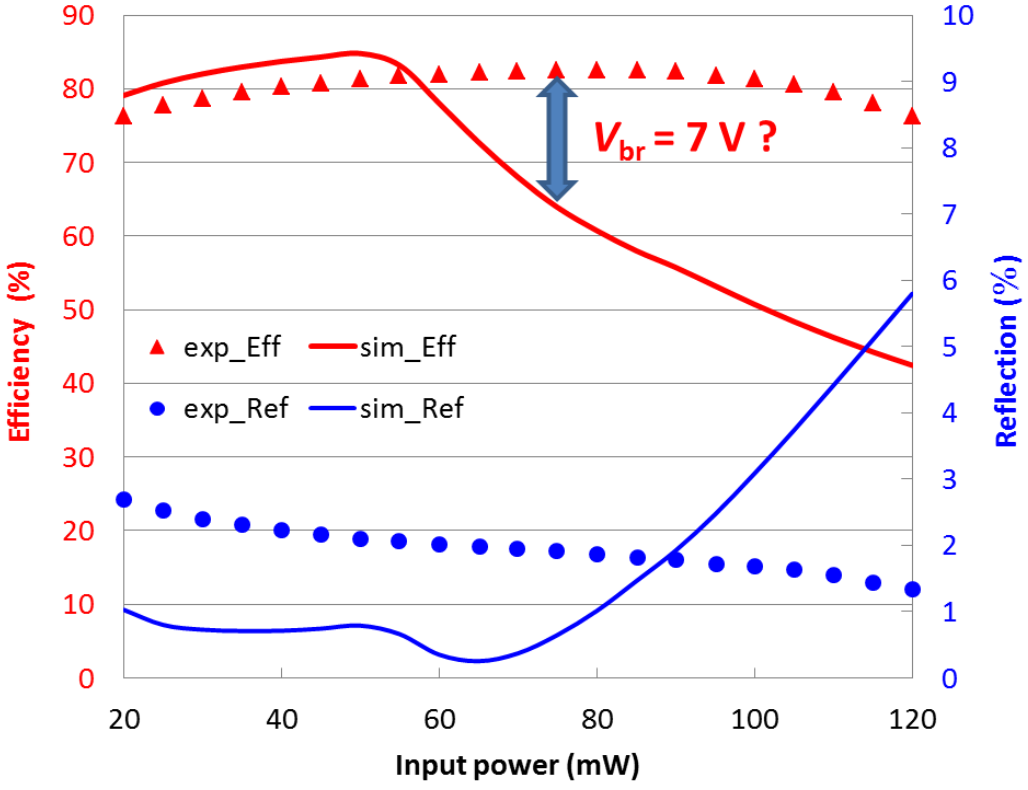


(b)

Figure 4.1: Proposed positive output voltage rectifier. (a) Structure and size. (b) Photograph.



(a)



(b)

Figure 4.2: Simulation and experimental results of the high-efficiency rectifier. (a) Efficiency vs. load resistance. (b) Efficiency vs. input power.

fixed at 190 Ω. In the case of the simulation, maximum efficiency is 84.7 % at the input power of 50 mW. In the case of the experiment, maximum efficiency of 82.5 % is obtained at input power of 80 mW. The experiment results almost agree with the simulation when the input power is below 60 mW. However, they are greatly different with the simulation results when the input power is over 60 mW. There are some differences between simulation and experiment results as same as the rectifying circuit in Chapter 3.4. The diode model of di_hp_HSMS286F_20000301, which is a high frequency diode model in ADS library, is used in the simulation. This diode model uses the SPICE parameter where the breakdown voltage B_{V} is 7 V. The reverse current will reach the limitation value of I_{BV} when the reverse voltage reaches B_{V}, and it will increase when the reverse voltage exceeds the B_{V} until the reverse direction of the diode is completely conducted. In simulation, the impedance of the diode is greatly changed when the voltage applied on the diode exceeds the breakdown voltage. Hence, the reflection and diode losses increase rapidly which leads to a decrease in efficiency. However, in experiment, the real breakdown voltage of the diode is far over 7 V that the efficiency falls slowly as the diode loss is increasing even though the power exceeds the power value at peak efficiency point. There is an actual example that a diode with breakdown voltage of 9 V in SPICE parameter can bear a reverse voltage over 20 V in experiment [70].

4.3 Self-powered DCM Buck-boost Converter

4.3.1 Self-powered Non-inverting Buck-boost Converter

Compared to the externally-powered buck-boost converter in Chapter 3, this chapter proposes a self-powered non-inverting buck-boost converter as shown in Fig. 4.3. The main circuit also consists of capacitors, an inductor, an N-MOS and a diode whereas the diode and GND position are changed. Due to those changes, the converter affords a positive output voltage with a positive input voltage. The control-pulse circuit only includes two oscillators which are powered by the input voltage of the converter. Similarly, the operating waveform is as same as Fig. 3.4(b) while the current flowing direction is different. There are three state intervals when the LF oscillator is at work-state. The on-state is that the current flows through the inductor and N-MOS to the GND when the gate voltage is at

high-level. The off-state is that the current flows through the inductor and diode to the load resistance when the gate voltage is at low-level. The zero-state is that no current flows through the circuit which is as same as the sleep-state of the LF oscillator.

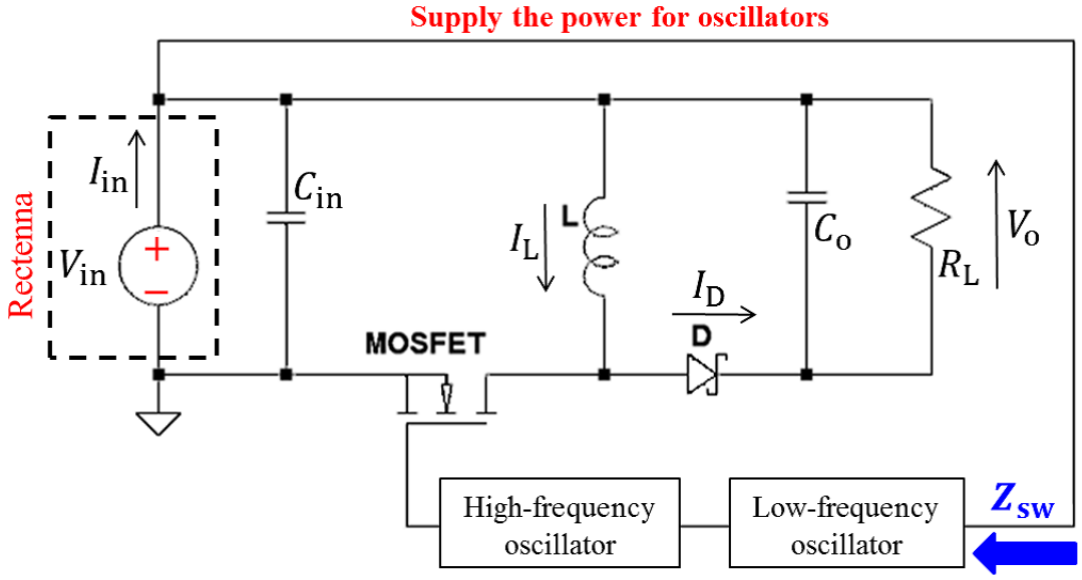


Figure 4.3: Block diagram of the self-powered non-inverting buck-boost converter.

Therefore, this buck-boost converter also operates at discontinuous conduction mode. Assuming R'_{in} to be input resistance of this converter, it is the combination of R_{in} (Eq. (3.37) mentioned in Chapter 3.3) and the impedance of the control-pulse circuit Z_{sw} in parallel as seen in Fig. 4.3. Hence, R'_{in} satisfies the following equation:

$$R'_{in} = \frac{R_{in}}{1 + \frac{R_{in}}{Z_{sw}}}. \tag{4.1}$$

To measure the impedance of the control-pulse circuit Z_{sw}, the simulation and experiment on the control-pulse circuit are conducted and Fig. 4.4 shows the schematic of the simulation circuit and the simulation waveform in LTspice. As same as the previous converter, LF and HF oscillators utilize LTC6992 and LTC6900, respectively. Figure 4.4(b) shows the operating waveforms such as LF pulse V_ι and the control pulse V_{gate} at the input voltage of 3 V. Figure 4.5 shows the measured waveforms of the control-pulse circuit at the supplied voltage of 3 V, where the high, low frequency are 10 kHz and 98 Hz, respectively. The amplitude of V_h and V_ι are both 3.96 V, which is almost equal to the supplied voltage of 3 V.

Figure 4.6(a) shows the simulation and experimental results of the impedance Z_{sw} which indicates that Z_{sw} is large enough to exceed 8 kΩ when the supplied voltage is over 3 V. This value also agrees with the calculated value of 8.5-14 kΩ, according to the data sheet of LTC6992 [71]. By the way, the power dissipation of the control-pulse circuit is also investigated as shown in Fig. 4.6(b), which indicates that the power consumption is small and increasing as the supplied voltage increases.

Practically, the input resistance of the buck-boost converter $R_{\mathrm{in}}^{'}$ is designed close to 190 Ω which is the optimal load of the rectifying circuit in RF-DC-DC circuit. Compared with Z_{sw}, 190 Ω is small enough, which leads to following:

$$R_{\mathrm{in}}^{'} \approx R_{\mathrm{in}}. \tag{4.2}$$

Therefore, Eq. (3.37) is also adapted to $R_{\mathrm{in}}^{'}$.

4.3.2 Parameters Selection

According to Eq. (3.37), the R_{in} is decided by the inductance, two pulse duty-on ratios and the high frequency. Furthermore, the designed rectifying circuit exhibits a peak efficiency at the load of 190 Ω. Hence, it is necessary to make R_{in} equal to 190 Ω with suitable value of four parameters. Figure 4.7 shows the schematic diagram of the HF oscillator LTC6900 and LF oscillator LTC6992. LTC6900 is a precision, low power oscillator that is easy-to-use and occupies very little PC board space. The oscillator frequency is programmed by a single external resistor (R_{SET}) as shown in Fig. 4.7(a). The three-state DIV input determines whether the master clock is divided by 1, 10 or 100 before driving the output, providing three frequency ranges spanning 1 kHz to 20 MHz. The oscillator can be easily programmed using the simple formula below [72]:

$$f_{\mathrm{h}} = \frac{10\mathrm{MHz}}{N}\frac{20\mathrm{k\Omega}}{R_{\mathrm{SET}}}, N = 1, 10, 100. \tag{4.3}$$

If we supply a 3 V voltage to pin 4 and assume R_{SET} as 200 kΩ, then, N becomes 100 and f_{h} can be calculated to be 10 kHz referring to Eq. (4.3). In

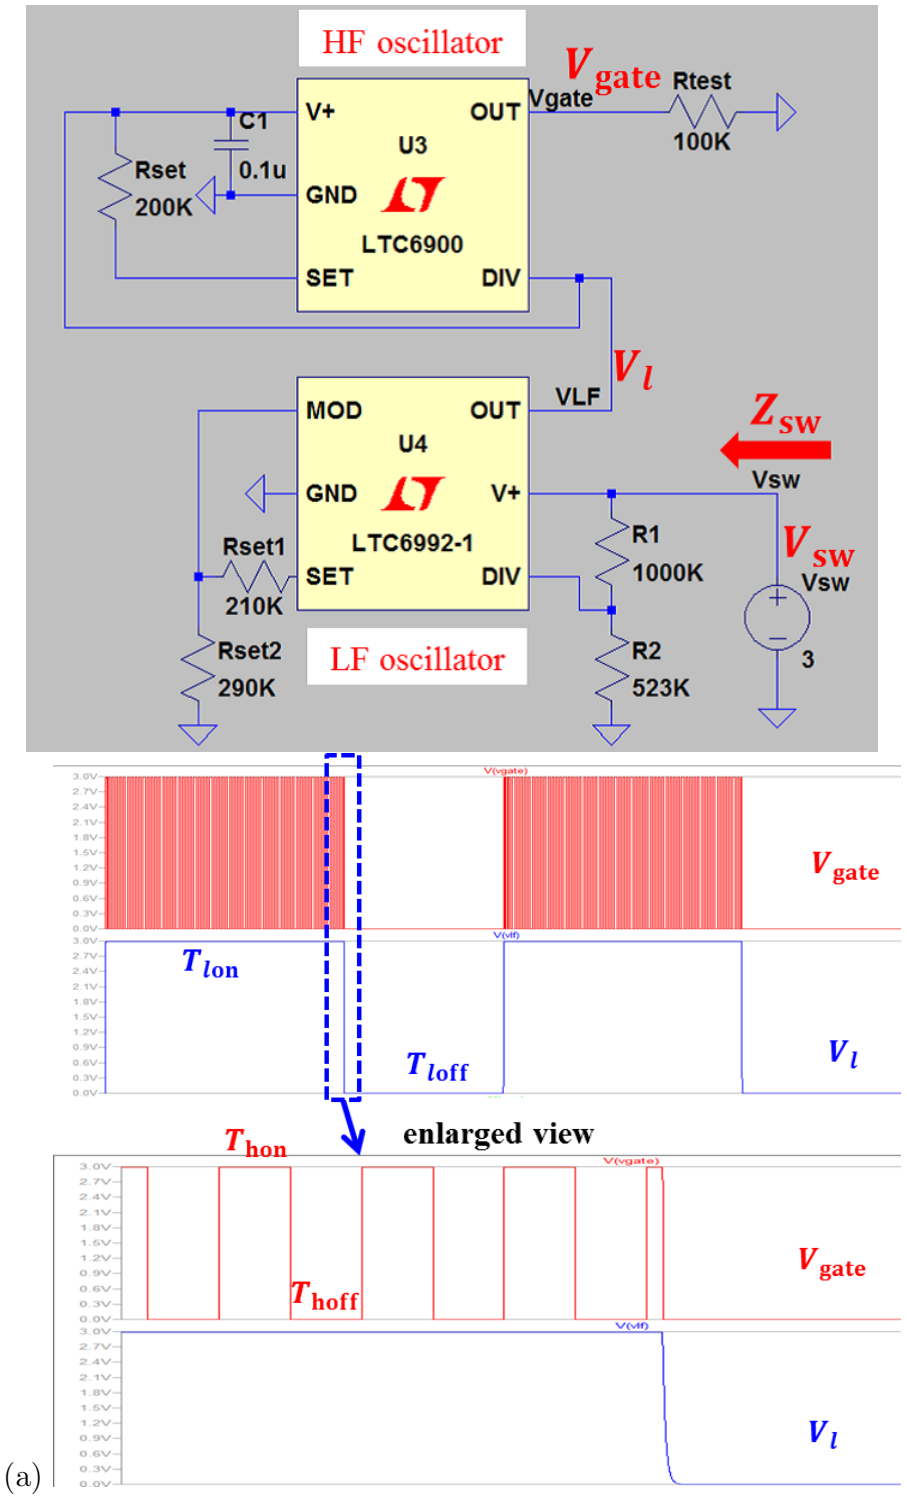

Figure 4.4: Control-pulse circuit of the buck-boost converter in simulation (LTspice). (a) Simulation circuit: LTC6992 is the LF oscillator; LTC6900 is the HF oscillator. (b) Simulated waveforms.

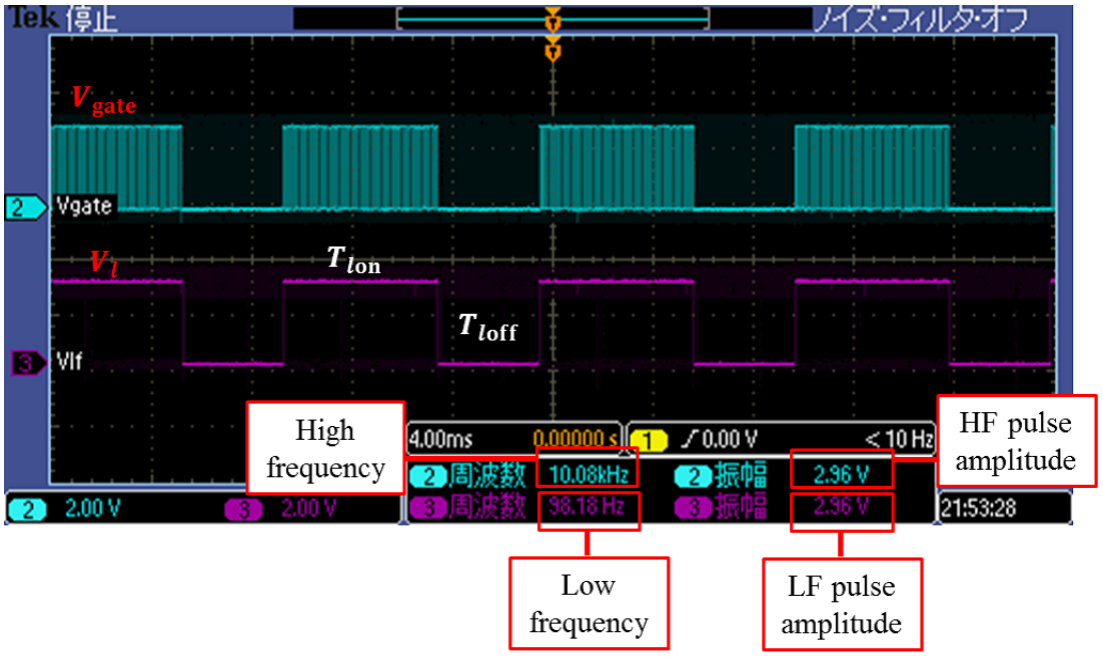

Figure 4.5: Measured waveforms of the control-pulse circuit.

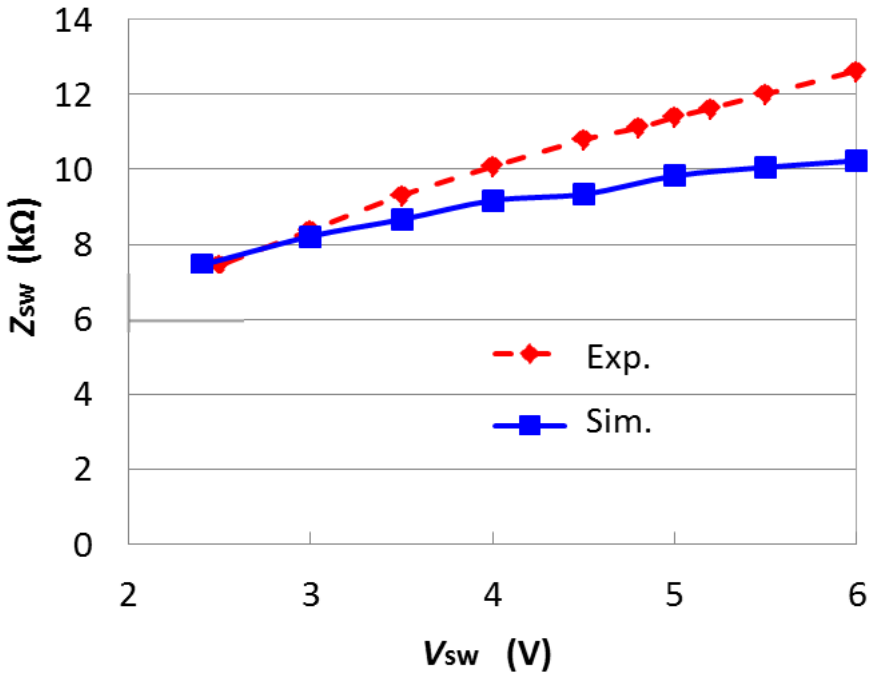
addition, LTC6900 operates from a single 2.7 to 5.5 V supply and outputs a square pulse with the duty-on ratio of 0.5. Hence, D_{h} is 0.5.

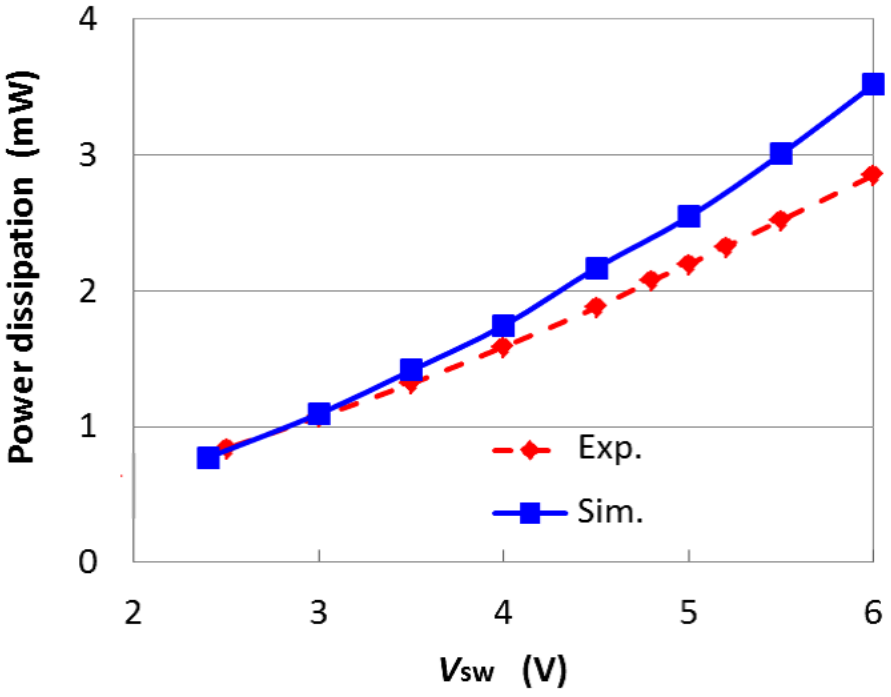
The LF oscillator LTC6992 is a silicon oscillator with an easy-to-use analog voltage-controlled pulse width modulation (PWM) capability. The resistance, R_{SET1} and R_{SET2}, program the LTC6992's internal master oscillator frequency. The output frequency is determined by this master oscillator and an internal frequency divider (N_{DIV}), programmable to eight settings from 1 to 16384. The divider ratio N_{DIV} that relates to R_1 and R_2 is set by a resistor divider attached to the DIV pin. With a single 2.25 to 5.5 V supply, the output frequency f_ι, exhibits wide from 3.81 Hz to 1 MHz, can be expressed as following [71]:

$$f_\iota = \frac{1\mathrm{MHz}}{N_{\mathrm{DIV}}} \frac{50\mathrm{k}\Omega}{R_{\mathrm{SET1}} + R_{\mathrm{SET2}}}, N_{\mathrm{DIV}} = 1, 4, 16....16384. \tag{4.4}$$

Here, the divider ratio N_{DIV} and $R_{\mathrm{SET1}} + R_{\mathrm{SET1}}$ are chosen to be 1024 and 530 kΩ, respectively. According to Eq. (4.4), f_ι becomes approximately 100 Hz. The LF f_ι does not effect R_{in} as seen from Eq. (3.37). Whereas the efficiency of the converter will decrease because switching loss is increased as f_ι rises. On the other hand, if f_ι is too low, gate-off time of the MOSFET gets longer which results in a big output capacitor to stabilize power supply to the load. Therefore, f_ι of 100 Hz is selected.

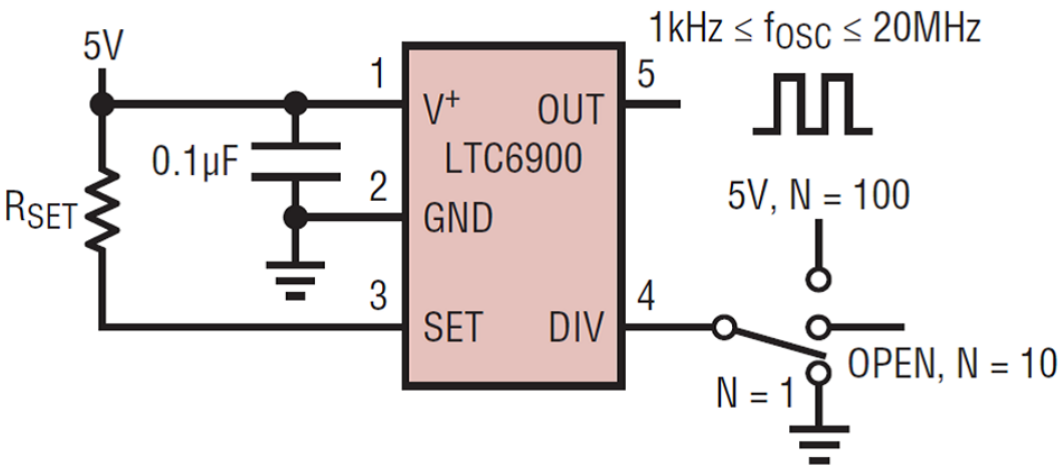


(a)

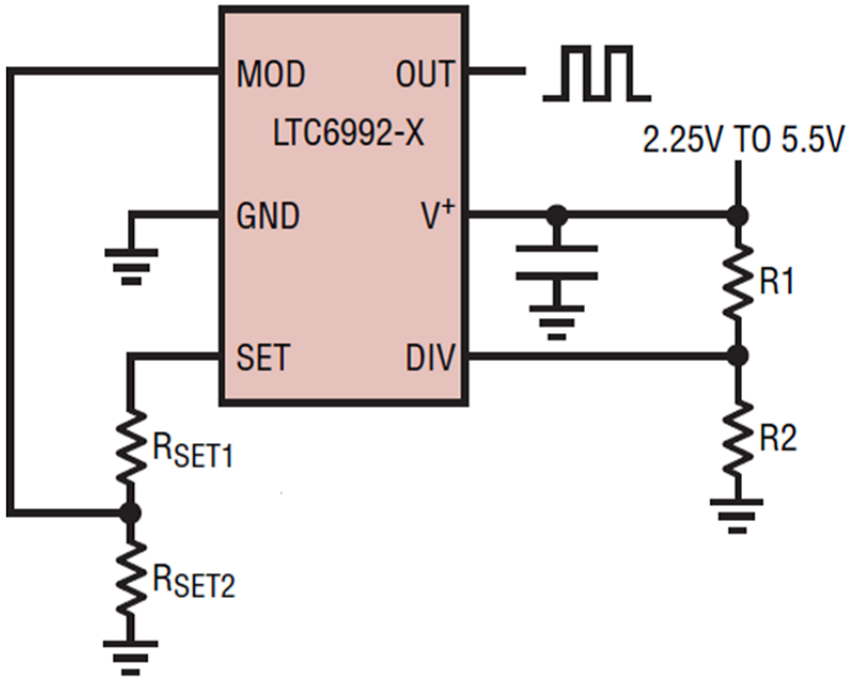


(b)

Figure 4.6: Simulation and experimental results of the control-pulse circuit. (a) Impedance Z_{sw}. (b) Power consumption.



(a)



(b)

Figure 4.7: Block diagram of oscillators. (a) HF oscillator LTC6900 [72]. (b) LF oscillator LTC6992 [71].

Figure 4.7(b) shows a simple circuit for generating an arbitrary duty cycle at a fixed frequency. The LF duty-on ratio D_ι can operate wide from 0 % to 100 % and it can be expressed as below [71]:

$$D_\iota = \frac{5}{4}\frac{R_{\mathrm{SET2}}}{R_{\mathrm{SET1}} + R_{\mathrm{SET2}}} - \frac{1}{8}. \tag{4.5}$$

We use a variable resistance of 530 kΩ which is divided into two parts such as R_{SET1} and R_{SET2}. We assign R_{SET2} to be 234 kΩ, then, D_ι becomes approximately 0.427. Here, a variable resistor is used, then the proportion of R_{SET2} and R_{SET2} is adjustable to change D_ι. Consequently, the R_{in} is changeable. So far, the four parameters are decided as following: $f_{\mathrm{h}} = 10$ kHz, $D_{\mathrm{h}} = 0.5$, $D_\iota = 0.427$, and inductance L is chosen to be 1 mH. Applying these parameters into Eq. (3.37), R_{in} becomes 187 Ω, which is very close to the optimal load (190 Ω) of the rectifying circuit. It means that the input resistance of the new buck-boost converter is designed to equal the optimal load of the rectifying circuit in theoretical analysis.

With respect to the other components of the converter such as diode, N-MOS, inductor and capacitors are the same as the one outlined in Table 3.3, while the input capacitor $C_{\mathrm{in}} = 220$ μF ($V_{\mathrm{rated}} = 35$ V) is selected. The ripple of the voltage is small if the input voltage supplied from a DC power source. But the input voltage of the converter utilizes the output voltage of the rectifying circuit where the ripple is very big. In order to limit the input voltage ripple of the converter in RF-DC-DC circuit, a relatively high input capacitance is selected. Due to input voltage ripple, the efficiency varying ripple is much big in Figs. 3.14(a) and 3.15. Additionally, the MOSFET gate driver is removed in this new buck-boost converter. A MOSFET gate driver is usually applied to short switching time to minimize the switching loss for a large gate capacitance MOSFET. However, the N-MOS FDS6298 has been designed specifically to improve the overall efficiency of DC-DC converters using either synchronous or conventional switching PWM controllers. It has been optimized for low gate charge, low $R_{\mathrm{DC(on)}}$ and fast switching speed [73]. Note that the output of the HF oscillator directly drives the gate of the N-MOS in Fig. 4.3. Compared with the control-pulse circuit of the previous converter, the new one will dissipate less power because of no power consumption from gate diver.

4.3.3 Input Resistance Verification

With surface-mount device (SMD) resistors instead of axial-lead resistors, the new buck-boost converter mounts on a 3 cm × 3 cm PCB as shown in Fig. 4.8. Then, to verify the input resistance, simulate the circuit using LTspice and conduct an experiment using the measurement circuit as shown in Fig. 4.9(a) where does not need an extra DC power source. Figure 4.9(b) shows the operating waveform of V_{gate} at the input voltage of 3 V. Observe that the high frequency is 10 kHz, and the amplitude is 2.88 V which is a little smaller than the one measured in control-pulse circuit in Chapter 4.3.2. This is because the impedance of gate-source is not big enough to neglect the output impedance of the HF oscillator resulting in a drop of V_{gate}. However, this voltage drop is sufficiently small that does not affect driving the gate of the N-MOS.

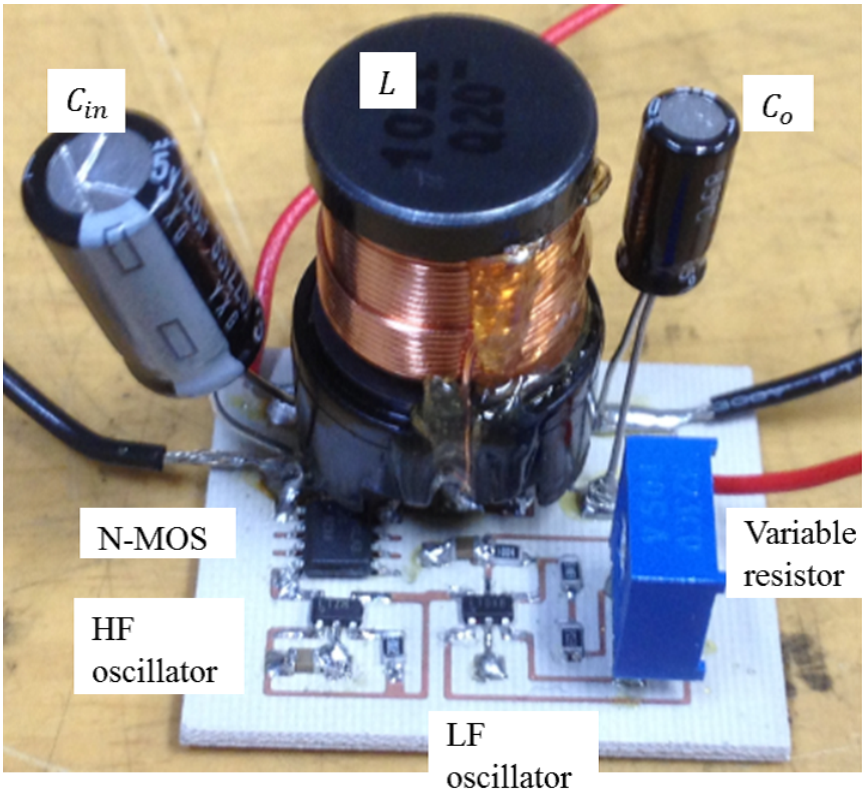


Figure 4.8: Photograph of the self-powered non-inverting buck-boost converter.

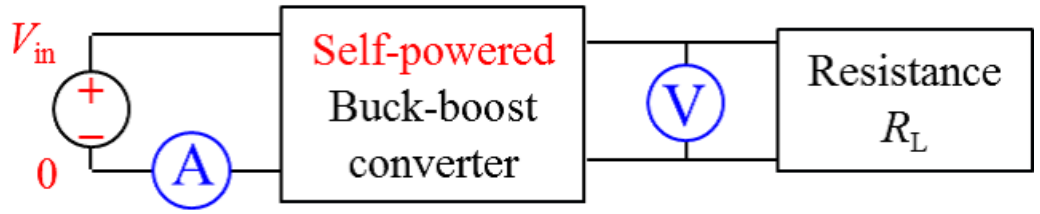
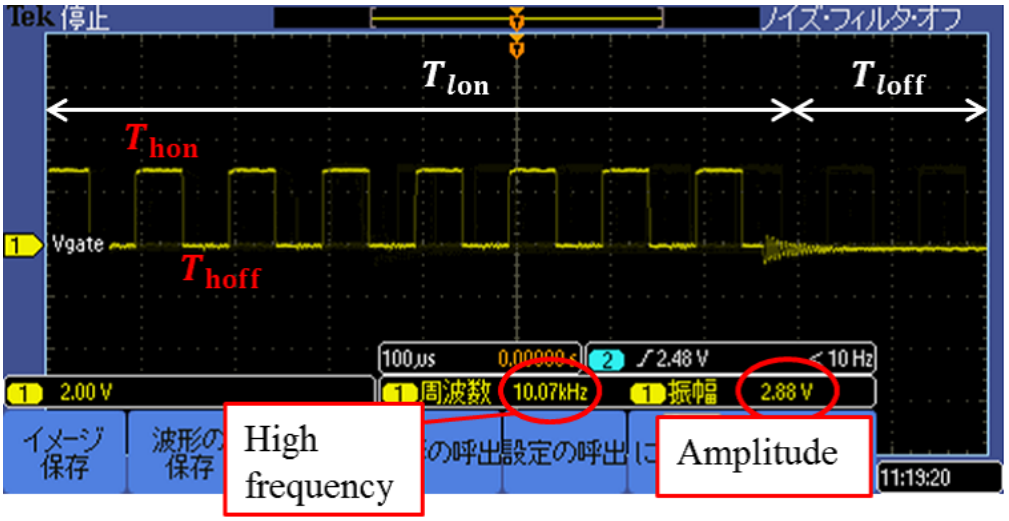
The simulation and experimental results of the self-powered buck-boost converter are shown in Fig. 4.10, where Sim_Eff and Exp_Eff represent the efficiency of the simulation and experimental, Sim_Rin and Exp_Rin represent the input resistance of the simulation and experimental, respectively. Figure 4.10(a), at a fixed input voltage of 3.5 V, shows the efficiency and the input resistance R'_{in}



(a)



(b)

Figure 4.9: Experiment setup and measured waveform of the converter. (a) Experiment setup. (b) Measured waveform of V_{gate}.

versus the load changing from 100 Ω to 10 kΩ. Here, the input voltage of 3.5 V is selected to agree with the output voltage of the rectifying circuit when it performs maximum efficiency at the optimal load for an RF input power of 80 mW. Furthermore, the input power of the converter calculated to be 63 mW which almost agrees with the output DC power of the rectifying circuit calculated from Table 4.1. In the case of R'_{in}, the simulation and experimental results are in well agreement with the designed value of 187 Ω when the load is wide changing from 200 Ω to 10 kΩ. At the load of 100 Ω, when the load resistance is smaller than the input resistance, the buck-boost converter operates at the CCM which leads to the input current increasing. As a result, the input resistance is decreased. In the case of the efficiency, it increases at low load resistance and decreases at the high load resistance. The output current is decreasing as the load increases at a fixed input power. The major loss of the converter is dominated by the loss such

as diode loss, switching loss, inductor and other resistance losses when the load resistance is below 3000 Ω. Whereas the major loss of the converter is dominated by the loss of the output capacitor that a part of the output current flows through the output capacitor as the load resistance is too big to neglect the impedance of the capacitor. The measured efficiency is over 85 % in the load range from 400 to 6000 Ω.

Similarly, Figure 4.10(b), at a fixed load resistance of 800 Ω, shows the efficiency and the input resistance $R_{\text{in}}^{'}$ versus the input voltage changing from 2.5 to 4.5 V. At this input voltage range, the input power is varying from 31 to 104 mW. Note that the $R_{\text{in}}^{'}$ is also almost steady at 190 Ω and is independent of the input voltage. As for the efficiency, the measured one is over 85 % at the whole input voltage range. In the case of the simulation, the efficiency is increasing as the input voltage increases. In the case of the experiment, the efficiency is increasing at the beginning and then slightly decreases as the input voltage increases. Because of the limitation from the operation voltage of HF and LF oscillators, the input voltage is restrained among the range of 2.5 to 6 V. The switching loss increases because of a low gate control voltage V_{gate} when the input voltage is low. The diode loss, inductor and other resistance loss will increase at a high input voltage due to current increasing. Additionally, as seen from Fig. 4.6(b), the power consumption of oscillators is increasing as the supplied voltage increases.

In addition, for both figures in Fig. 4.10, the measured $R_{\text{in}}^{'}$ is slightly bigger than the simulation results. The reason is that the wire resistance and the noise of real pulse wave cuts the on-state time which minimizes the input current. Furthermore, the experiment efficiency is approximately 5 point lower than the simulation one because the series resistance loss in capacitor and the wire resistance loss are not considered in simulation. In Chapter 4.3.1, we have discussed that the input resistance of this new buck-boost converter $R_{\text{in}}^{'}$ is the combination of the main circuit R_{in} and the control-pulse circuit Z_{sw} in parallel. In practice, using measurement circuit in Fig. 4.9(a), the input resistance, calculated from measured input voltage and input current, is the value of $R_{\text{in}}^{'}$ which already includes R_{in} and Z_{sw}. According to the simulation and experiment results reported above, the input resistance $R_{\text{in}}^{'}$ is almost equal to the value of R_{in}, which well agrees with the theory analysis. Consequently, that the new buck-boost converter has constant input resistance characteristic is verified both by simulation and experiment results.

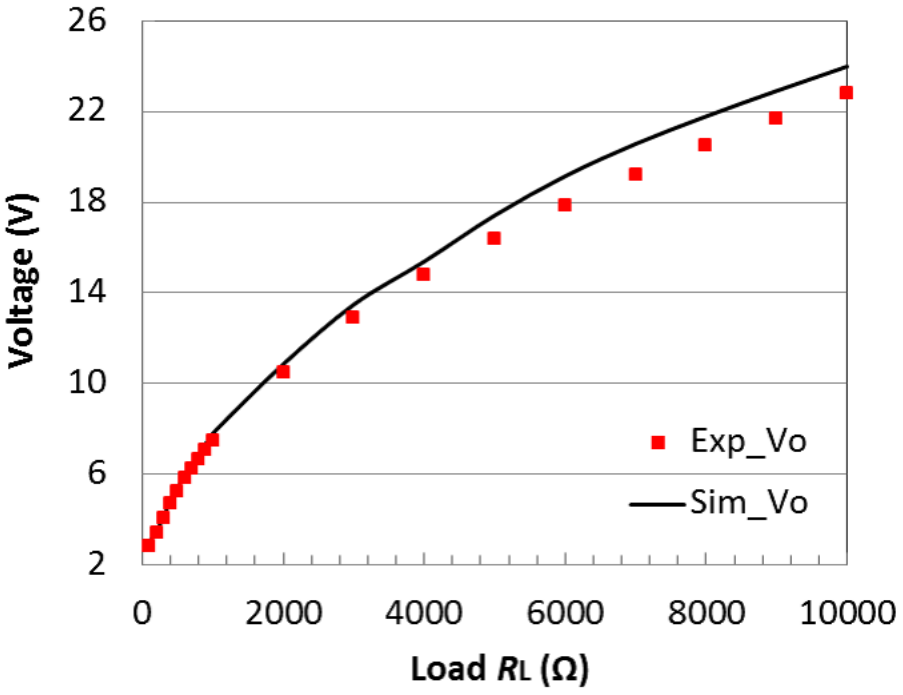
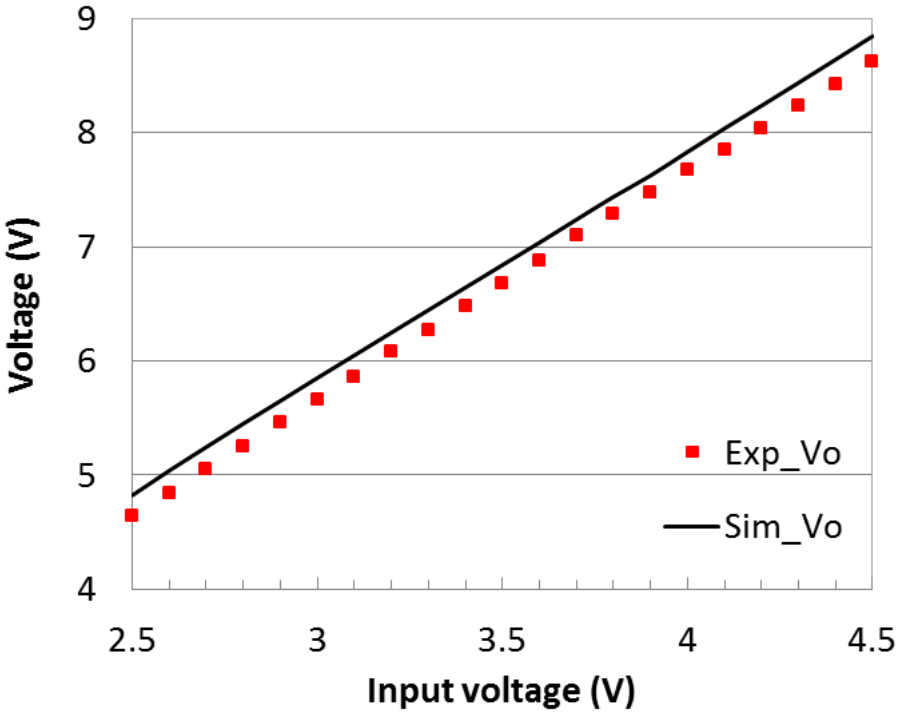
(b)

Figure 4.10: Simulation and experimental results of the self-powered buck-boost converter. (a) Efficiency and input resistance R'_{in} vs. load resistance for a fixed input voltage of 3.5 V. (b) Efficiency and input resistance R'_{in} vs. input voltage for a fixed load of 800 Ω.



(a)



(b)

Figure 4.11: Simulation and experimental results about output voltage of the self-powered buck-boost converter. (a) Output voltage vs. load resistance for a fixed input voltage of 3.5 V. (b) Output voltage vs. input voltage for a fixed load of 800 Ω. Exp_V_o, Sim_V_o are the experiment result and simulation result, respectively.

With respect to the input/output voltage relationship of this buck-boost converter, apply the formula of $\frac{V_o^2}{R_L} = \frac{V_{in}^2}{R_{in}}$ to Eq. (3.37), it yields:

$$V_o = \sqrt{\frac{D_h^2 D_\iota}{2Lf_h} V_{in}^2} \cdot R_L^{\frac{1}{2}}, \tag{4.6}$$

$$V_o = \sqrt{\frac{D_h^2 D_\iota}{2Lf_h} R_L} \cdot V_{in}, \tag{4.7}$$

which indicates that the relationship between V_o and R_L is a parabolic curve with horizontal axis when the input voltage V_{in} is fixed. Similarly, the relationship between V_o and V_{in} is linear when the load resistance R_L is fixed. Figure 4.11 gives the simulation and experiment results about output voltage of the buck-boost converter. Figure 4.11(a) shows the output voltage versus load resistance for a fixed input voltage of 3.5 V where the output voltage is increasing as the load increases, and the shape of the curve well agrees with Eq. (4.6). Figure 4.11(b) shows the output voltage versus input voltage for a fixed load resistance of 800 Ω. Where the output voltage is linearly increasing as the input voltage increases, and the shape of the curve well agrees with Eq. (4.7). For both figures, the experiment results are in good agreement with the simulations. It is clear that the output voltage is boosted by the buck-boost converter, which indicates that this resistance conversion buck-boost converter only plays a booster role here.

4.4 Experiment on Self-powered RF-DC-DC Circuit

Similarly, summarize the efficiency-load relation of the rectifier and buck-boost converter as mentioned above in Table 4.2. As expected, the overall efficiency of the RF-DC-DC circuit should be steady and over 67 % in the load range of 200 Ω to 10 kΩ. Then,we conduct an experiment on the self-powered RF-DC-DC circuit using the experiment architecture in Fig. 4.12(a) with 2.45 GHz microwave power. Here, we can obtain a DC power at the load port with the incident microwave power where an extra DC power source is needless. The measured items are listed in Table 4.3. Using these measured items, the overall efficiency, the efficiency of

Table 4.2: Efficiency and load relationships of the high-efficiency rectifier and self-powered buck-boost converter in experimental results.

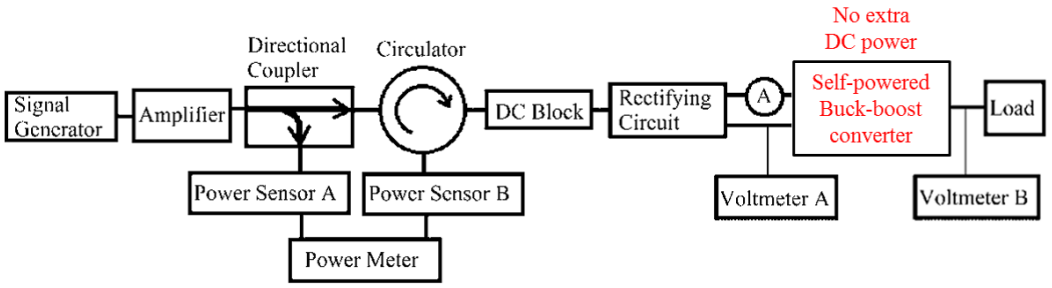
	R_{L}	R_{in}	Efficiency
High-efficiency rectifier	190 Ω		82.5 %
Self-powered buck-boost converter	200 Ω-10 kΩ	almost 190 Ω	over 82 %
Self-powered RF-DC-DC circuit	200 Ω-10 kΩ		predicted value 67 %

Table 4.3: Measured items of the self-powered RF-DC-DC circuit.

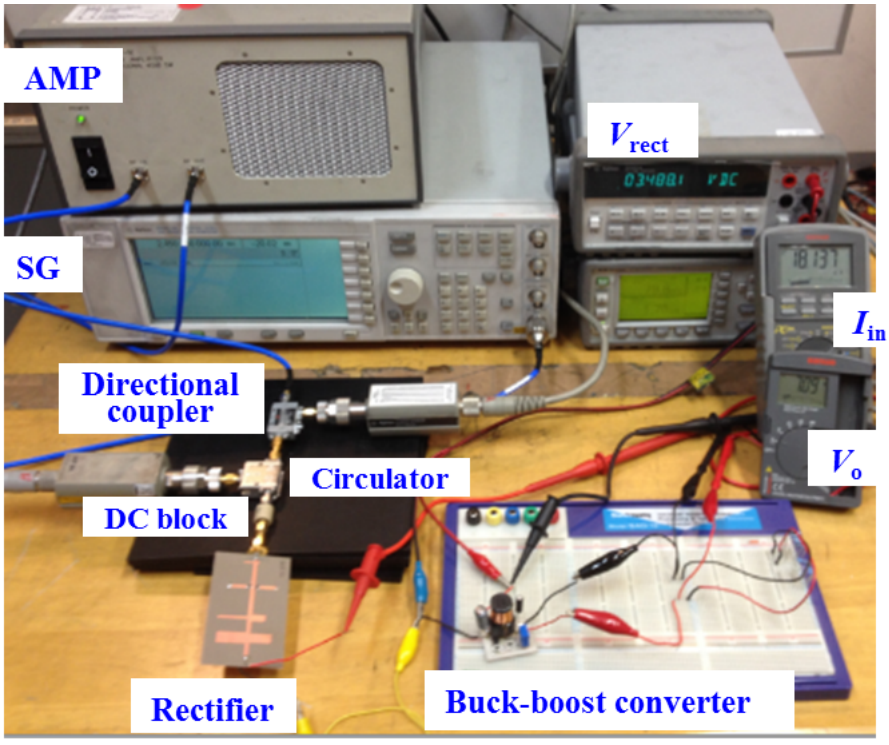
Item	Represent
Power sensor A	Input RF power of RF-DC-DC circuit
Power sensor B	Reflection RF power
Voltmeter A	Output voltage of rectifier V_{rec}
Voltmeter B	Output voltage of RF-DC-DC circuit I_{o}
Ammeter	Input current of buck-boost converter I_{in}

the RF-DC rectifier alone, the efficiency of the buck-boost converter alone, the tracking efficiency and the input resistance of the converter can be calculated.

Firstly, several efficiency curves are shown in Fig. 4.13 and each efficiency curve is explained by the block diagram in Fig. 4.14. The red RF-DC-DC curve is the overall efficiency of the RF-DC-DC circuit. The blue RF-DC (with converter) curve is the efficiency of the rectifier when it is connected to the converter. In contrast, the black RF-DC (without converter) curve is the efficiency of a general rectifier. The green DC-DC curve is the efficiency of the buck-boost converter when it is utilized in the RF-DC-DC circuit. With a fixed input RF power of 80 mW, the variation of overall efficiency of the RF-DC-DC circuit over a load range of 100 Ω to 10 kΩ is shown in Fig. 4.13(a). It is obvious that the efficiency of the rectifier (with converter) is almost constant over 80 % in that wide load range. Compared with the general rectifier (black), it seems that the rectifier



(a)



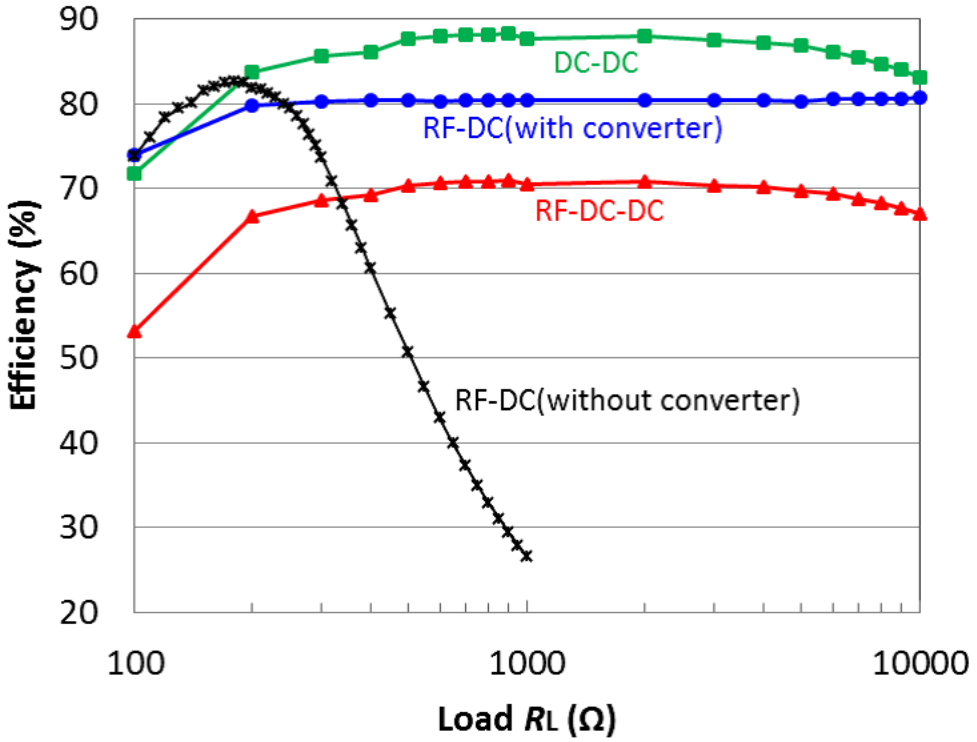
(b)

Figure 4.12: Experiment setup for measuring the efficiency of the self-powered RF-DC-DC circuit. (a) Experiment setup. (b) Experiment photograph.

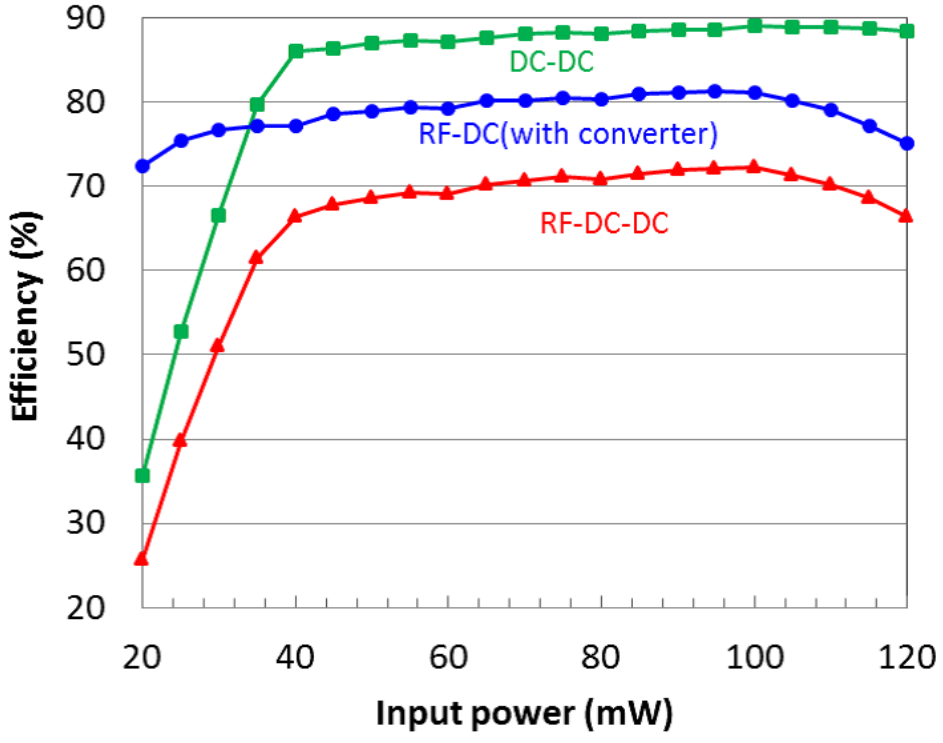
(with converter) always operates at the peak efficiency despite the load resistance. The efficiency of the buck-boost converter (blue) is over 82 % in that wide load range. Consequently, the overall efficiency, which is the multiplication of previous two efficiencies, is almost constant over 66 % in this ultra-wide load range of 200 Ω to 10 kΩ (a ratio of 1:50). Specially, the overall efficiency is over 70 % in the load range of 400 to 4000 Ω (a ratio of 1:10). The overall efficiency is low at the load of 100 Ω because the input resistance of the converter is mismatching with the optimal load of the rectifier which reduces the rectifying efficiency. As the efficiency of the converter decreases at high load resistance as mentioned in Chapter 4.3.3, the overall efficiency is also slightly decreasing as the load resistance increases.

With a fixed load resistance of 800 Ω, Figure 4.13(b) shows the overall efficiency versus the input power changing from 20 to 120 mW. Note that the overall efficiency exceeds 66 % in the input power range of 40 to 120 mW. The overall efficiency is low when the input power is below 40 mW. Referring to Chapter 4.3.3, the output voltage of the rectifier is smaller than 2.5 V when the input power is lower than 40 mW at the load of 190 Ω. However, a necessary minimum operation voltage for control-pulse oscillators is also 2.5 V. Therefore, the buck-boost converter can not work well when the input power of the RF-DC-DC circuit is below 40 mW, which leads to a decrease in overall efficiency. When the input power exceeds 100 mW, the optimal load of the rectifier becomes lower than the designed value of R'_{in}. As a result, the impedance mismatching occurs between the rectifier and converter. Then the overall efficiency is decreasing as the efficiency of the rectifier decreases. In practice, if the input power is much higher, the output voltage of the rectifier probably reaches the overvoltage (6 V) of control-pulse oscillators which would decrease the efficiency of the converter even break the converter. However, the output DC voltage (V_{DC}) of the rectifier is restrained by the breakdown voltage (B_{V}) of the HF diode which satisfies the equation: $V_{\text{DC}} \approx B_{\text{V}}/2$. As the breakdown voltage of the HF diode is 7 V, the rectifying diode would breakdown first before the output voltage reaching 6 V. It means that the rectifying diode of the rectifier plays another important role in overvoltage protection for control-pulse circuits here. Thus, considering the efficiency and overvoltage, this RF-DC-DC circuit is suggested to be used in the power range of 30 to 140 mW.

The tracking efficiency η_{track}, as defined in Eq. (3.38), is also investigated.

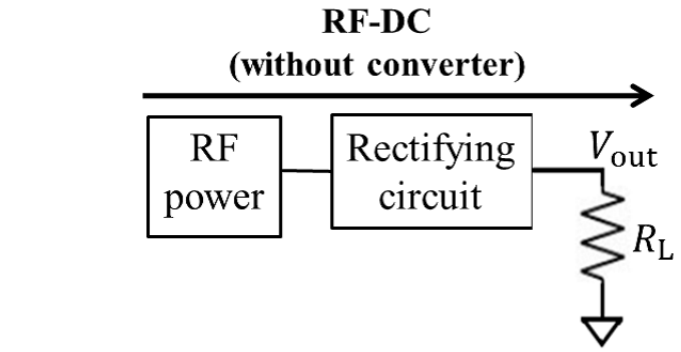


(a)

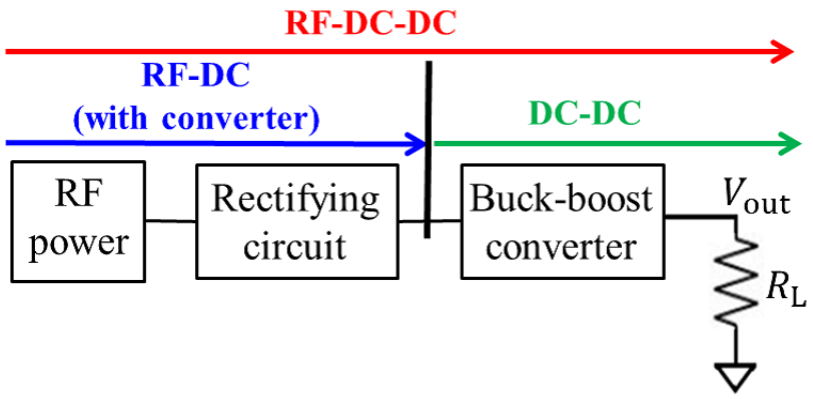


(b)

Figure 4.13: Measured overall efficiency of the self-powered RF-DC-DC circuit. (a) Efficiency comparison of the RF-DC-DC circuit and the general rectifier for a fixed input power of 80 mW. (b) Overall efficiency vs. input power for a fixed load of 800 Ω.



(a)



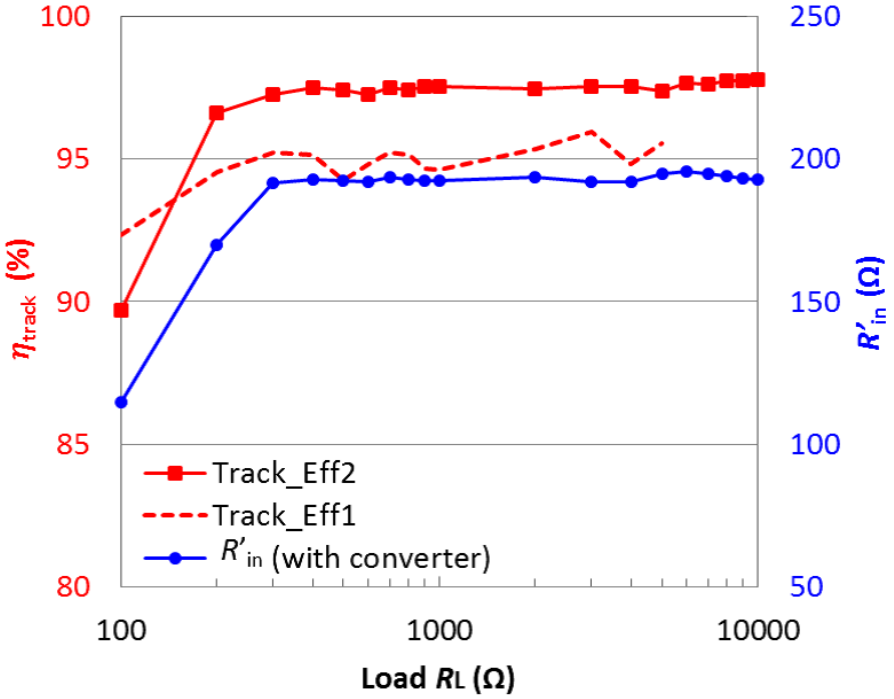
(b)

Figure 4.14: Illustration for the efficiency of each part in RF-DC-DC circuit. (a) General rectifier. (b) RF-DC-DC circuit.

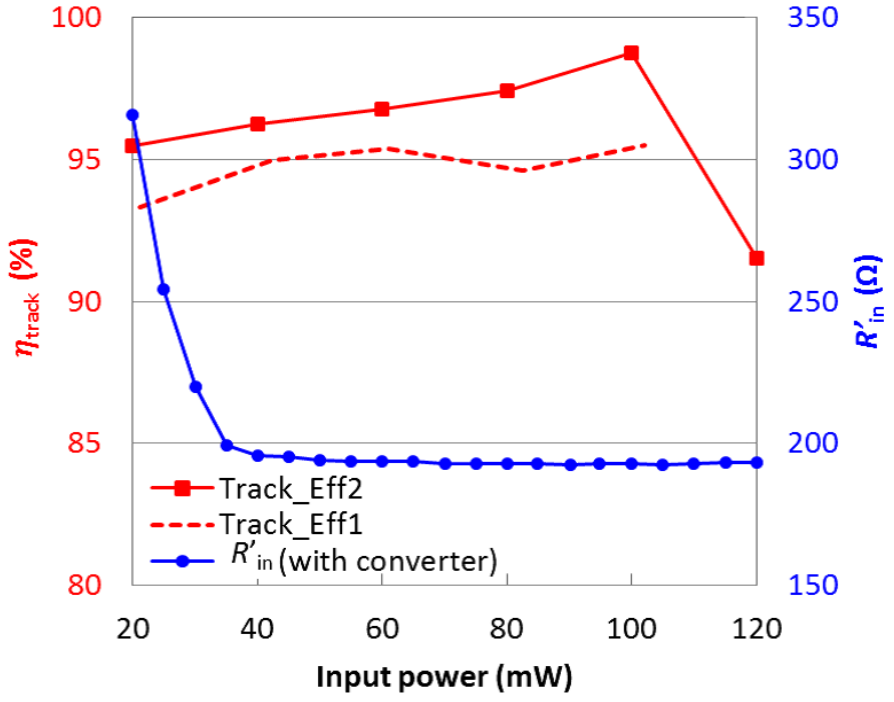
Figure 4.15(a) shows the tracking efficiency and R'_{in} versus load resistance at a fixed input power of 80 mW. Note that the variation tendency of the tracking efficiency is in accord with the input resistance because the former heavily depends on the latter. Track_Eff1 and Track_Eff2 are the tracking efficiency of the externally-powered RF-DC-DC circuit (in Chapter 3.5) and self-powered RF-DC-DC circuit, respectively. It is obvious that Track_Eff2 is constant as high as 97 % in the load range of 200 Ω to 10 kΩ, and is almost 5 percentage points bigger than Track_Eff1 because the impedance matching of the self-powered RF-DC-DC circuit is completely implemented. The R'_{in} is almost constant at the designed value of 190 Ω when the load is over 300 Ω. While it is much smaller than 190 Ω as the load is below 300 Ω and the same phenomenon can be seen in the buck-boost converter from Fig. 4.10(a), where the reason has been explained. Therefore, the overall efficiency is low when the load is below 300 Ω as shown in Fig. 4.13(a).

On the other hand, Figure 4.15(b) shows the tracking efficiency η_{track} and input resistance R'_{in} versus input power at a fixed load resistance of 800 Ω. Similarly, the R'_{in} is almost constant at 190 Ω when the input power is over 40 mW whereas it strictly deviates from 190 Ω when the input power is below 40 mW. In practice, if the input microwave power is too low to obtain the output voltage of 2.5 V in the rectifier, the control-pulse oscillators could not be driven, and the gate voltage of the MOSFET becomes zero which causes the switching to be off. In this case, the input resistance of the buck-boost converter seems to be infinite since the switching is open. Then the output voltage of the rectifier is increasing up to 2.5 V so that it is able to drive the oscillators which leads to switching on. In this case, the input resistance of the buck-boost converter decreases and move to agree with the designed value. After that, the output voltage begins to decrease again until it is too low to drive oscillators, and the operation repeats like above again and again. At this operation condition, the efficiency of the converter is very low. Therefore, R'_{in} is bigger than 190 Ω when the input power is below 40 mW, which is the reason of that the overall efficiency is low at low input power level as shown in Fig. 4.13(b). As for tracking efficiency, Track_Eff2 is also higher than Track_Eff1 and keeps constant over 95 % in the power range of 20 to 100 mW. While it suddenly falls because the optimal load is much smaller than 190 Ω at the input power of 120 mW. This is also the reason of that the overall efficiency is decreased at 120 mW in Fig. 4.13(b).

Figure 4.16 shows the reflection comparison between the rectifier (without converter) and the RF-DC-DC circuit. The reflection of the rectifier heavily depends on the impedance of the rectifying diode which is affected by the output load resistance or the output voltage. In fact, the reflection of the RF-DC-DC circuit is as same as the rectifier, which is also directly related to the output voltage of the rectifier part and the input resistance of the converter. As seen from Fig. 4.16(a), the reflection of the RF-DC-DC circuit is almost constant and is much lower than that of the rectifier (without converter) because the R'_{in} is almost constant at this load range. In Fig. 4.16(b), the reflection of the RF-DC-DC circuit is much higher at low power level because of impedance mismatching as mentioned previously. Additionally, the reflection of the RF-DC-DC circuit is slightly higher (approximate 0.5 percentage point) than that of the rectifier (without converter) because of subtle differences between the actual R'_{in} and 190 Ω.

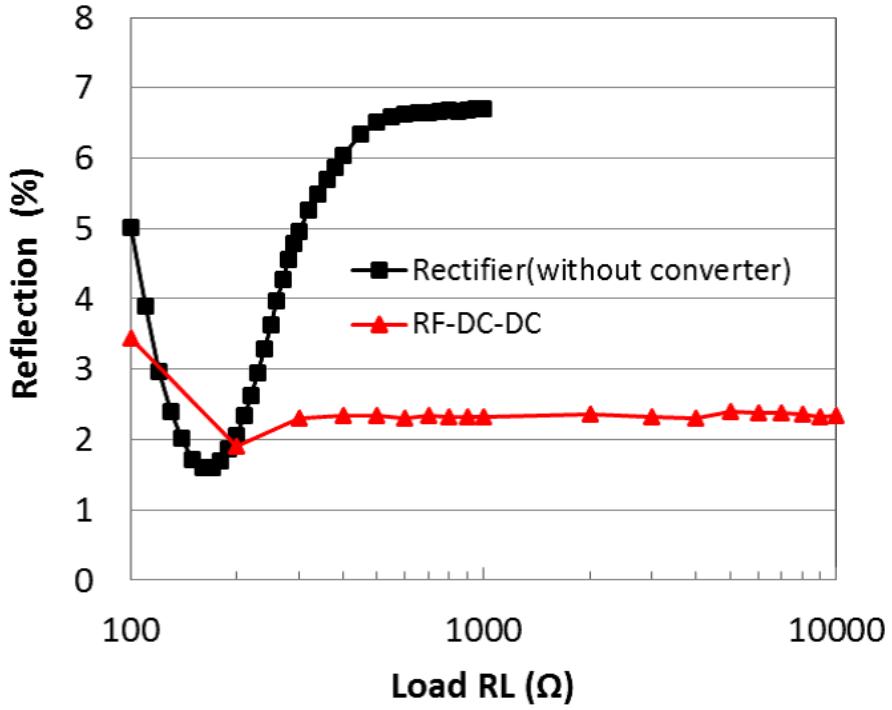


(a)

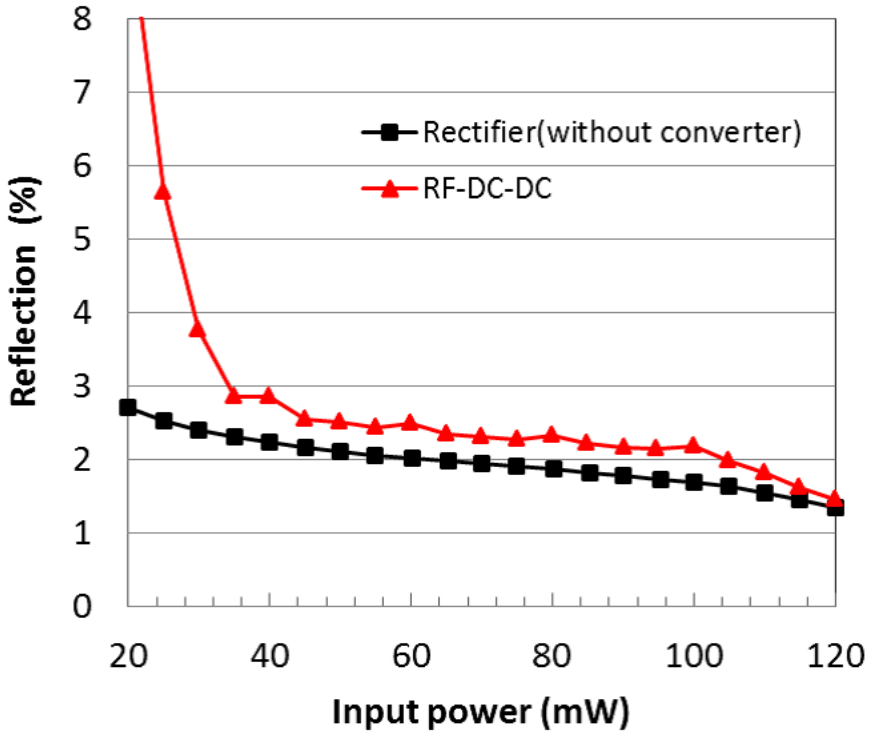


(b)

Figure 4.15: η_{track} comparison and R'_{in}. (a) η_{track} and R'_{in} vs. load resistance for a fixed input power of 80 mW. (b) η_{track} and R'_{in} vs. input power for a fixed load of 800 Ω. Track_Eff1 and Track_Eff2 are the tracking efficiency of the externally-powered and self-powered RF-DC-DC circuit, respectively.



(a)



(b)

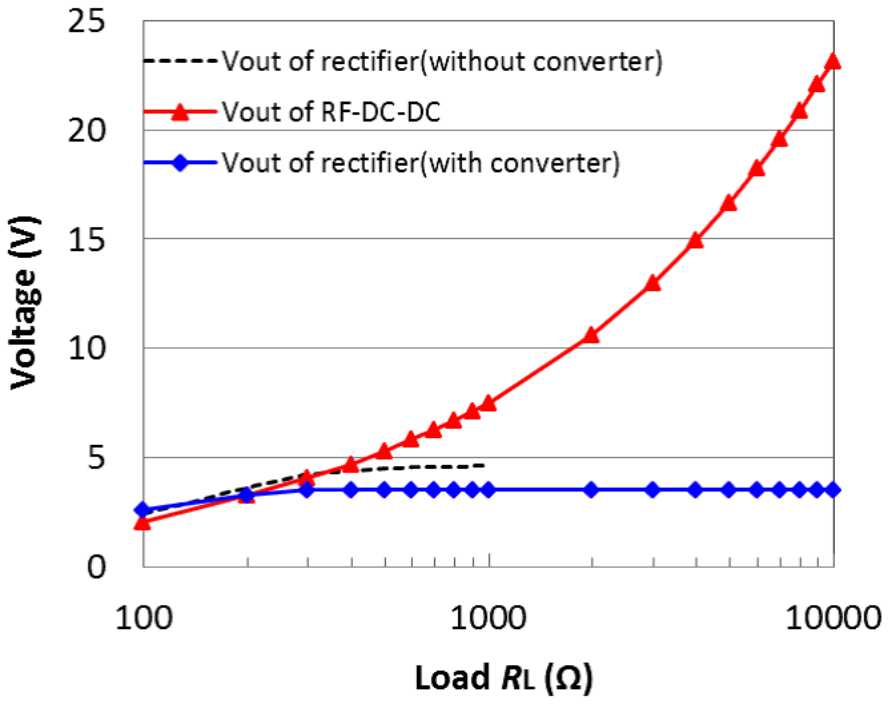
Figure 4.16: Reflection comparison between the general rectifier and the RF-DC-DC circuit. (a) Reflection vs. load resistance for a fixed input power of 80 mW. (b) Reflection vs. input power for a fixed load of 800 Ω.

Next, Figure 4.17 shows the output voltage of each single part of the RF-DC-DC circuit and rectifier (without converter). In Fig. 4.17(a), as expected, the V_{out} of the rectifier (with converter) is almost constant at 3.5 V because the variation of R'_{in} is sufficiently small. Observe that the V_{out} of the RF-DC-DC circuit, a boosted voltage, which well agrees with the curve in Fig. 4.11(a). In contrast, the V_{out} of the rectifier (without converter) is also given by the black point curve. In Fig. 4.17(b), the V_{out} of the rectifier (with converter) is increasing as the input power increases where the variation is as same as the one without converter, and the V_{out} of the RF-DC-DC circuit is increasing with the input power. Compared with the voltage conversion of the buck-boost converter (without rectifier), Figure 4.18 gives the output-input voltage curve of the buck-boost converter in the RF-DC-DC circuit. It is obvious that the two curves are in good agreement when the input voltage is higher than 2.5 V. The input voltage is boosted just a little by the converter because of a low efficiency at low input voltage level.

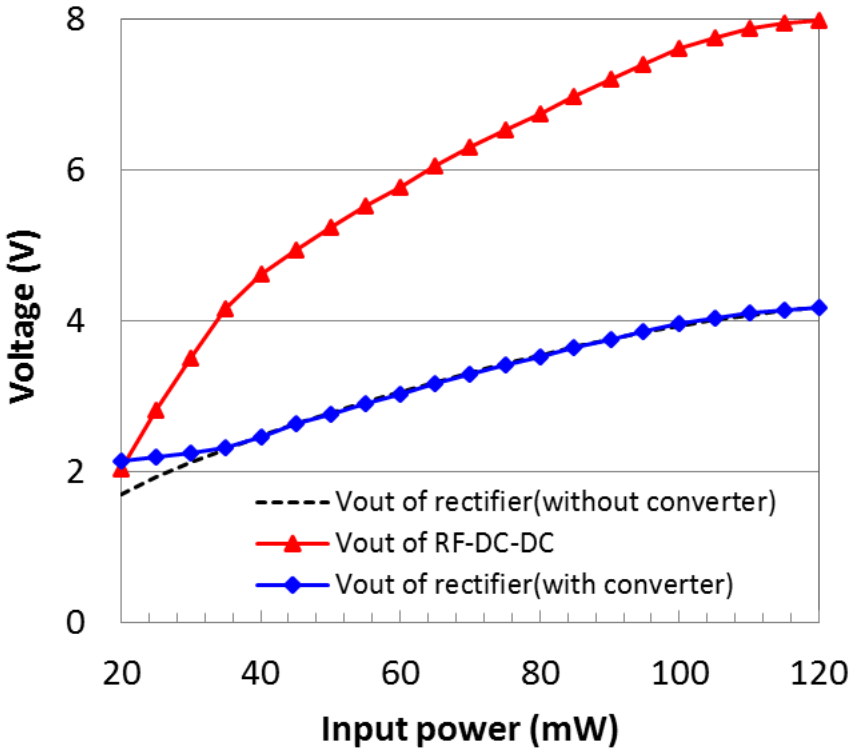
4.5 Summary

This chapter, firstly, a high-efficiency rectifying circuit used for 2.45 GHz microwave is designed and measured. Compared with the circuit designed in Chapter 3.4, this rectifier also uses a class-F load part while it reverses the polarity of the HF diode to obtain a positive output voltage and removes the DC block capacitor in the structure. The measured peak efficiency is 82.5 % at the optimal load of 190 Ω for an input microwave power of 80 mW.

Secondly, we design a self-powered non-inverting DCM buck-boost converter. Compared with the buck-boost converter designed in Chapter 3.3, there are mainly six improvements as follows. (1) It can obtain a positive output voltage with a positive input voltage just changing the position of MOSFET and diode. (2) An additional DC power source is needless because the control-pulse circuit is powered by the input voltage of the converter. (3) The input resistance of the buck-boost converter R'_{in} is designed to be equal to the optimal load of the rectifier (190 Ω). (4) The MOSFET gate driver is removed which attributes to a low power consumption of the control-pulse circuit. (5) A relatively big input capacitor (100 μF) is used to restrain the ripple of output voltage from the rectifier. (6) A variable resistance is used which makes the low frequency duty-on ratio be manual adjustable, then the input resistance R'_{in} is adjustable. Based on the simulation and experimental



(a)



(b)

Figure 4.17: Output voltage of each part of the RF-DC-DC circuit. (a) Output voltage vs. load resistance for a fixed input power of 80 mW. (b) Output voltage vs. input power for a fixed load of 800 Ω.

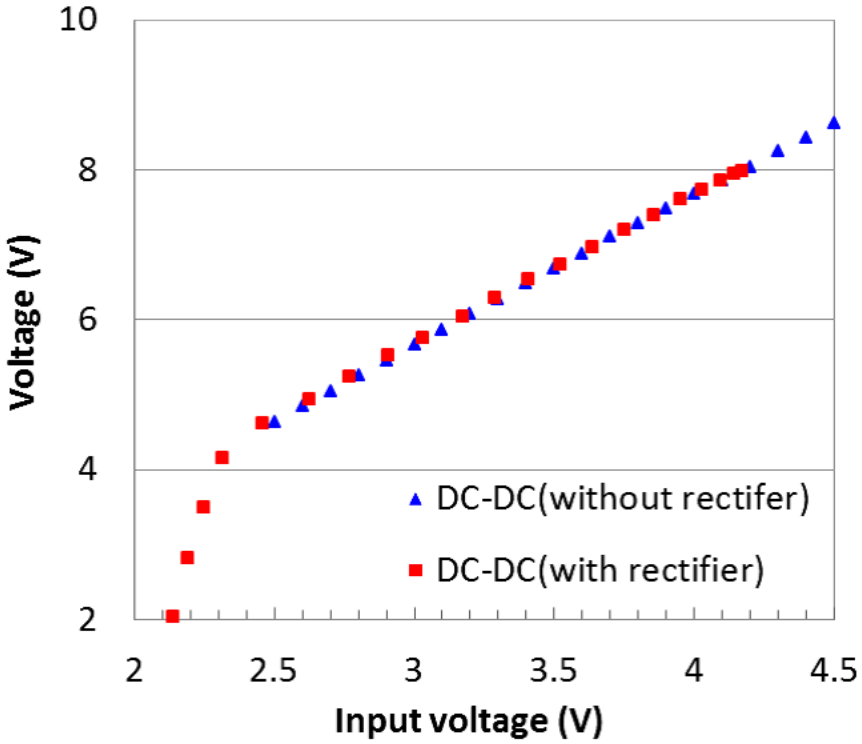


Figure 4.18: Input/output voltage relationships of the buck-boost converter in RF-DC-DC circuit.

results, the input resistance of the converter is almost constant at 190 Ω despite the changes of load resistances and input powers, which is in accordance with the theoretical analysis. Moreover, the measured efficiency of the converter exceeds 83 % for a wide load range of 200 Ω to 10 kΩ, and the input voltage is boosted by the buck-booster converter.

Finally, we conduct an experiment on RF-DC-DC circuit using the self-powered buck-boost converter and the rectifier. The conversion efficiency of the rectifier is approximately steady at 80 %, despite the load resistance varying from 200 Ω to 10 kΩ for an input microwave power of 80 mW. Compared with the peak efficiency of 82.5 % at the optimal load, the maximum power tracking efficiency is over 97 %. Furthermore, the overall efficiency of the RF-DC-DC circuit is constant over 66 % in an ultra-wide load range of 200 Ω to 10 kΩ (a ratio of 1:50). On the other hand, with a fixed load of 800 Ω, the overall efficiency of the RF-DC-DC circuit is also constant over 66 % for the input power of 40 to 120 mW. According to the experimental results, the proposed self-powered RF-DC-DC circuit exhibits a high efficiency in an ultra-wide load range.

A comparison between Figs. 3.14 and 4.13 shows that the varying ripple of

the overall efficiency is small in the self-powered RF-DC-DC circuit. Similarly, the varying ripple of the input resistance is also small in the self-powered RF-DC-DC circuit by comparison with Figs. 3.15 and 4.15. Make a comparison between externally-powered RF-DC-DC circuit and self-powered RF-DC-DC circuit in Table 4.4 where the superiors of the self-powered RF-DC-DC circuit are obvious.

In this Chapter, a self-powered RF-DC-DC circuit as an improved rectifying circuit, which exhibits a high efficiency in an ultra-wide load range, is developed. However, there are still some problems to be solved such as: (1) As the supplied voltage limitation from control-pulse circuit, the input RF power of the RF-DC-DC circuit is limited in the power range of 30 to 140 mW. It is expected to be used for a much more wide power range. (2) The efficiency of the buck-boost converter is expected to be much more high (such as 95 %) to reduce the loss caused by the converter, which would make the overall efficiency of the RF-DC-DC circuit close to the peak efficiency of the general rectifying circuit as much as possible. (3) The RF-DC-DC circuit is expected to be adapted to much small load resistance such as the range of 100 mΩ to 10 Ω. (4) This resistance conversion buck-boost converter is also expected to be valuable for other WPT system such as inductive coupling and magnetic or electromagnetic resonant coupling.

Table 4.4: Comparison between externally-powered and self-powered RF-DC-DC circuits. Z_{opt} is the optimal load of the rectifier. P_{RF} is the input RF power.

Item	externally-powered RF-DC-DC circuit	self-powered RF-DC-DC circuit
Power supply	require an extra DC power	supplied by the input power
$\eta_{\text{max(rf-dc)}}$	79.2 %	82.5 %
Z_{opt} and R_{in}	$R_{\text{in}} = 133\ \Omega$; $Z_{\text{opt}} = 160\ \Omega$.	$R_{\text{in}}^{'} \approx Z_{\text{opt}} = 190\ \Omega$
R_{in}	unadjustable	adjustable
V_{in} ripple	large	small
η_{track} vs. load	> 94 % in 200-5000 Ω (1:25)	> 97 % in 200-10000 Ω (1:50)
η_{track} vs. P_{RF}	> 93 % in 20-100 mW (1:5)	> 95 % in 20-100 mW (1:5)
η_{all} vs. load	> 60 % in 100-5000 Ω (1:50)	> 66 % in 200-10000 Ω (1:50)
η_{all} vs. P_{RF}	> 61 % in 40-100 mW (1:2.5)	> 66 % in 40-120 mW (1:3)

Chapter 5

Experiment on Driving a DC Motor Using MPT

5.1 Introduction

In this chapter, the RF-DC-DC circuit proposed previous is used to drive a dynamic load resistance device. We conduct several experiments on driving a low-power DC motor using microwave power transmission. As the self-powered buck-boost converter in Chapter 4 exhibits a low efficiency at low input power level, we design a relatively high output voltage rectifier and an improved buck-boost converter whose control-pulse circuit is supplied by the output voltage of the converter. By comparison, we also design a relatively low output voltage rectifier and an improved buck-boost converter whose control-pulse circuit is supplied by the input voltage of the converter. This chapter proposes a compact power-receiving device which consists of a rectenna array and the improved self-powered buck-boost converter. With the combination of two different rectenna arrays and two different converters, there are four different power-receiving devices. Finally, using those power-receiving devices, some MPT experiments on driving the DC motor using continuous-wave (CW) and pulsed-wave are conducted.

5.2 Background

The Mars Exploration Rover mission is part of NASA's Mars Exploration Program, a long-term effort of robotic exploration of the red planet. Primary among the mission's scientific goals is to search for and characterize a wide range of rocks and soils that hold clues to past water activity on Mars. The spacecraft are targeted to sites on opposite sides of Mars that appear to have been affected by liquid water in the past. NASA's twin robot geologists, the Mars Exploration Rovers, launched toward Mars on June 10 and July 7, 2003, in search of answers about the history of water on Mars. They landed on Mars January 3 and January 24 PST, 2004 [74]. Power supply technology for rovers is an important issue. So far, several means for electric power supply are used for Mars exploration rover, such as solar cells, lithium batteries and a radioisotope power system. However, there are some problems such as the increase of weight and the limitation of activity time and area. For example, using solar power limits the places on Mars that the rover can explore. They are restricted to landing and traveling around the equatorial region where they can get enough sunlight to re-energize their batteries. Therefore, MPT, an innovative way for powering moon or planet exploration rovers, is proposed [75]. Similarly, for a wide area and continuous Mars observation, MPT for Mars exploration airplane is also proposed [26].

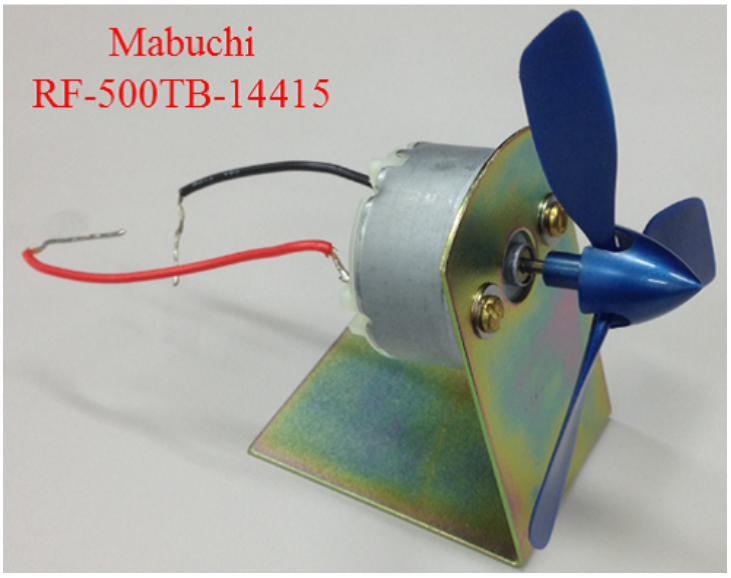
Both rover and airplane proposed above are mainly actuated by DC motors. A static solar power station generates DC power and changes it into microwave power, then transmits microwave power to a distant rover or airplane. The rover or airplane, equipped with rectenna (or rectenna array), receives microwave power and changes it into DC power, which actuates DC motors of rover or a propeller of airplane. As we know, input V-I characteristic of DC motor exhibits variable which depends on its revolution speed and mechanical load. Therefore, the emulated input resistance of DC motor is variable. As a result, the rectifying efficiency is variable when the rectenna is connected to a DC motor. The motor would not work well even stop when it is changed from one operating condition to another because of power shortage caused by impedance mismatch.

Therefore, to solve the problems mentioned above, this chapter only focuses on the study of driving a DC motor using MPT. We design a power-receiving device which has capability of efficiently driving a dynamic load resistance device (such as a DC motor) in the MPT system.

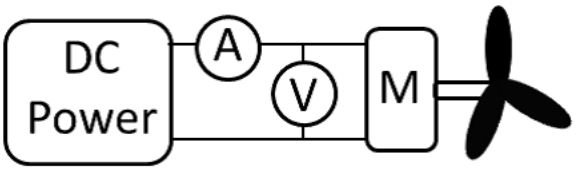
5.3 Low-power DC Motor

If the load resistance characteristics of a DC motor match the optimal load of the rectenna, the output characteristics of the rectenna will be equivalent to those when the rectenna is loaded by a load resistance [38]. It means that a rectenna can drive a DC motor with the maximum efficiency when the load characteristic of the motor equals to the optimal load of the rectenna. However, powered by the microwave, a motor is difficult to maintain a steady revolution speed due to the change of mechanical loads, which leads to a decrease in efficiency of the rectenna. Therefore, if we insert a constant input resistance buck-boost converter between the rectenna and the DC motor, the output impedance of the rectenna maintains constant despite operating conditions of the motor. Consequently, the efficiency of the rectenna will keep constant. Hence, it is necessary to check the input V-I characteristics or the input resistance characteristics of a DC motor before designing a rectenna.

The DC motor used in this study is an RF-500TB-14415 motor made by Mabuchi Motor Co., Ltd as shown in Fig. 5.1(a). This type of motor is usually used for low-power household electrical appliances such as audio-video equipment. The operating voltage range is from 1.5 to 9 V and the output power is widely from 0.01 to 2 W [76]. A DC power source is used to measure the input load characteristics of the motor connected with a small fan as a reference mechanical load. The block diagram of the measurement circuit is shown in Fig. 5.1(b), where an ammeter and a voltmeter measure the input current I_{m} and the input voltage V_{m}, respectively. Then the emulated input resistance R_{m} and input power P_{m} can be calculated by $R_{\mathrm{m}} = V_{\mathrm{m}}/I_{\mathrm{m}}$ and $P_{\mathrm{m}} = V_{\mathrm{m}}I_{\mathrm{m}}$, respectively. To determine R_{m} and P_{m}, the input current is measured with a changed input voltage. The results are shown in Fig. 5.2, which indicates that the input resistance R_{m} increases from 36 to 140 Ω and the input power P_{m} increases from 10 to 645 mW when the input voltage increases from 0.6 to 9 V. Of course, instead of the small fan, if a heavy mechanical load was used, the input resistance would be lower because of a higher current consumption. As the same reason, R_{m} decreases at a higher input voltage. When the input voltage exceeds 5 V, the revolution speed of the fan becomes very fast which results in a heavy resistance of air, then the increase of the current consumption leads to the decrease of R_{m}.



(a)



(b)

Figure 5.1: Photograph of the DC motor and measurement setup for input load resistance R_{m}. (a) Photograph. (b) Measurement setup. An ammeter and a voltmeter measure the input current I_{m} and the input voltage V_{m}, respectively.

5.4 Rectenna Design

5.4.1 Antenna Design

The rectenna is very important for converting wireless RF power into DC power. A rectenna usually contains a receiving antenna and a rectifying circuit. The receiving antenna collects microwave incident power and the rectifying circuit converts microwave power into DC power. In the previous chapters, we only focused on the discussion about rectifying circuits. This chapter will discuss about the design of an antenna.

An antenna is an electrical device for radiating or receiving radio waves. On transmission, an antenna accepts energy from a transmission line and radiates it into space, and on reception, an antenna gathers energy from an incident wave

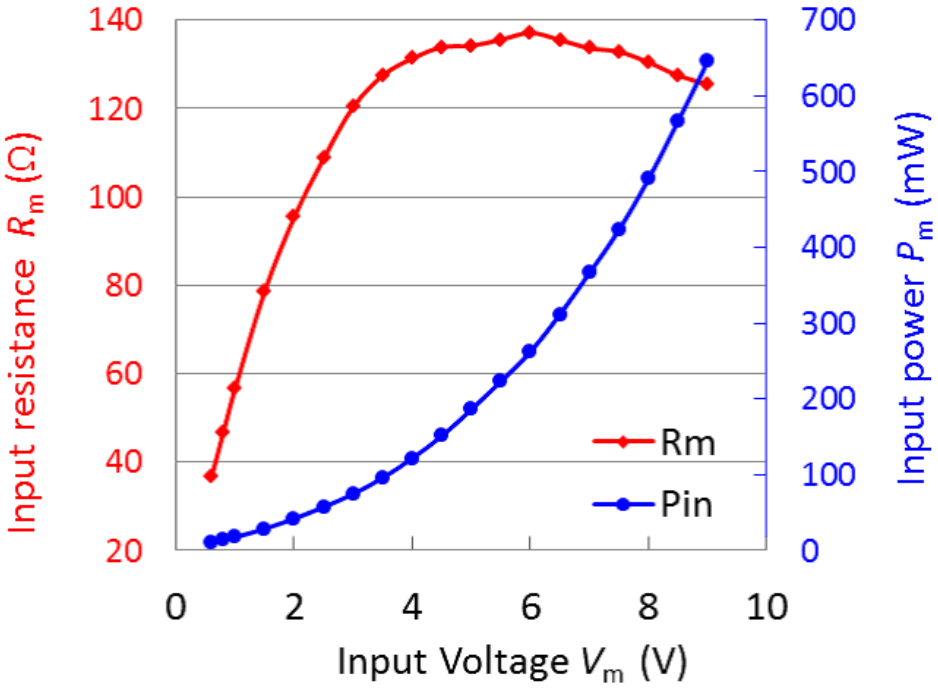


Figure 5.2: Measured input load characteristics of the DC motor.

and sends it down a transmission line. In this chapter, an antenna designed to receive microwave from transmission side. According to different shape and application, there are linear antenna, planar antenna, aperture antenna and so on. For microwave power transmission, a microstrip patch antenna (or array) is commonly used by many researchers [13]-[15]. Patch antenna, with a simple shape, performs a relatively high gain so that it can receive much more power in a limited microwave power density environment. In addition, microstrip patch antennas are excellent in low fabrication cost and readily amenable to mass production [77].

In this experiment, since a horn antenna is used as a microwave transmission antenna, we design a linear polarization circular patch antenna as a receiving antenna. With respect to the dielectric substrate for the rectifier circuit, we all use the same dielectric substrate of NPC-F260 as shown in Table 3.4, where the thickness of the substrate H is 0.8 mm in previous chapters. However, the thickness of the substrate decreases resulting in dielectric losses increasing so that the gain of the patch antenna will decrease, which has been reported in the literature [78][79]. In this experiment, it requires a high gain for receiving as much power as possible in a limited power density environment. Therefore, we design two antennas with two different thickness of dielectric substrates (NPC-F260). Here, these two antennas such as H = 1.6 mm and H = 0.8 mm are referred to as H16 and H08, respectively.

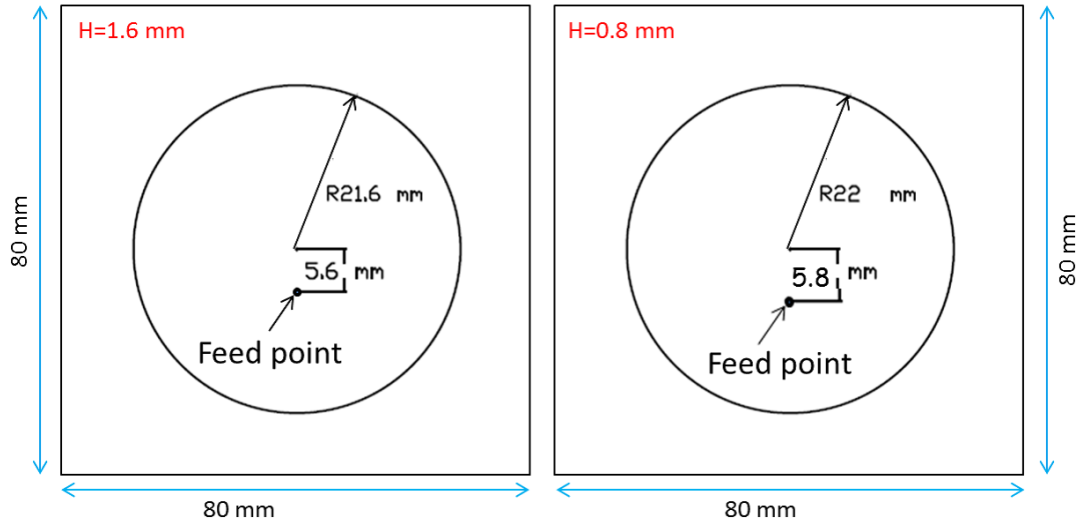

Figure 5.3: Designed antenna sizes.

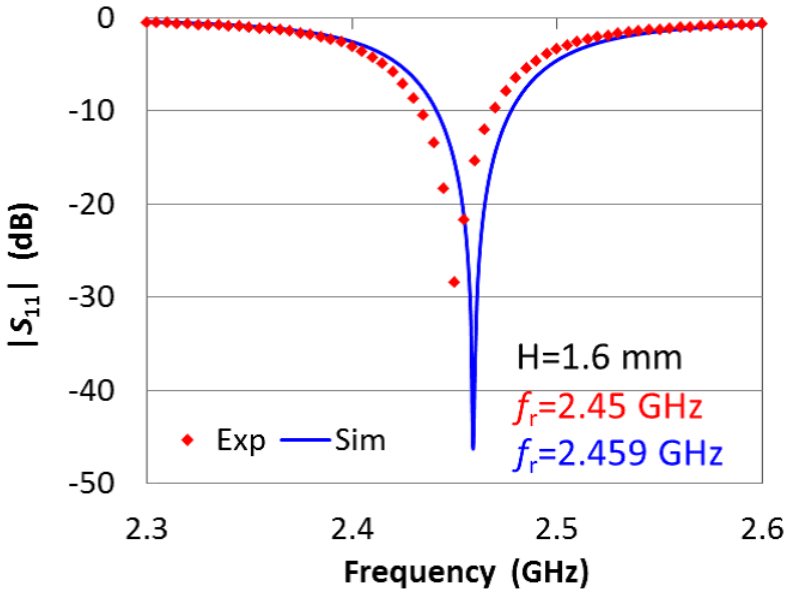
We simulate two antennas by using HFSS simulator of ANSYS and fabricate them. Figure 5.3 shows the shape and sizes of antennas, where the whole size are both 80 mm × 80 mm, and the radius are 21.6, 22 mm, the distances from center to feed point are 5.6, 5.8 mm, respectively. Figure 5.4 shows the simulation and measured results of $|S_{11}|$. Note that the simulation results of two antennas are both a little different with the measured results. However, we make sure that the measured results are both resonant at the frequency of 2.45 GHz, where the $|S_{11}|$ of H16 and H08 are -28 dB and -24 dB, respectively.

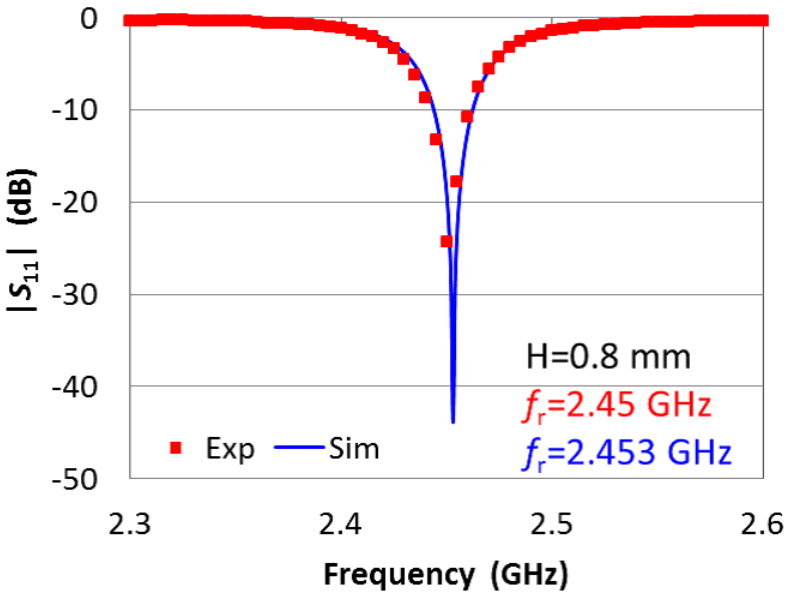
The gain of an antenna is a very important factor in rectenna. The simulation results of antenna's gain are shown in Fig. 5.5, where the gain of H16 and H08 antennas are 7.04 dBi and 6.24 dBi, respectively. Then, as for measurement, compared to a standard half-wave dipole antenna with a known gain of 2 dBi, the gain of designed antenna can be calculated. We set the same power density condition to measure the receiving power of two designed antennas and the standard dipole antenna, then the gain of each antenna can be calculated referring to the receiving power. The effective aperture of the antenna A_e can be calculated by following:

$$A_e = \frac{G_A \lambda^2}{4\pi}, \tag{5.1}$$

where, G_A is the power gain, and λ is the free-space wavelength at 2.45 GHz. The results can be seen from Table 5.1. Note that the effective aperture of the H16 antenna is bigger than that of the H08 antenna. This means one H16 antenna can



(a)



(b)

Figure 5.4: Simulated and measured $|S_{11}|$ of antennas. (a) Antenna H16 $|S_{11}|$ = -28 dB. (b) Antenna H08 $|S_{11}|$ = -24 dB.

Table 5.1: Comparison of H16, H08 and standard antennas for receiving power, gain and effective aperture.

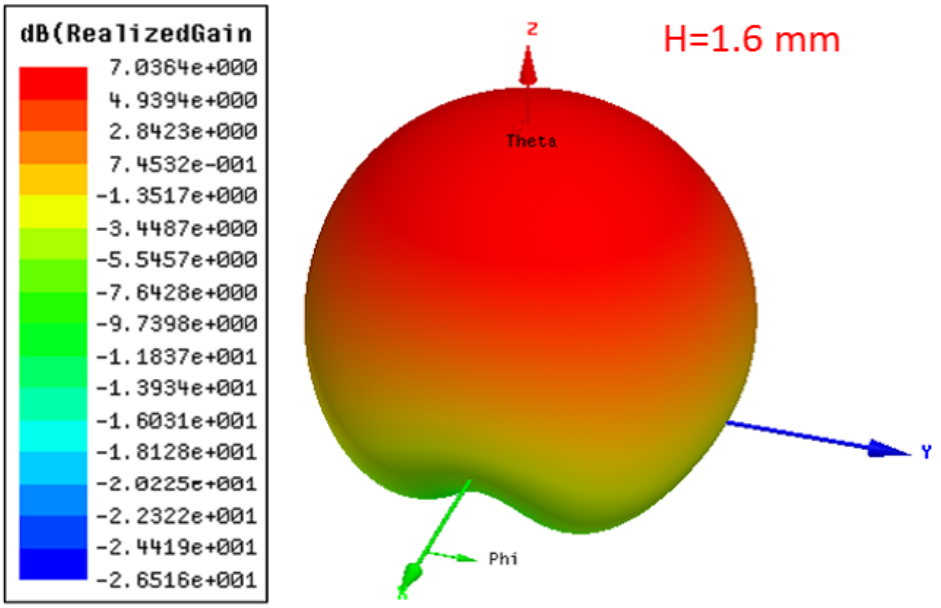
Antenna	H16	H08	Standard
Receiving power (mW)	13.53	11.1	4.92
Gain (dBi)	6.39	5.53	2
Effective aperture (cm^2)	51.6	42.3	18.8

receive approximately 52 mW while H08 antenna can receive approximately 42 mW at the same microwave density of 1 mW/cm^2 which is the standard value of the radiation protection guidance. Consequently, we choose the H16 antenna as a receiving antenna because it is superior in capability of receiving power.

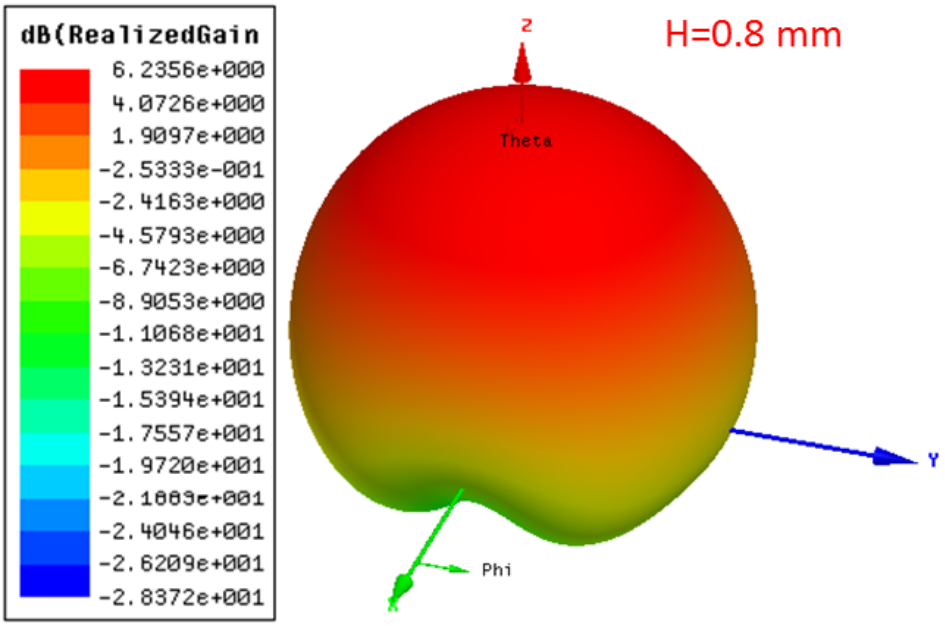
5.4.2 Small Rectifying Circuit

In order to make a compact rectenna, we design a small rectifying circuit to match with the size of antennas. As mentioned in Chapter 4.5, the output voltage of the rectifying circuit supplies voltage for the control-pulse circuit of the buck-boost converter. The overall efficiency of the RF-DC-DC circuit is low when the input power is below 40 mW because the output voltage of the rectifier is low so that it results in a low efficiency of the buck-boost converter. Therefore, it demands a higher output voltage in a lower input power level. On the other hand, a higher RF-DC conversion efficiency is also required. Considering all requirements mentioned above, we design a small rectifier A with a higher optimal load resistance to get a higher output voltage at the same power level. Compared with rectifier A, a small rectifier B with a normal optimal load resistance is also designed.

We use the same dielectric substrate of NPC-F260 and the thickness is 0.8 mm which is the same as the previous design. Similarly, an input matching circuit and two HSMS286F HF diodes are used in the rectifier, while the output filter consists of several open stubs without $\lambda/4$ line. Here, with respect to 2.45 GHz microwave in the NPC-F260 substrate, $\lambda/4$ line is approximate 21 mm which is almost the half length of the whole circuit as shown in Fig. 3.11. $\lambda/4$ line mainly addresses the fundamental frequency content of the output voltage. If we sufficiently deal with the other high order harmonics, the overall high frequency



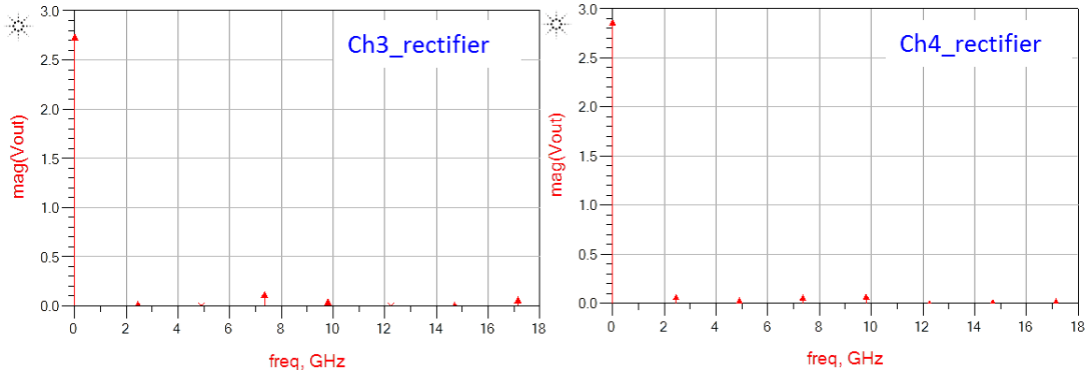
(a)



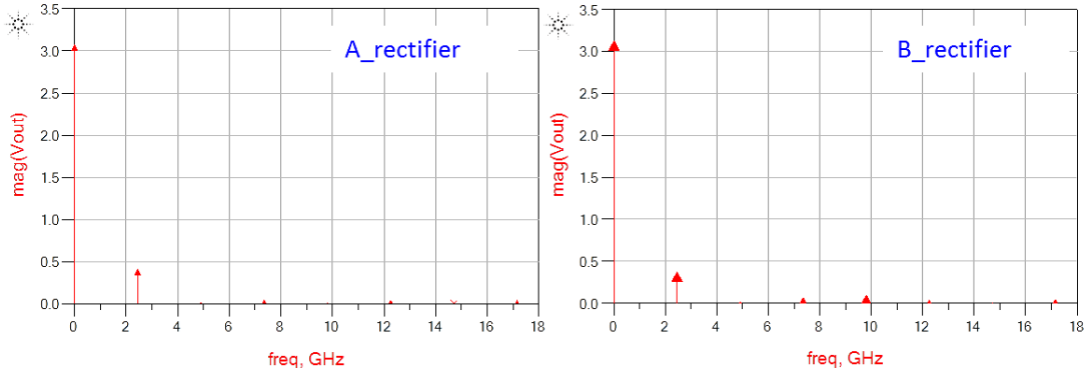
(b)

Figure 5.5: Simulated gains of antennas. (a) The gain of H16 antenna is 7.04 dBi. (b) The gain of H08 antenna is 6.24 dBi.

harmonic loss also can be restrained at a low level even without $\lambda/4$ line. Furthermore, the losses of high frequency harmonic contents are small for 2.45 GHz microwave. Figure 5.6 shows the simulation results of output voltage spectrum of four rectifiers. In Fig. 5.6(a), Ch3_rectifier and Ch4_rectifier are the rectifiers designed in Chapter 3 and Chapter 4, respectively. Figure 5.6(b) shows the results of the rectifier A and B. Observe that the fundamental frequency content in A and B are bigger than that in Ch3_rectifier and Ch4_rectifier, while the high order harmonics of the former is smaller than the latter one. As a result, the overall high frequency harmonic loss of the former is approximately equivalent to the latter one.



(a)



(b)

Figure 5.6: Simulated output voltage spectrum of rectifiers. (a) Ch3_rectifier and Ch4_rectifier are the rectifiers (with $\lambda/4$ line) designed in Chapter 3 and Chapter 4, respectively. (b) A_rectifier and B_rectifier are the rectifiers (without $\lambda/4$ line) designed in this chapter.

Figure 5.7 shows the photograph of the designed rectifier A, B and Ch4_rectifier as a contrast. The size of both rectifier A and B are 35 mm×50 mm, which is

almost the half size of the Ch4_rectifier. Figure 5.8 shows the measured efficiency-load characteristics of the rectifier A and B at different input power levels. The results clearly indicate that the efficiency of the rectifier depends on the connected load and the input power. As for rectifier A, the optimal load is almost constant at 300 Ω in the input power range of 10 to 60 mW. The maximum efficiency is 80.8 % for a load of 300 Ω and an input power of 60 mW. As for rectifier B, the optimal load is almost constant at 160 Ω in the input power range of 10 to 60 mW. The maximum efficiency is 80 % for a load of 160 Ω and an input power of 80 mW. It is clear that the optimal load of the rectifier A is almost twice as big as that of the rectifier B.

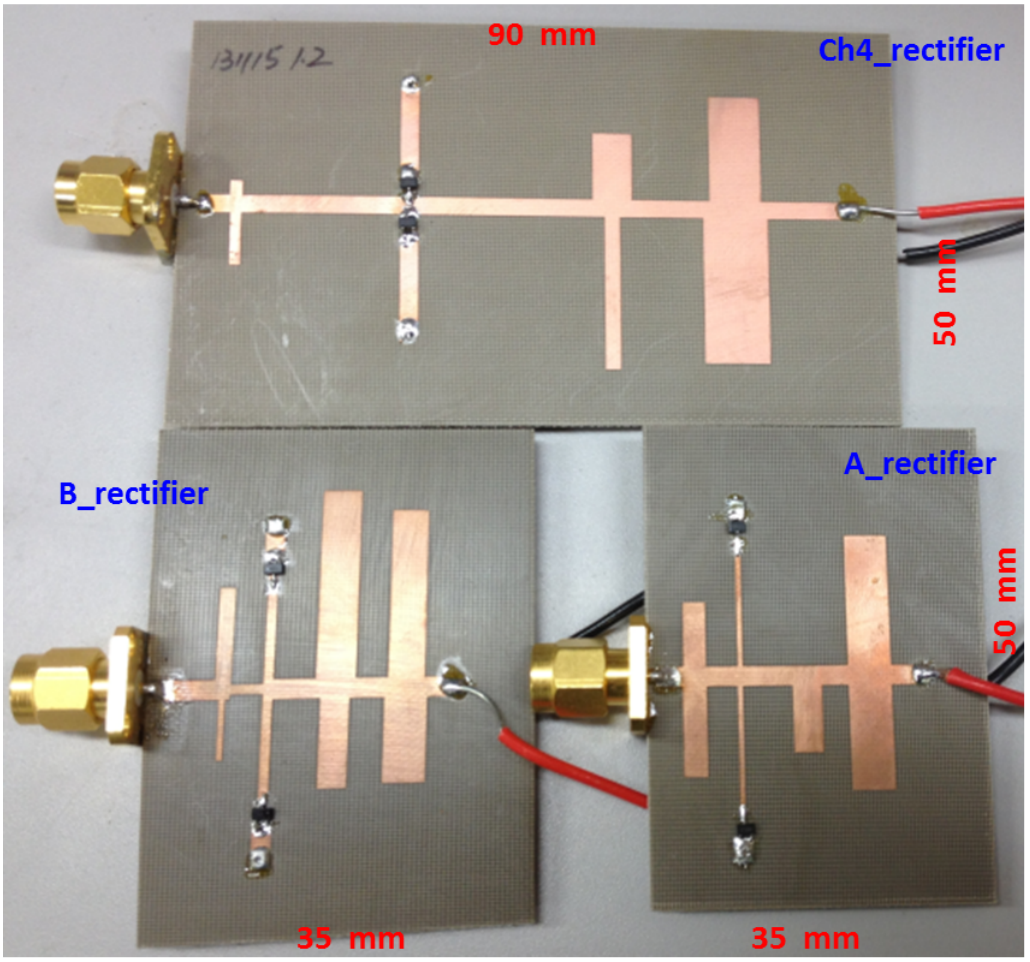


Figure 5.7: Photograph of designed rectifiers: A, B and Ch4_rectifier.

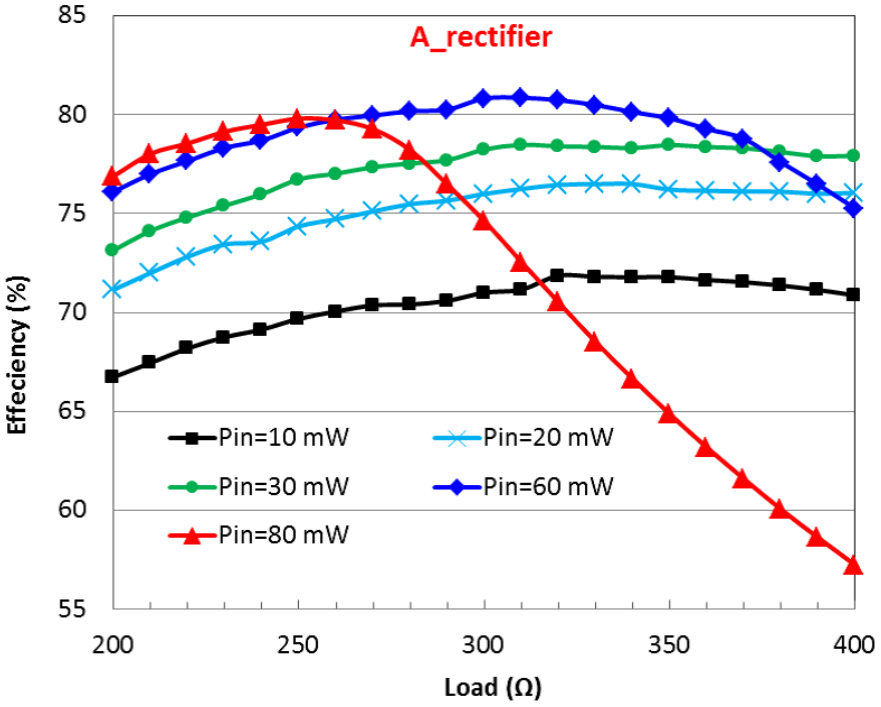
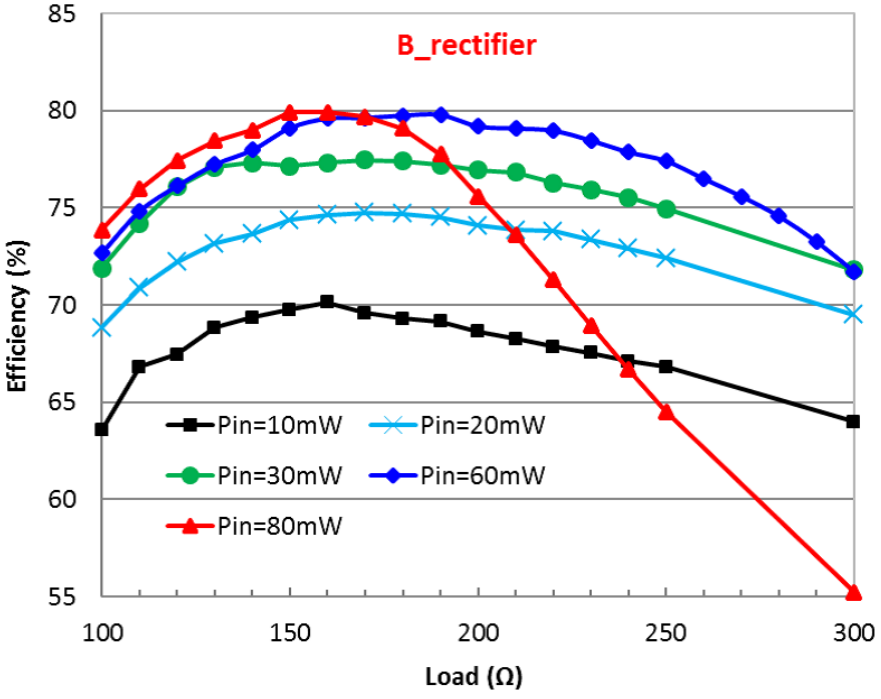
We also investigate the output voltage of both rectifiers and compare them in Fig. 5.9, where A_Eff, A_Vo are the efficiency and output voltage of the rectifier A, B_Eff, B_Vo are the efficiency and output voltage of the rectifier B. Figure 5.9(a) compares the efficiency and output voltage versus load resistance at a fixed input



(a)



(b)

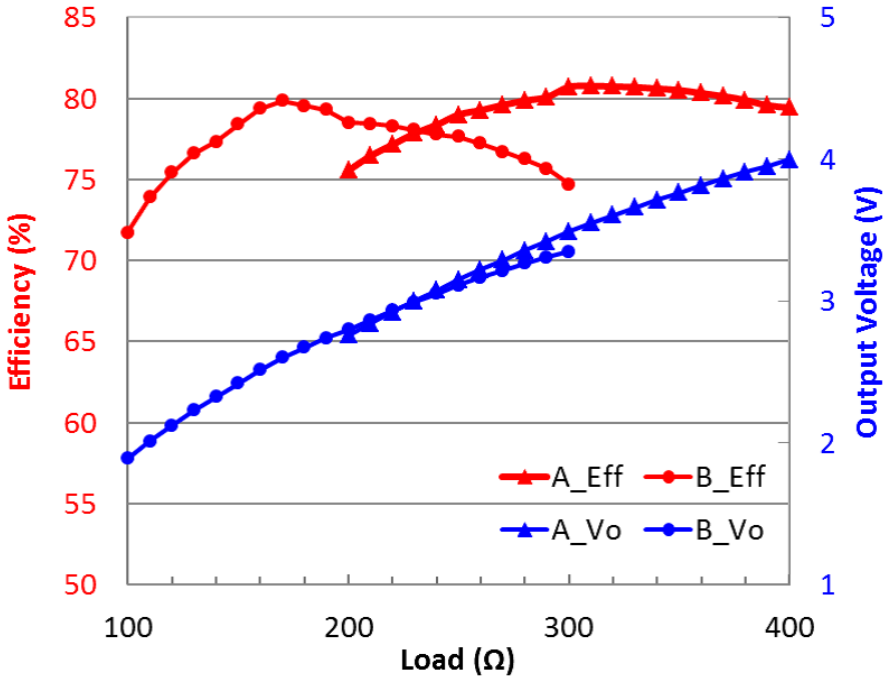
Figure 5.8: Measured efficiency results of the rectifier A and B for different input powers. (a) Efficiency-load characteristics of the A rectifier. The optimal load is almost 300 Ω. (b) Efficiency-load characteristics of the B rectifier. The optimal load is almost 160 Ω.

Table 5.2: Comparison of four rectifiers. Z_{opt} presents the optimal load of the rectifier. V_{out} (80 mW and Z_{opt}) means the output voltage of the rectifier at the optimal load for the same input power of 80 mW. −3.2 V means that the Ch3_rectifier obtains a negative output voltage which has been mentioned in Chapter 3.

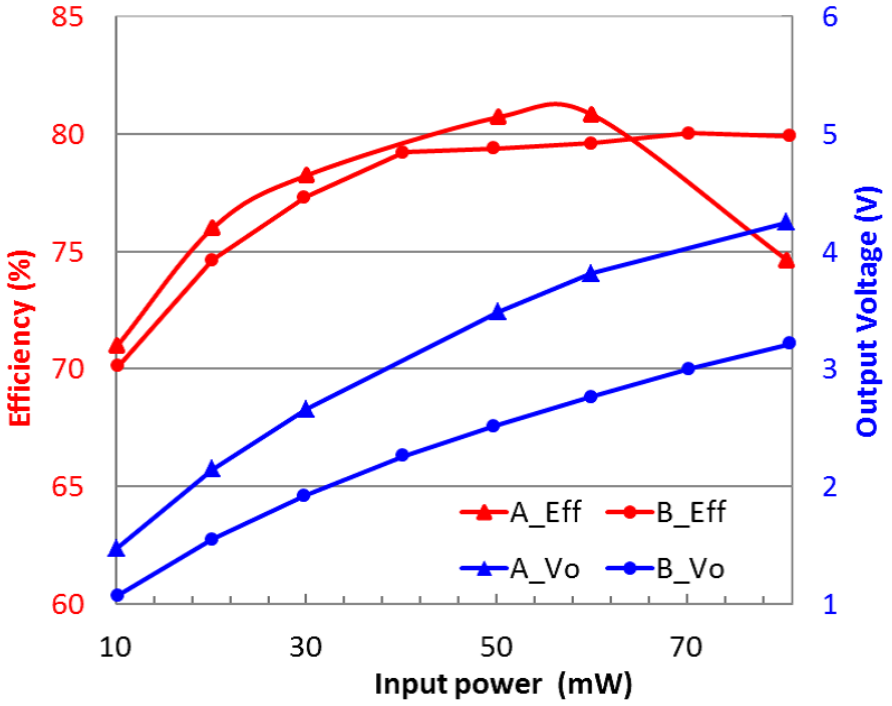
Rectifier	Ch3	Ch4	A	B
Peak efficiency	79.2 %	82.5 %	80.8 %	80 %
Z_{opt} (Ω)	160	190	300	160
V_{out} (80 mW and Z_{opt}) (V)	−3.2	3.5	4.3	3.2
Size (mm)	90×50	90×50	35×50	35×50

power of 50 mW. Observe that the rectifier A presents a higher efficiency and output voltage at a higher load resistance while the rectifier B exhibits a higher efficiency and output voltage at a lower load resistance. In Fig. 5.9(b), when the input power is changing from 10 to 80 mW, the output voltage of both rectifiers are increasing while rectifier A obtains a higher output voltage than rectifier B, the efficiency of the rectifier B is increasing and levels off, while the efficiency of the rectifier A is increasing at the beginning and decreases at a higher power level. The reason is as following. Rectifier A obtains a higher output voltage which leads to a higher reverse voltage applied on the rectifying diode. Consequently, the reverse voltage applied on the diode exceeds the breakdown voltage at a lower input power level which results in efficiency decreasing of the rectifier A.

Until now, we have designed and measured four rectifiers which have each merits and demerits as summarized in Table 5.2. Note that the higher optimal load rectifier obtains a higher output voltage and the output voltage of the A rectifier is 1 V bigger than that of the B rectifier. Ch3_rectifier and rectifier B have almost the same peak efficiency and the same optimal load while the size of the rectifier B is half smaller than Ch3_rectifier. Compared to Ch4_rectifier, the efficiency of the rectifier A is slightly lower but it obtains a higher output voltage with a half small size.



(a)



(b)

Figure 5.9: Comparison of the measured efficiency and the output voltage. (a) Efficiency and output voltage vs. load for a fixed input power of 50 mW. (b) Efficiency and output voltage vs. input power for the optimal load of 300 Ω (rectifier A) and 160 Ω (rectifier B), respectively. A_Eff, A_Vo are the efficiency and output voltage of the rectifier A; B_Eff, B_Vo are the efficiency and output voltage of the rectifier B.

5.5 Compact Power-receiving Device

5.5.1 Improved Buck-boost Converter

A buck-boost converter with a constant input resistance is previously proposed to improve the efficiency-load characteristics of the rectifier in Chapter 4.3. However, the converter operates at low efficiency for input power levels below 40 mW, because the control-pulse oscillator can not be powered by the input voltage of the converter at such low power levels. To overcome this issue, an improved buck-boost converter is designed as shown in Fig. 5.10. Compared to the previous one in Chapter 4.3, the improved buck-boost converter is smaller and simpler because it uses only HF oscillator and a small inductor L (220 μH). As seen the operating waveforms from Fig. 5.10(b), the operating condition has no sleep-state. More importantly, the power for the control-pulse oscillator is supplied by the output voltage of the converter, which is referred to as O-type. By comparison, the control-pulse oscillator is powered by the input voltage of the converter is also designed, which is referred to as I-type. As we have mentioned, the buck-boost converter designed in Chapter 4.3 exhibits a boost converter where the output voltage is larger than input voltage. Therefore, O-type converter is suitable for lower power level because of a higher supplied voltage for the control-pulse oscillator.

Similarly, the input resistance of the converter R_{in} can be calculated using Eq. (3.37). The other parameters are as follows: $L = 220$ μH, f_{h}=20 kHz, D_{h}=0.5, D_{ι} should equal 1 because there is no low-frequency oscillator in this case. This gives an R_{in} value of 35 Ω. According to Eq. (3.37), the input resistance R_{in} of this buck-boost converter will remain a constant value of 35 Ω even though the connected load resistance is above 35 Ω. Hence, when the DC motor described in Chapter 5.3 is connected to the buck-boost converter as a load, its input load resistance of 36 to 140 Ω satisfies the load requirements of the buck-boost converter. The components of the circuit used in this converter are given in Table 5.3 and the photograph of fabricated circuits are shown in Fig. 5.11, which has a size of 25 mm$\times$25 mm. For both converters, the components of the circuit used are the same and the only difference is the connection method.

Similarly, we use the measurement circuit in Fig. 4.9(a) to evaluate the efficiency and R_{in} of the buck-boost converter with a DC power source, and the

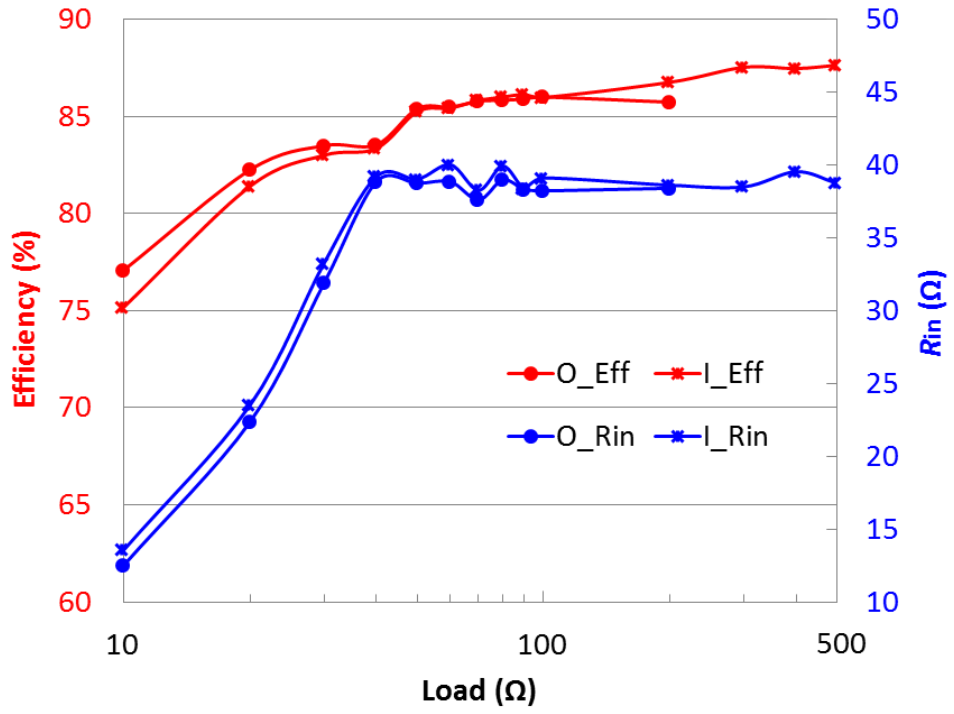
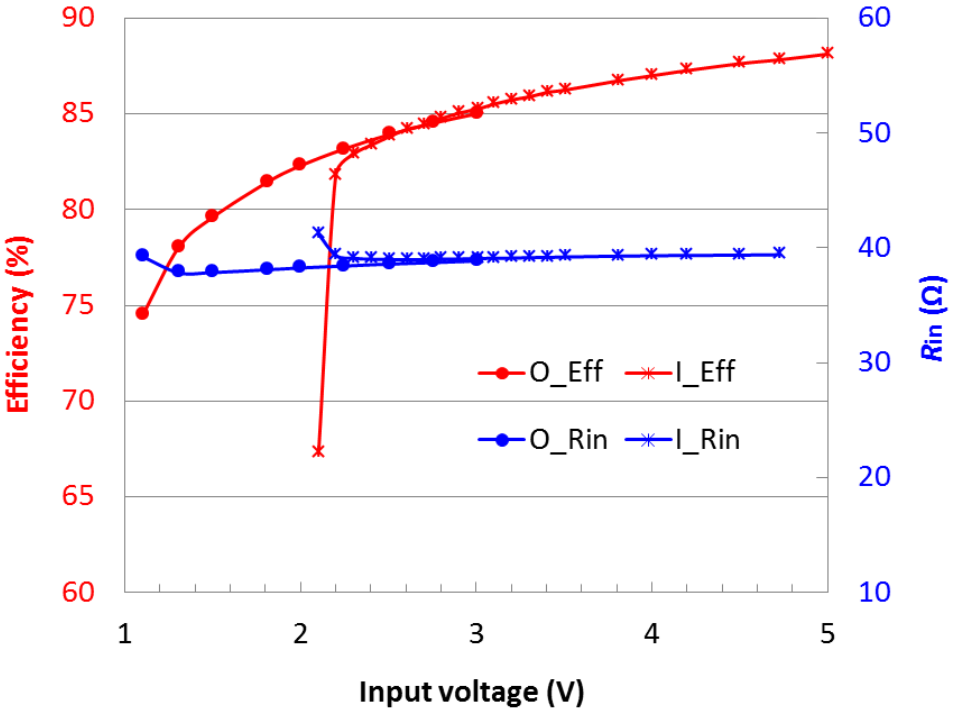
Table 5.3: Components of the improved buck-boost converters.

Component	Maker	Part NO.	Description
High-frequency oscillator	Linear Technology	LTC6900	$I_{SS} = 0.5$ mA ($f = 3$ MHz); $V_{SSmin} = 2.7$ V
N-MOS	Fairchild	FDS6298	$V_{DSS} = 30$ V; $R_{DS(on)} = 12$ mΩ ($V_{GS} = 4.5$ V)
Schottky Diode	Diodes Incorporated	DFLS130L	$V_{RRM} = 30$ V; V_{FM}= 0.21 V
Inductor	Taiyo Yuden	NS12555T221	$L = 220$ μH; $R_{dc} = 0.27$ Ω; $I_{dc} = 1$ A
Capacitor C_{in}	Panasonic	6SVPE220M	220 μF ($V_{rated} = 6.3$ V)
Capacitor C_o	Panasonic	10SVPE220M	220 μF ($V_{rated} = 10$ V)

comparison results of two type converters are shown in Fig. 5.12. Here, O_Eff, I_Eff are the efficiency of O-type and I-type converters, respectively. O_Rin, I_Rin are the input resistance of O-type and I-type converters, respectively. In Fig. 5.12(a), at a fixed input voltage of 3 V, the efficiency and R_{in} of the I-type are measured with load changing from 10 to 500 Ω, while those of the O-type are measured with load changing from 10 to 200 Ω in order to avoid the oscillator of the O-type over-voltage. The efficiency and R_{in} variation tendencies are approximately the same. The efficiency of the O-type is slightly better than the one of the I-type when the load is below 50 Ω and that relation is inverted when the load is over 100 Ω because the supplied voltage for oscillator is simultaneously varying with the output voltage of the O-type converter. As expected, the R_{in} is constant to be 38 Ω which is close to the designed value of 35 Ω when the load is over 40 Ω. In Fig. 5.12(b), at a fixed load of 50 Ω, the efficiency and R_{in} of the I-type are measured with input voltage changing from 2.1 to 5 V, while that of O-type is measured with input voltage changing from 1.1 to 3 V. It is obvious that the O-type converter has the capability of handing lower input voltage and the I-type converter has the capability of handing higher input voltage. Additionally, the R_{in} of both type converters are constant and independent of the input voltage.



(a)



(b)

Figure 5.12: Comparison of measured results between O-type and I-type buck-boost converters. (a) Efficiency and R_{in} vs. load for a fixed input voltage of 3 V. (b) Efficiency and R_{in} vs. input voltage for a fixed load of 50 Ω.

Table 5.4: Comparison of four buck-boost converters such as the converter in Chapter 3, Chapter 4 and O-type, I-type converters in this chapter.

Converter	Ch3	Ch4	I-type	O-type
Power supply	extra DC power source	input voltage	input voltage	output voltage
Voltage polarity	inverting	non-inverting	non-inverting	non-inverting
Control circuit	HF, LF oscillators and gate driver	HF, LF oscillators	HF oscillator	HF oscillator
Size	large	medium	small	small

Until now, we have designed and measured four buck-boost converters which have each merits and demerits as summarized in Table 5.4. Those four converters all operate at discontinuous conduction mode with constant input resistance characteristic and play a boost converter role in the application. The O-type and I-type have the small size and O-type has the capability of handing lower power without extra DC power supply.

5.5.2 Compacting Rectenna Array and Buck-boost Converter

A single rectenna consists of the antenna designed in Chapter 5.4.1 and the rectifier as shown in Fig. 5.13. The optimal load of the A rectifier and B rectifier described in Chapter 5.4.2 are 300 Ω and 160 Ω, respectively. While the input resistance of the buck-boost converter described in Chapter 5.5.1 is almost 35 Ω. Therefore, in order to match the input resistance of the buck-boost converter, a common method that several rectennas are connected in parallel as a rectenna array is usually applied to decrease the optimal load of the rectenna [80]. Then we set 9 A_rectennas connected in parallel as A rectenna array and 4 B_rectennas connected in parallel as B rectenna array, respectively. The optimal load of the A rectenna array and the B rectenna array can be calculated to be approximately 33 Ω and 40 Ω, respectively.

Additionally, in order to make the rectenna array in a compact board, we use a multilayer substrate with the antennas in the upper layer and the rectifiers in the lower layer and GND in the middle layer. The buck-boost converter is also in the lower layer, and is connected to the output of the rectenna array. We connect the feed point of the antenna and the input port of the rectifier by a through hole which is isolated from the middle layer. The GND in rectifiers and buck-boost converter are all connected to the middle layer by other through holes. Figure 5.14 shows a side-view diagram of the multilayer substrate. In the upper layer, antennas are arranged in an equilateral triangle position with the separation between two near antennas of 75 mm, which is almost 0.61 λ (λ is a free-space wavelength at 2.45 GHz). The rectenna array has two types such as A and B, and the buck-boost converter also has two types such as O-type and I-type. With those different types, there are four different combinations of the rectenna array and the buck-boost converter such as A rectenna array + O-type converter (9AO), A rectenna array + I-type converter (9AI), B rectenna array + O-type converter (4BO) and B rectenna array + I-type converter (4AI), respectively. The rectenna and converter combination is referred to as compact power-receiving device here. The photograph of the 9AO and 4BI power-receiving devices are shown in Fig. 5.15.

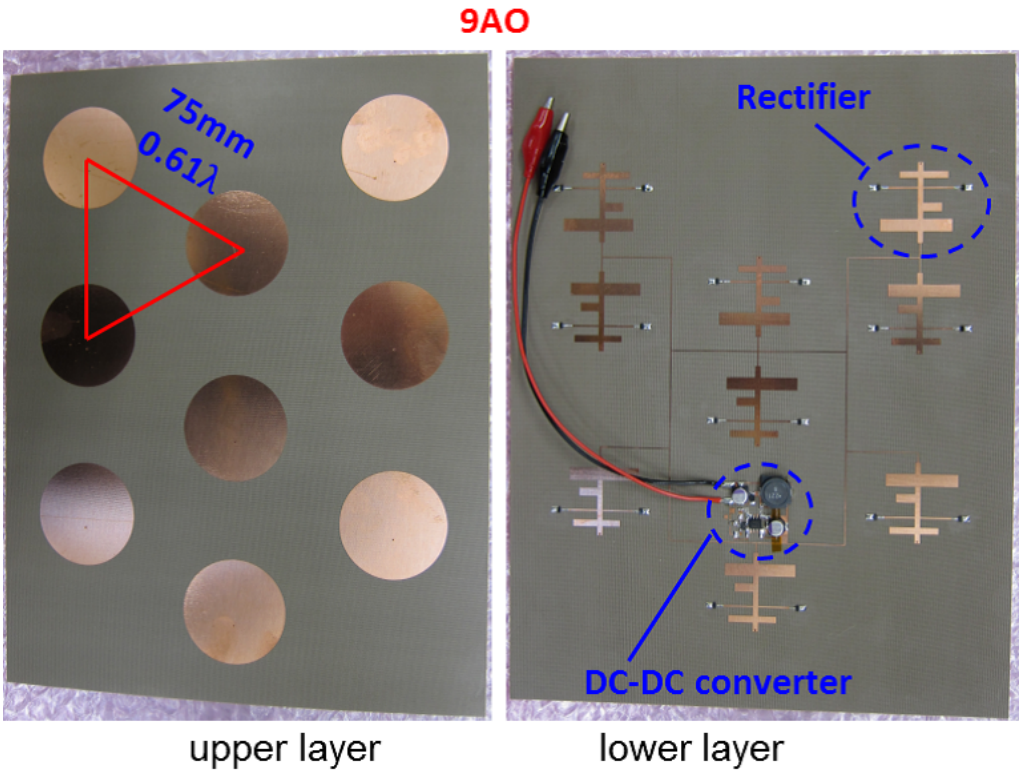
5.6 MPT Experiment Using Continuous-wave

5.6.1 Power Received by Antenna Array

In order to evaluate the overall efficiency of the compact power-receiving device, it is first necessary to measure the power received by the antenna array P_{rall}. Figure 5.16(a) shows a block diagram of the experimental setup used to measure P_{rall} of 9 antennas. It consists of a signal generator (SG), an amplifier, a directional coupler, a horn antenna and the receiving antenna array (without the rectifying circuits or buck-boost converter). The SWH-22 horn antenna of ARA Technologies Inc. we used has an aperture size of 36 mm×25 mm and a gain of 16.3 dBi. According to the antenna far field distance d_{f} calculation, $d_{\text{f}} = 2D^2/\lambda$, where D is the largest dimension of the aperture, the far field distance d_{f} is calculated to be 21 cm. Hence, we set the microwave power transmission distance at 3 m which is much longer than d_{f}.

The power meter measures the input power of the transmission antenna through power sensor A, and measures the received power of each individual antenna one by one through power sensor B. In order to eliminate the influence from the reflection of near antennas, the other eight antennas are all connected to a 50 Ω dummy load as one antenna is being measured. The example of 9 antennas measurement is shown in Fig. 5.16(b). For comparison, the power received by just



(a)

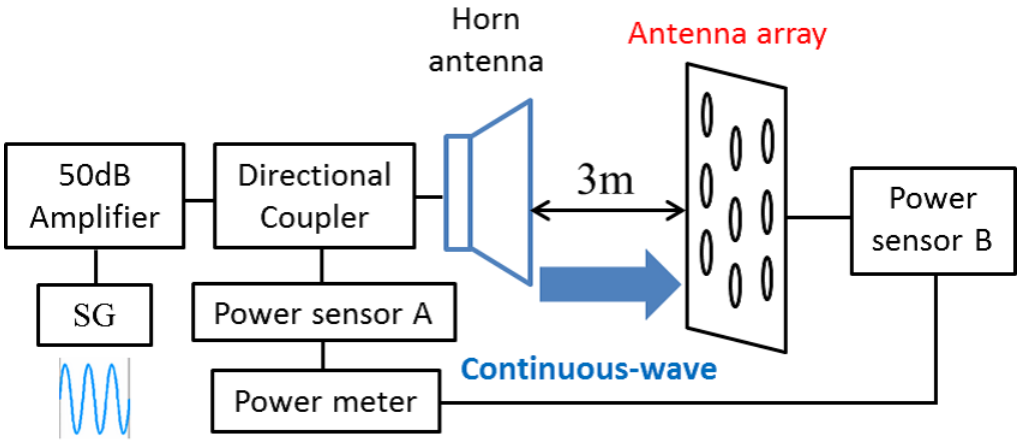
b1	0.691	0.692	0.692	0.691	0.689	0.69	0.691	0.689	0.698
b2	0.774	0.77	0.772	0.771	0.768	0.768	0.772	0.772	0.781
b3	0.955	0.956	0.956	0.957	0.955	0.954	0.956	0.956	0.965
c1	0.856	0.86	0.86	0.859	0.857	0.854	0.858	0.857	0.868
c2	0.843	0.844	0.843	0.846	0.846	0.847	0.844	0.842	0.854
c3	0.731	0.735	0.734	0.736	0.732	0.732	0.73	0.731	0.744

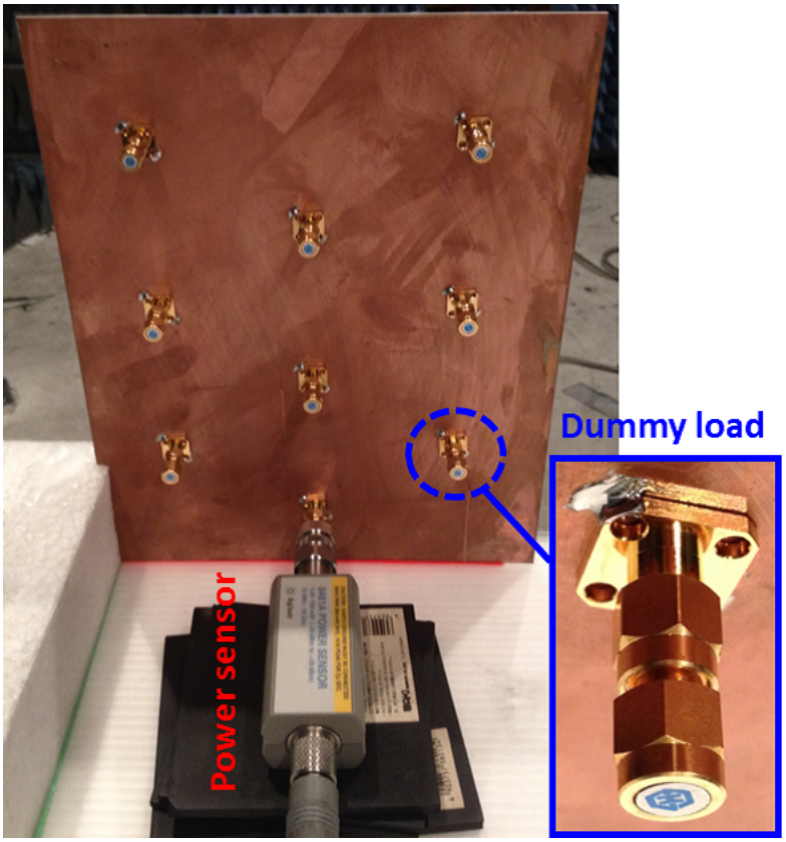
a single antenna, placed at the center position, is also measured, and power received by each antenna of nine antennas are expressed relative to this as shown in Fig. 5.17. These power proportion relation should be constant at different power densities because the gain of antennas are changeless. As shown in Table 5.5, it is obvious that the relative power proportion between a single antenna and antenna array is independent of the power density. The power received by the individual antennas in the array is lower than that received by the single antenna because of overlapping of the effective apertures in the antenna array. Similarly, using the same measurement method, the receiving power of 4 antennas array is also measured. Figure 5.18 shows that the overall power received by the 9 antennas array P_{Aall} and 4 antennas array P_{Ball} in different power densities P_{den}. P_{Aall} increases linearly from 95 to 800 mW and P_{Ball} increases linearly from 45 to 376 mW as the power density is increased from 0.25 to 2.08 mW/cm^2.

5.6.2 Experiment on Driving DC Motor Using Continuous-wave

Figure 5.19 shows a block diagram of the experimental setup used to drive the DC motor by MPT with Continuous-wave power. It consists of the same transmitting



(a)



(b)

Figure 5.16: Experiment setup for measuring the receiving power of the antenna array. (a) Experiment setup. (b) Photograph of the antenna array setup. Power sensor measures the receiving power of each antenna with all other antennas connected to a 50 Ω dummy load.

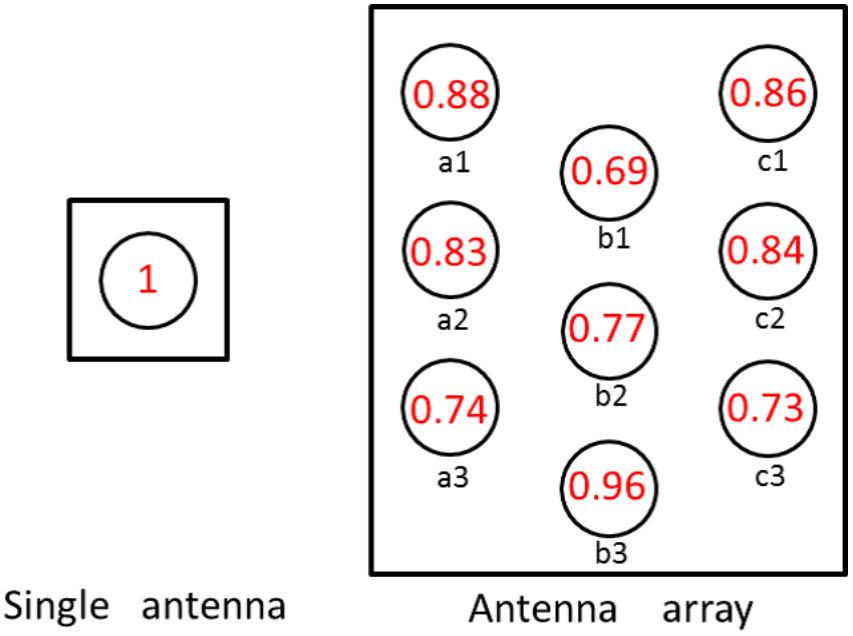


Figure 5.17: Relative power received by 9 antennas array and a single antenna.

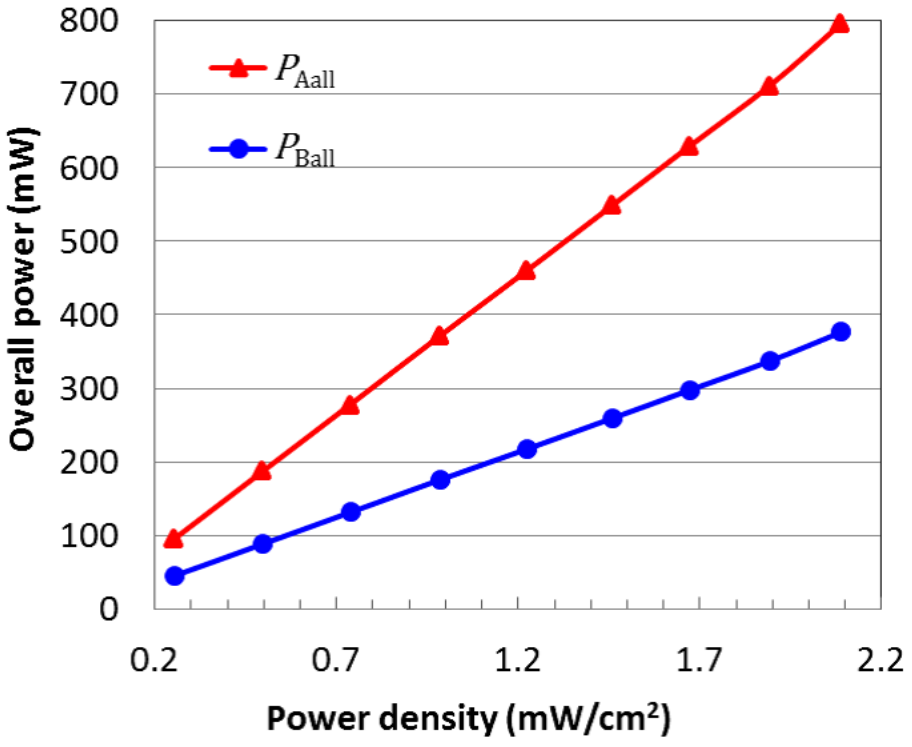

Figure 5.18: Overall powers received by 9 and 4 antennas array such as P_{Aall} and P_{Ball}.

setup as Fig. 5.16, the compact power-receiving device and the DC motor. Of cause, the microwave power transmission distance is also 3 m. The power meter measures the input power of the transmission antenna through a power sensor. An ammeter and a voltmeter measure the input current I_{m} and the input voltage V_{m} of the DC motor, respectively. Firstly, we replace the DC motor with load resistances in Fig. 5.19 to test the compact power-receiving device using CW. Here, the overall efficiency η_{prd} is defined as the ratio of the power output from the buck-boost converter to the power received by the antenna array:

$$\eta_{\mathrm{prd}} = \frac{V_{\mathrm{m}} I_{\mathrm{m}}}{P_{\mathrm{rall}}} \times 100\,\%. \tag{5.2}$$

Figure 5.20(a) shows the overall efficiency η_{prd} of four types power-receiving devices such as 9AO, 9AI, 4BO, 4BI, for load resistances of 10 to 100 Ω with power density P_{den} of 0.98 mW/cm^2. As the load is changing from 30 to 100 Ω, the η_{prd} of the 9AO and 9AI are constant above 70 %, which is slightly higher than that of the 4BO and 4BI of 61 %. This is because that the P_{den} of 0.98 mW/cm^2 reaches the peak efficiency power level for A_rectifier while it is a lower level for B_rectifier according to the results in Chapter 5.4.2. As the load is below 30 Ω, the η_{prd} of four types are low due to the efficiency decrease of the buck-boost converter as shown in Fig. 5.12(a). Figure 5.20(b) shows the output voltage of the power-receiving device, which is also the input voltage of the DC motor V_{m}. Observe that the V_{m} of the 9AO and 9AI are higher than that of the 4BO and 4BI because the former exhibit a higher efficiency than the latter at the same input power and the same load resistance.

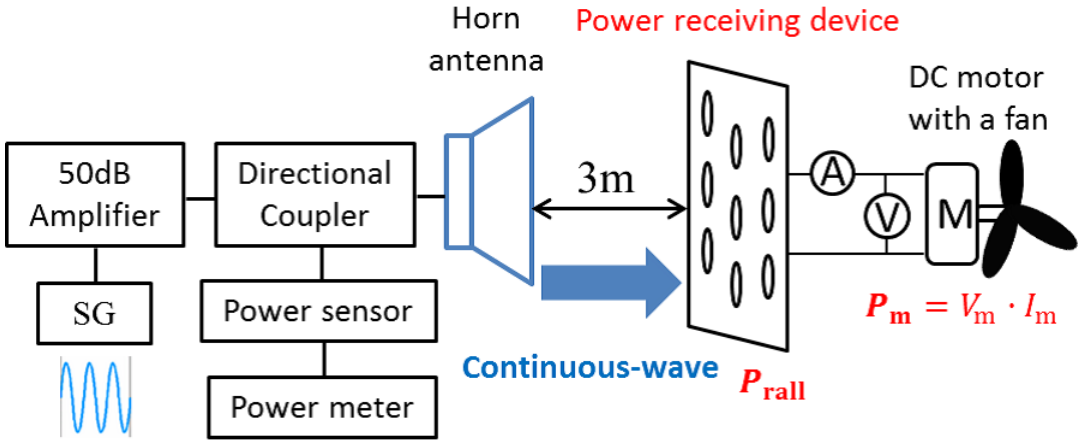

Figure 5.19: Experiment setup for driving DC motor by MPT using CW.

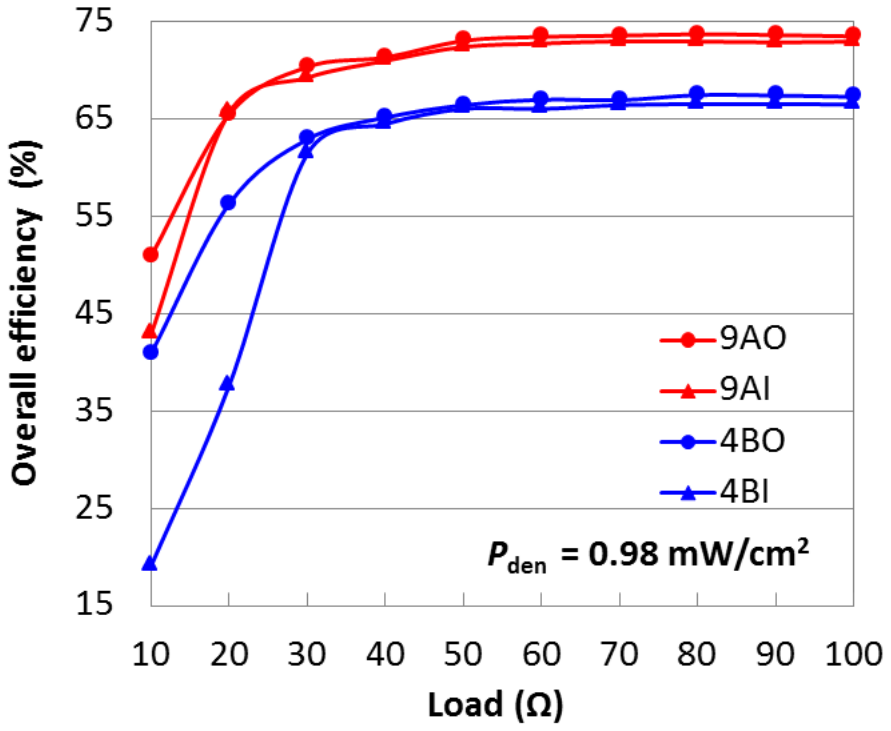
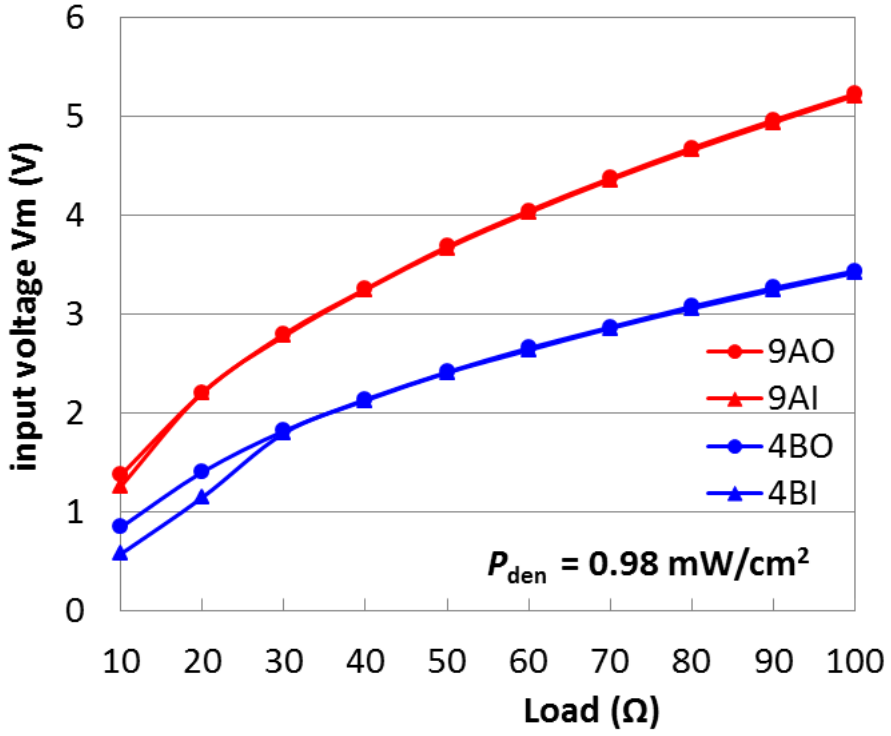


(a)



(b)

Figure 5.20: Comparison of measured overall efficiency and V_{m} for a fixed power density of 0.98 mW/cm^2. (a) Overall efficiency vs. load resistance. (b) V_{m} vs. load resistance.

Figure 5.21(a) shows the overall efficiency η_{prd} at load resistance of 30 Ω for P_{den} changing from 0.25 to 2.08 mW/cm^2. It is obvious that the η_{prd} of the O-type is higher than that of the I-type both in A_rectifier and B_rectifier for a lower power density level. Compared with 9AI, 9AO performs a higher efficiency when P_{den} is below 0.98 mW/cm^2 while it performs a lower efficiency as P_{den} over 0.98 mW/cm^2. However, compared with 4BI, 4BO performs a higher efficiency when P_{den} is below 0.98 mW/cm^2 while it performs approximately the same efficiency level with the 4BI when P_{den} is over 0.98 mW/cm^2. This is because that the A rectifier obtains a higher output voltage than B rectifier even at the same power density level resulting in efficiency decrease of the O-type converter when the power density is up to a higher level. As for 4BO, the output voltage of the rectifier B is not too large to lead to efficiency decrease of the converter even P_{den} is up to 2.08 mW/cm^2. As shown in Fig. 5.21(b), the V_{m} of the 4BI and 4BO are both below 3 V.

Next, we test the DC motor using MPT in CW power and the measurement overall efficiency results are shown in Fig. 5.22. Similarly, as the power density changing from 0.25 to 2.08 mW/cm^2, the four types overall efficiency are shown in Fig. 5.22(a). Compared with the case of 30 Ω load resistance, the η_{prd} of the 9AO and 9AI almost perform the same variation tendency while the η_{prd} of the 4BO and 4BI perform a little difference in the case of the DC motor. The reason is as following: The input load resistance of the motor R_{m} is increasing as the power density increases which leads to a higher V_{m} and the R_{m} is much larger than 30 Ω in the case of the DC motor. The larger R_{m} leads to V_{m} increase again which results in a higher efficiency of the 4BO because the efficiency of the O-type converter is increasing as the gate voltage increases. The overall efficiency of the 9AO is over 50 % as P_{den} is changing from 0.25 to 2.08 mW/cm^2 while the overall efficiency of the 9AI is over 61 % as P_{den} is changing from 0.5 to 2.08 mW/cm^2. As seen from Fig. 5.22(b), the V_{m} of the 4BO is slight higher than that of the 4BI. Compared with Fig. 5.21(b), V_{m} in Fig. 5.22(b) is higher because the R_{m} is much larger than 30 Ω. In conclusion, 9AO is better for a lower power density level as below 0.98 mW/cm^2 and 9AI is better for a medium power density level as below 1.9 mW/cm^2 and 4BO is better for a higher power density level as over 1.9 mW/cm^2.

5.7 MPT Experiment Using Pulsed-wave

Recently, the simultaneous use of MPT and wireless communication has been proposed for ZigBee sensor devices and wireless LAN devices [32]-[34]. The authors proposed that scheduled pulsed-wave power transmission would eliminate or reduce interference between microwave power transmission and communication. Accordingly, we also test the compact power-receiving device using a pulsed-wave power transmission as shown in Fig. 5.23. Similarly, we test it using both load resistances and the DC motor. Here, we set the duty ratio of the pulsed-wave as D_{pw}. Then, the overall efficiency $\eta_{\mathrm{prd}}^{'}$ presents as follows:

$$\eta_{\mathrm{prd}}^{'} = \frac{V_{\mathrm{m}} I_{\mathrm{m}}}{P_{\mathrm{rall}} D_{\mathrm{pw}}} \times 100\,\%. \tag{5.3}$$

Figure 5.24(a) shows the overall efficiency of the 9AO versus the duty ratio of the pulsed-wave when it is loaded by a 30 Ω resistance or the DC motor. The measurement condition is that the power density is 0.98 mW/cm^2 and the pulsed-wave frequency is 25 kHz. Except for a duty ratio of 0.2, similar results are seen for both types of load. A bigger duty ratio leads to a higher input power so that the efficiency of the rectenna is increased. Therefore, the overall efficiency generally increases as the duty ratio is increasing from 0.2 to 1. Furthermore, the overall efficiency for driving the DC motor is over 44 % even though the duty ratio is widely changed from 0.2 to 1. Figure 5.24(b) shows the overall efficiency versus the frequency of the pulsed-wave for driving the DC motor at the power density of 0.98 mW/cm^2 and the duty ratio of 0.5. In this case, the overall efficiency performs a small variation, almost constant at 59 % in the frequency range of 0.33 to 41.7 kHz. As seen from the Eq. (5.3), the overall efficiency is independent of the frequency of the pulsed-wave, which is in agreement with the experiment results. Therefore, the proposed power-receiving device is also suitable for MPT in pulsed-wave power.

5.8 Summary

In this chapter, we conduct several experiments on driving a DC motor using MPT system both in CW and pulsed-wave. Firstly, the background of the study

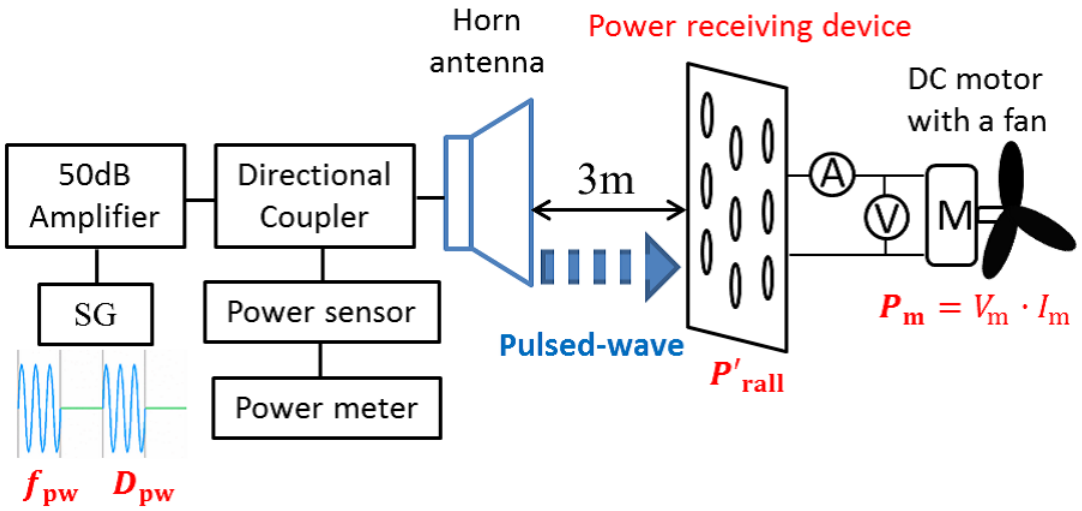

Figure 5.23: Experiment setup for driving DC motor by MPT using pulsed-wave.

that a DC motor is driven by MPT system is introduced. Then, as a test model, we choose a low-power DC motor and the input resistance of the motor is measured. Secondly, we design two antennas with different thicknesses of dielectric substrate of 1.6 and 0.8 mm, and the gain of two antennas are evaluated. We choose the thicker one as the receiving antenna because it exhibits a high gain. Thirdly, to make a compact rectenna array, we design two relatively smaller size rectifiers (A and B) with the measured peak conversion efficiencies of 80.8 % and 80 % at the optimal loads of 300 and 160 Ω, respectively. Fourthly, we design two improved buck-boost converters such as I-type and O-type converters according to the control-pulse oscillator supplied by the input voltage or the output voltage. Fifthly, we compact the antenna array and the rectifier array with the improved buck-boost converter in a multilayer substrate as a power-receiving device. Using those two rectifiers and two converters, there are four combinations of power-receiving devices such as 9AO, 9AI, 4BO, 4BI. Sixthly, we conduct several experiments on driving the DC motor with MPT in CW power using those four combination devices. The overall efficiency of the 9AO is above 60 % in the power density range of 0.25 to 0.98 mW/cm^2 and the overall efficiency of the 9AI is above 60 % in the power density range of 0.5 to 2.08 mW/cm^2. Finally, that the DC motor driven by MPT in pulsed-wave power using 9AO combination device is also tested. In the pulsed-wave case, the overall efficiency is above 44 % in the duty ratio range of 0.2 to 1 for a power density of 0.98 mW/cm^2. Additionally, at a fixed duty ratio of 0.5, the overall efficiency is almost constant at 59 % for the pulsed-wave frequency changing from 0.33 to 41.7 kHz. In conclusion, by

both CW and pulsed-wave power, the designed compact power-receiving device performs a relatively high efficiency for driving the DC motor. It is also expected to be valuable for other wireless power transmission applications.

Chapter 6

Conclusion

6.1 Summary and Conclusion

Many researchers are always perplexed by the problem of efficiency-load characteristics in rectenna. This thesis develops a rectenna adapted to ultra-wide load range for microwave power transmission system. We propose a novel resistance conversion DC-DC converter which plays an impedance matching role in rectenna. Connected to this special DC-DC converter, the rectenna seems to operate in a steady load resistance condition despite a varying load resistance connected to the converter. Consequently, when we set the input resistance of the DC-DC converter equal to the optimal load of a general rectenna, the rectenna can keep operating at the peak efficiency point independent of load resistances of the converter.

In Chapter 1, the history of wireless power transmission and microwave power transmission are introduced. An overview of rectenna researches in the world is summarized and the objectives of this thesis are expressed.

In Chapter 2, after giving an overview of efficiency improvement methods in rectenna researches and a comparison of impedance matching methods in WPT studies, we test a PWM controlled boost converter for impedance matching in rectifying circuit. We build a model of a RF-DC-DC circuit which consists of a rectifying circuit and a boost converter, and simulate it using harmonic balance analysis of ADS. Based on the simulation results, the RF-DC-DC circuit obtains a steady high overall efficiency (over 70 %) for a load range from 370 to 1300 Ω, which is wider than that of the rectifier at the same efficiency level. The boost converter

connected to the RF-DC rectifier can limit the maximum reverse voltage of the rectifying diode under breakdown voltage at a wide range of load resistances. The simulation results clearly explain the principle of a DC-DC converter exhibiting as an impedance matching application for rectifying circuit. Therefore, an RF-DC-DC circuit is verified to be available for improving efficiency-load relation of rectenna in this chapter. However, the simulated PWM controlled boost converter just compresses a wide output load range into a narrow input resistance range in some degree. It is insufficient for impedance matching in rectenna.

In Chapter 3, from a new viewpoint, the input/output voltages and input/output resistances relationships of three basic topologies DC-DC converters are discussed. Based on the discussion results, a DCM inverting buck-boost converter, whose input resistance is independent of the load resistance or input power, is chosen for impedance matching in rectenna. We design a negative input voltage buck-boost converter to track the maximum efficiency of the rectifying circuit because the input resistance of the converter can match with the optimal load of the rectifying circuit. As expected, the measured input resistance of the buck-boost converter is approximately 133 Ω despite the changes of the load resistance and input power. Moreover, the measured efficiency of the converter exceeds 80 % for a wide range of loads or input powers. Then we design a rectifying circuit with negative output voltage and obtain a maximum RF-DC conversion efficiency of 79.2 % at an optimal load of 160 Ω with the 2.45 GHz microwave power of 82 mW. Next, we verify that the proposed converter successfully tracks the maximum efficiency of the rectifying circuit. The conversion efficiency of the rectifier is approximately steady at 75 %, despite the load resistance varying from 100 to 5000 Ω for an input microwave power of 82 mW. This means that the maximum power tracking efficiency is over 94 %, compared to the maximum efficiency of 79.2 % at the optimal load. Additionally, the overall efficiency of the RF-DC-DC circuit is approximately steady over 60 %, despite the load resistance changing from 100 to 5000 Ω. According to the experimental results, the proposed RF-DC-DC circuit is an effective MPPT method for low power rectenna. However, the proposed buck-boost converter is difficult for practical applications because of the requirement of an extra DC power supply. Additionally, owing to the loss of the buck-boost converter, the overall efficiency of the RF-DC-DC circuit is much lower than the maximum efficiency of the general rectifying circuit. Therefore, it is necessary to improve the efficiencies both of the rectifying circuit and the converter.

In Chapter 4, firstly, a relatively high-efficiency rectifying circuit is designed and measured. The measured peak efficiency is 82.5 % at the optimal load of 190 Ω for an input RF power of 80 mW. Secondly, we design a self-powered non-inverting DCM buck-boost converter. Compared with the buck-boost converter designed in Chapter 3, it is much superior in capability of handling variable load. Based on the simulation and experimental results, the input resistance of the converter is almost constant at 190 Ω despite the changes of load resistances and input powers, which is in accordance with the theoretical analysis. Moreover, the measured efficiency of the converter exceeds 83 % for a wide load range of 200 Ω to 10 kΩ, and the input voltage is boosted by the buck-booster converter. Finally, we conduct an experiment on RF-DC-DC circuit consisting of the self-powered buck-boost converter and the rectifier. The conversion efficiency of the rectifier is approximately steady at 80 % despite the load resistance varying from 200 Ω to 10 kΩ for an input microwave power of 80 mW. Compared with the peak efficiency of 82.5 % at the optimal load, the maximum power tracking efficiency is over 97 %. Furthermore, the overall efficiency of the RF-DC-DC circuit is constant over 66 % in this ultra-wide load range of 200 Ω to 10 kΩ (a ratio of 1:50). On the other hand, for a fixed load of 800 Ω, the overall efficiency of the RF-DC-DC circuit is also constant over 66 % for the input power of 40 to 120 mW. According to the experimental results, the proposed self-powered RF-DC-DC circuit exhibits a high efficiency in an ultra-wide load range.

In Chapter 5, we conduct several experiments on driving a DC motor using MPT system both in CW and pulsed-wave. Firstly, the background of the study that a DC motor is driven by MPT system is introduced. Then, as a test model, we choose a low-power DC motor and measure the input resistance of it. Secondly, we design two types antenna with dielectric substrate's thickness of 1.6 and 0.8 mm and evaluate them. We choose the thicker one as the receiving antenna because it exhibits a high gain. Thirdly, to make a compact rectenna array, we design two relatively smaller size rectifiers (A and B) with the measured peak conversion efficiencies of 80.8 % and 80 % at the optimal loads of 300 and 160 Ω, respectively. Fourthly, we design two improved buck-boost converters such as I-type and O-type according to the control-pulse oscillator supplied by the input voltage or the output voltage. Fifthly, we compact antenna array and rectifier array with the improved buck-boost converter in a multilayer substrate as a power-receiving device. Using those two rectifiers and two converters, there are four combinations of power-receiving devices such as 9AO, 9AI, 4BO, 4BI. Sixthly, we conduct several

experiments on driving the DC motor with MPT in CW power using those four combination devices. The overall efficiency of the 9AO is above 60 % in the power density range of 0.25 to 0.98 mW/cm^2 and the overall efficiency of the 9AI is above 60 % in the power density range of 0.5 to 2.08 mW/cm^2. Finally, we also test the DC motor driven by MPT in pulsed-wave power using 9AO combination device. In the pulsed-wave case, the overall efficiency is above 44 % in the duty ratio range of 0.2 to 1 for a power density of 0.98 mW/cm^2. Additionally, at a fixed duty ratio of 0.5, the overall efficiency is almost constant at 59 % for the pulsed-wave frequency changing from 0.33 to 41.7 kHz. In conclusion, by both CW and pulsed-wave power, the designed compact power-receiving device performs a relatively high efficiency for driving a load resistance variable device such as a DC motor.

6.2 Thesis Contributions

The contributions of this thesis can be summarized as follows: (1) A relatively high-efficiency rectifier for low-power (80 mW) is developed in Chapter 4. (2) A relatively small size and high-efficiency rectifier for low-power (50 mW) is developed in Chapter 5. (3) The input/output resistance relationships of three topologies DC-DC converters in both CCM and DCM are discussed in Chapter 3, which is expected to be a valuable reference for impedance matching in WPT system. (4) A self-powered buck-boost converter as a resistance conversion circuit whose input resistance is constant and independent of load resistances or input powers. It has been successfully used in rectenna for maximum power point tracking in Chapter 4. It is also expected to be used in other WPT system and energy harvesting system because its constant input resistance characteristics are independent of the operating frequency. (5) A rectenna adapted to pulsed-wave MPT system is firstly discussed here in Chapter 5 and it is expected to be used in coexistent power transmission and communication system. (6) A power-receiving device is developed to effectively drive a DC motor by MPT in Chapter 5, which will be a good reference for researches on airplane or robot powered by WPT system.

6.3 Suggestion for Future Work

This thesis has solved several issues in MPT system. However, a lot work remains to be done and some of the possible future research directions are suggested as follows: (1) In order to effectively simulate the rectifier, a precise HF diode model in ADS or other simulator such as microwave office is required. (2) Because of the supplied voltage limitation from the control-pulse circuit, the input RF power of the RF-DC-DC circuit is limited in the power range of 30 to 140 mW. It is expected to be improved for a much more wide power range. (3) It is necessary to develop a high efficiency (up to 95 %) of the buck-boost converter which can reduce the loss caused by the converter to make the overall efficiency of the RF-DC-DC circuit close to the peak efficiency of the general rectifying circuit. (4) A rectenna, adapted to much small load resistance such as the range of 100 mΩ to 10 Ω, is necessary for charging a battery or driving a high power motor. (5) The impedance conversion buck-boost converter is also expected to be used for other WPT system such as inductive coupling and resonant coupling system. (6) RF harvesting technology and multi-method of energy harvesting technologies are expected to be developed for the application of powering sensor network nodes.

Appendix A

Single Shunt Rectifying Circuit

Figure A.1 shows a block diagram of a general rectenna which usually contains an antenna, an input filter, a rectifying component, an output filter and a load. A rectifying circuit is a rectenna circuit without antennas. Many researchers usually discuss the antenna and the rectifying circuit separately. A single shunt rectifying circuit is often used in the rectenna because it performs a high efficiency with a simple circuit structure. The single shunt rectifying circuit has full-wave rectifying capability with one single diode. As shown in Fig. A.2, a single shunt rectifying circuit usually contains an input filter, a rectifying diode, a $\lambda_g/4$ line, a capacitor and a load. Referring to [58], the theory of the single shunt rectifying circuit can be explained as follows.

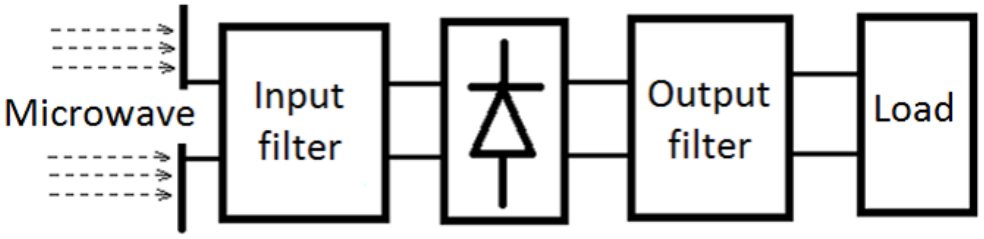

Figure A.1: Block diagram of a general rectenna. It usually contains an antenna, an input filter, a rectifying component, an output filter and a load.

As shown in Fig. A.2, the current $I_1(t)$ is still the high frequency sine wave which can be expressed with Eq. (A.1) and the waveform is shown in Fig. A.3.

$$I_1(t) = I_0 \sin(\omega t). \tag{A.1}$$

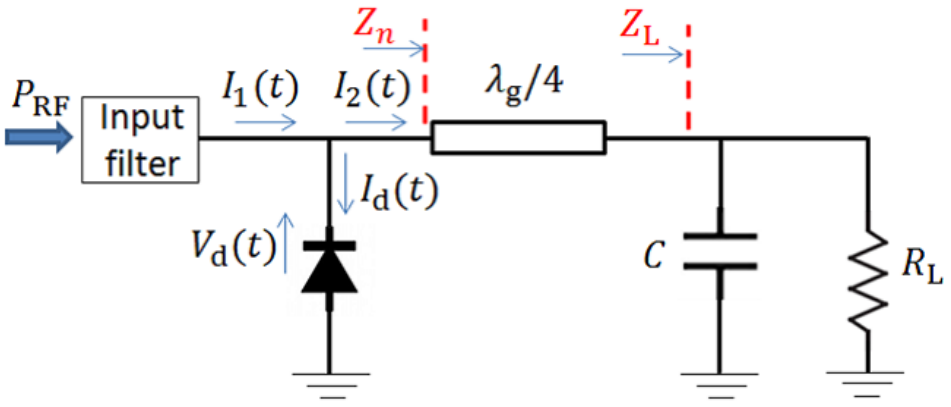

Figure A.2: Block diagram of a single shunt rectifying circuit. It usually contains an input filter, a rectifying diode, a $\lambda_g/4$ line, a capacitor and a load.

Suppose the rectifying diode is ideal, then the diode is open at half period of $0 \leq \omega t < \pi$. It yields the current $I_2(t)$ as following:

$$I_2(t) = I_0 \sin(\omega t), (0 \leq \omega t < \pi). \tag{A.2}$$

Additionally, for rectifying circuit, the impedance of the output filter Z_n seems to be open for odd harmonics and short for even harmonics. It means that only even harmonics current flows through $I_2(t)$. Therefore, $I_2(t)$ satisfies:

$$I_2(\omega t + \pi) = I_2(\omega t). \tag{A.3}$$

Combine Eqs. (A.2) and (A.3), $I_2(t)$ can be rewritten as following:

$$I_2(t) = I_0 |\sin(\omega t)|, (0 \leq \omega t < 2\pi), \tag{A.4}$$

and the waveform of $I_2(t)$ is shown in Fig. A.4 which is a full-wave rectified waveform.

As for the diode current I_d, it satisfies $I_d = I_1 - I_2$. Then:

$$I_d(t) = I_0 \sin(\omega t) - I_0 |\sin(\omega t)|, \tag{A.5}$$

which indicates that the diode current I_d is a half-wave rectified waveform. As for the diode voltage V_d, it is 0 when the diode is on. When diode is off, the voltage applied on the diode includes the DC voltage at the load port (V_L) and the odd harmonics components. Therefore, the diode voltage V_d can be written as:

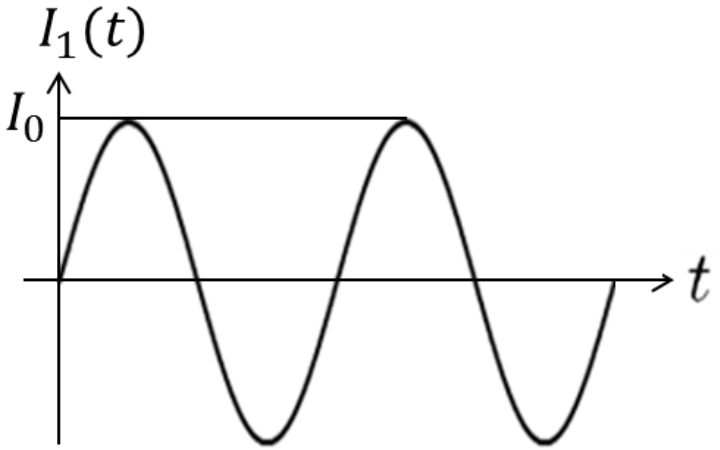

Figure A.3: Current waveform of I_1.

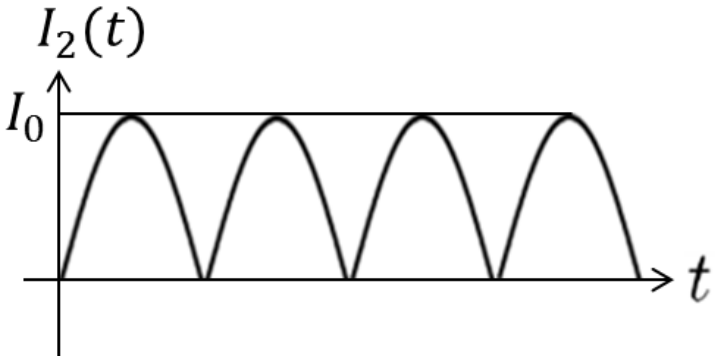

Figure A.4: Current waveform of I_2.

$$V_{\mathrm{d}}(t) = \begin{cases} 2V_{\mathrm{L}}, (0 \leq \omega t < \pi) \\ 0, (\pi \leq \omega t < 2\pi) \end{cases} \tag{A.6}$$

Figure A.5 shows the waveform of V_{d} and I_{d}.

As shown in Fig. A.2, the impedance of Z_{L} and Z_{n} can be written as following:

$$Z_{\mathrm{L}} = \frac{1}{j\omega C + \frac{1}{R_{\mathrm{L}}}}, \tag{A.7}$$

$$Z_{\mathrm{n}} = \frac{Z_{\mathrm{L}} + jZ_0\tan(\beta_{\mathrm{n}}\lambda_{\mathrm{g}}/4)}{Z_0 + jZ_{\mathrm{L}}\tan(\beta_{\mathrm{n}}\lambda_{\mathrm{g}}/4)} Z_0. \tag{A.8}$$

where Z_0 is the characteristic impedance and β_{n} is the phase velocity. ωC is close to infinity as capacitance C is large enough for high frequency. As a result, Z_{L}

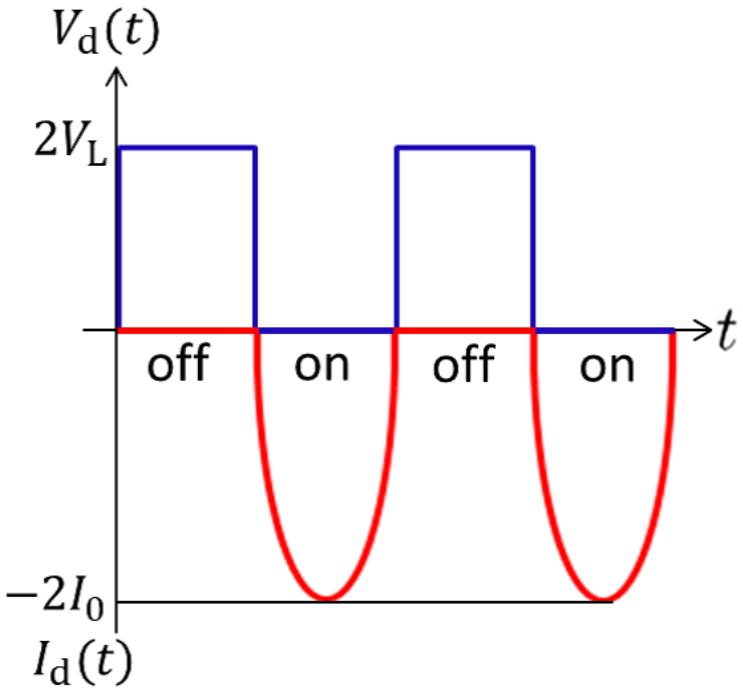

Figure A.5: Voltage and current waveforms of the diode: V_d, I_d.

is close to 0 when ωC is close to infinity. In this case, the impedance Z_n can be rewritten as follows:

$$Z_n = \begin{cases} Z_L, \text{close to 0 (even harmonics)} \\ \frac{Z_0^2}{Z_L}, \text{close to } \infty \text{ (odd harmonics)}, \end{cases} \tag{A.9}$$

which indicates that the impedance of the output filter Z_n is open for odd harmonics and is 0 for even harmonics. Thus, the single shunt rectifying circuit is similar to the class-F amplifier in addressing harmonics problems. Consequently, the single shunt rectifying circuit is also named as class-F rectifier.

ELECTROMAGNETIC HARVESTING TO POWER ENERGY MANAGEMENT SENSORS IN THE BUILT ENVIRONMENT

Evans Sordiashie, M.S.

University of Nebraska, 2012

Adviser: Mahmoud Alahmad

Recently, a growing body of scholarly work in the field of energy conservation is focusing on the implementation of energy management sensors in the power distribution system. Since most of these sensors are either battery operated or hardwired to the existing power distribution system, their use comes with major drawbacks. Battery maintenance and associated labor costs can make implementing sensors very expensive. Although hardwired sensors require very little post-installation maintenance, any energy savings they may procure is offset by the amount of energy expended during the course of the sensors normal operation. In response to these energy challenges, this thesis proposes an electromagnetic harvesting device that powers such sensor technologies by scavenging low electromagnetic field energy. First, the quantities of magnetic flux densities around common current carrying conductors in the built environment are estimated according to the equivalent amount of power that can be generated. Then, a prototype of the harvesting device for scavenging low magnetic flux is designed and developed. Finally, the device is evaluated for real-world implementation using a novel prototype board.

ACKNOWLEDGEMENT

I would like to thank my adviser, Dr. Mahmoud Alahmad, for his continued support and presence as a source of advice, guidance, and assistance during my academic career.

I would also like to extend my appreciation to my research colleague, Timothy Wisnieski for his continued support throughout this research.

DEDICATION

I would like to dedicate this work to my wonderful family who are my inspiration, my happiness, and my source of energy.

GRANT INFORMATION

This project is funded and sponsored by the Durham School of Architectural Engineering and Construction.

Chapter 1

INTRODUCTION

The efficient management of our energy needs in the built environment requires that we carefully account for each trickle of energy we consume. Recently, engineers have been using efficient energy management sensors as a way to monitor energy and accomplish energy control tasks. Unfortunately, these senor technologies use energy in the performance of such tasks. This thesis focuses on electromagnetic harvesting as a way to power wireless energy monitoring sensors in the built environment. Energy can be saved if sensors are powered by free electric energy scavenged from the built environment. This research looks into creating an effective energy management system that both utilizes an ambient energy source and reduces costs through low maintenance requirements.

1.1 Motivation

This chapter presents the motivation for this research as well as an overview of the various chapters of the research. Since the oil crisis of the 1970s, novel ways to conserve energy have continued to be a top research priority for energy scholars in the United States. Population growth coupled with an insatiable quest for newer electronic technologies has led to a demand for electricity that will surely continue to grow. Unfortunately, it is not yet clear if we are prepared to keep up with this increasing demand in the future. The World Energy Outlook estimates a 76% increase in electricity

use between the years of 2007 to 2030 with an average yearly growth rate of 2.5% (1). However, the demand for electricity has exceeded power transmission growth by 25% since 1982 (2). This is very alarming considering the fact that some 2 billion people currently have no access to electricity (1). Moreover, about 20% of the total CO_2 emissions in the U.S. result from electricity generation alone (3). Figures 1.1 and 1.2 give the U.S. electricity generation by source and equivalent CO_2 emissions from fossil fuels. Since just a little over 13% of our electricity needs are currently generated from renewable energy sources, carbon emissions will continue to endanger the health of the planet for years to come.

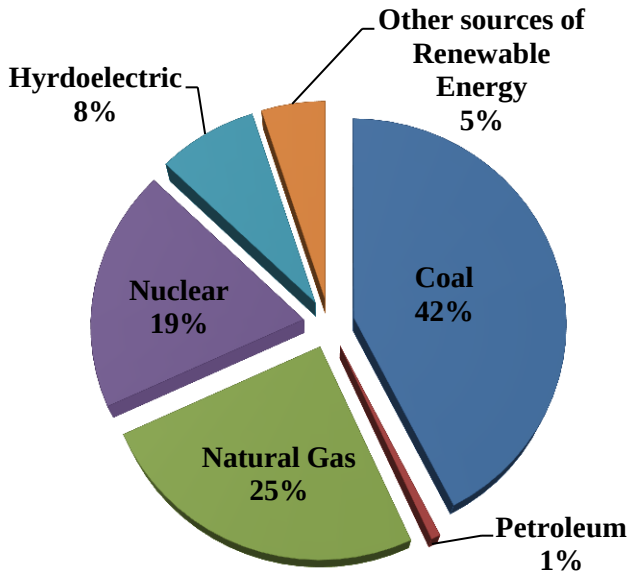

Figure 1.1: US Net Electricity Generation by Energy Source for 2011

Jan, (Source: Energy Information Administration (EIA), Electric Power Monthly, January 30, 2012, Table 1.1), (4).

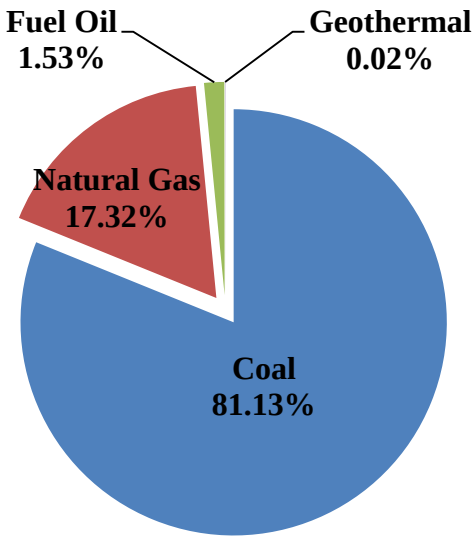

Figure 1.2: CO_2 Emissions from Fossil Fuels Due to Electricity Generation in 2009 (3).

While it should be noted that some scholars have found the relationship between global warming and carbon emissions debatable (5), (6), (7), it is well agreed that our natural resources are being depleted for energy generation.

1.2 Problem Formulation

As part of the effort to curb the rate at which our natural resources are being depleted, it is very important that we not only look for ways to generate energy from renewable sources but also to lower our own energy usage. This means efficiently managing our energy usage both at the residential and commercial level as well as in the built environment as a whole. Recent technologies (8), (9), (10) are focusing on monitoring energy at the node level to conserve energy in the built environment. A node

or outlet is any point in the electrical distribution system at which current is drawn to power electric equipment (11). Real-time energy consumption data can be collected by attaching sensor monitoring devices to these nodes. This has been accomplished in a variety of ways in the prior literature. The investigators in (8), for example, attached wireless sensors to every node in the electrical distribution system for energy monitoring and conservation purposes. However, the sensors themselves consume some energy during normal operation.

Generally, sensors are either battery operated, hardwired from the existing electrical system or are both battery operated and hardwired. Such configurations ensure that the sensor continues to operate during power outages. In a hardwired system, some of the conserved energy will in turn be reused by the sensors during operation. This means that more actual energy will be conserved if the sensors do not draw energy from the existing electrical system. The lifespan of batteries in battery operated sensors last about 9 months in duration. Table 1.1 shows the power consumption data for some common energy monitoring sensors.

Table 1.1: Power Consumption Data for Some Common Energy Monitoring Sensors

Wireless Product	Current Consumption			Battery Voltage	Power Consumption
	Transmission mode	Reception mode	Sleep mode		
RCS-S09U Universal ISM Band FSK Transceiver Module (12)	15mA - 26mA	11mA -15mA	0.3 μA	2.2V-3.8V	33mW - 78mW

G-Link 2.4 GHz Wireless Accelerometer Node (Micro Strain) (13)	25mA	25mA	0.5mA	3.7V	92.5mW
IMOTE2 (Crossbow) (14)	33mA	33mA	390 μA	3.2V-4.5V	127.05mW
XBEE Zigbee/802.15. 4 Modules (DigiInternational) (15)	50mA	50mA	10 μA	2.8V-3.4V	155mW
DataBridge wireless I/O modules (16)	37mA - 120mA	37mA - 120mA	< 100uA	2.7V –3.6V	116.55mW - 378mW
Apex and Apex LT Modules (17)	170mA	37mA	5 μA	2.1V-3.6V	105.45mW - 484.5mW
Lt Series Transceiver Module (18)	12mA - 14mA	12mA - 14mA	11.5 μA-20 μA	2.1V-3.6V	34.2mW - 39.9mW
Si4420 Universal ISM Band FSK Transceiver (19)	13mA - 26mA	11mA -15mA	0.3 μA	2.2V-5.4V	41.8mW - 98.8mW

Batteries for battery operated sensors require periodic replacement after they lose all of their energy. Calculations for the total replacement costs must therefore include not only the cost of the batteries but also any additional labor requirements. An average home containing 30 nodes equipped with such sensors will thus be quite expensive to maintain.

As a way to tackle the power demand of these energy management sensors, this thesis proposes the use of electromagnetic energy harvesting to supply their power needs. Figure 1.3 is a conceptual diagram of the proposed energy harvesting method for supplying power to the sensors.

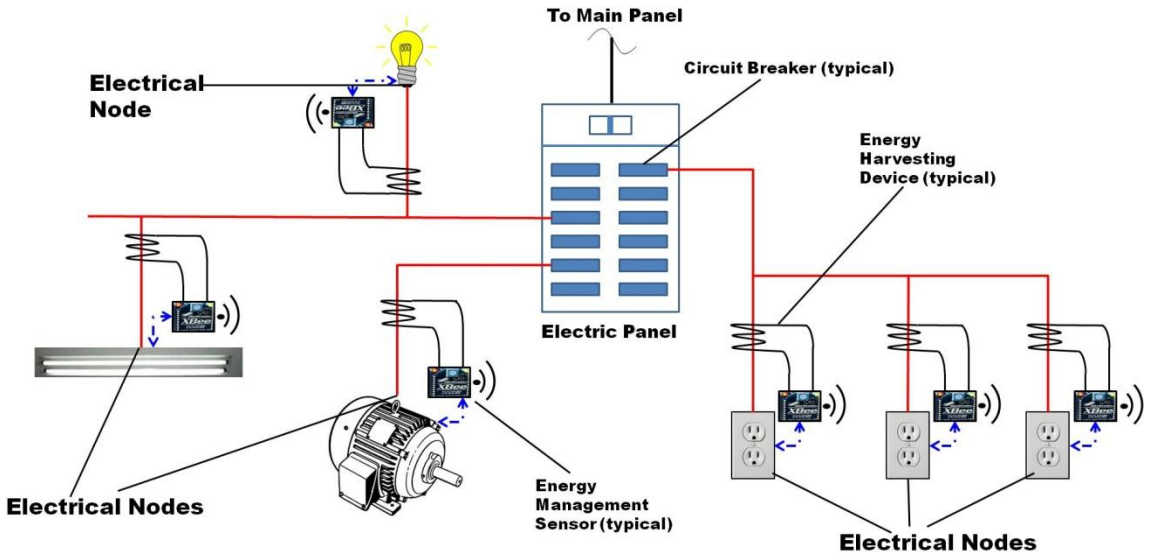

Figure 1.3: Conceptual Diagram of the Energy Harvesting Device in the Electrical System

1.3 Research Goals

One of the goals of this research is to develop a "free" energy source that can power energy management sensors in the built environment. Achievement of this goal will not only increase energy conversation in the built environment but also reduce sensor related maintenance costs. Thus, sensors will eventually be energy neutral and able to operate for an indefinite amount of time.

A second goal of this research is to investigate and determine if electromagnetic energy harvesting is a viable energy source for generating power for other low-powered devices. Electromagnetic harvesting will reduce human dependence on batteries to meet the energy requirements of low-powered devices in the built environment. In fact, it may even make low powered devices autonomous so that they could be employed in hazardous or inaccessible locations in the built environment. It should also be mentioned that one of the related benefits of using the proposed device is that it is an eco-friendly solution, and, with widespread use, may reduce pollution caused by battery disposal

landfills. Last but not least, it is hoped that the proposed work will promote innovations in the built environment that lead to increased energy conservation. This research will open doors to enable the design and manufacturing of future sensor products for electrical energy conservation that incorporate this energy harvesting technology.

1.4 Thesis Overview

The remaining sections of this thesis are broken into 7 major chapters. Chapter 2 gives background information on energy harvesting systems, definitions, and descriptions of common energy harvesting methods, related research and the objectives of this thesis. Chapter 3 gives an overview of electromagnetics and the theory of transformer basics. Chapter 4 describes the research objective, methodology and design. Chapter 5 provides a simulation of and gives experimental data on the proposed energy harvesting device. Chapter 6 summarizes some of the technical challenges involved with use of the device and possible future applications of the device. Finally, Chapter 7 concludes with a review of the information presented in this thesis.

Chapter 2

BACKGROUND

Chapter 2 introduces the definitions, terms, energy harvesting methods and related work that form the foundation for the work presented in this thesis. This chapter will also discuss the proposed work.

2.1 Energy Harvesting System

Energy harvesting systems are made up of three basic components: The energy source, energy scavenger (active component) and external electrical circuit. Figure 2.1 shows a typical energy harvesting system.

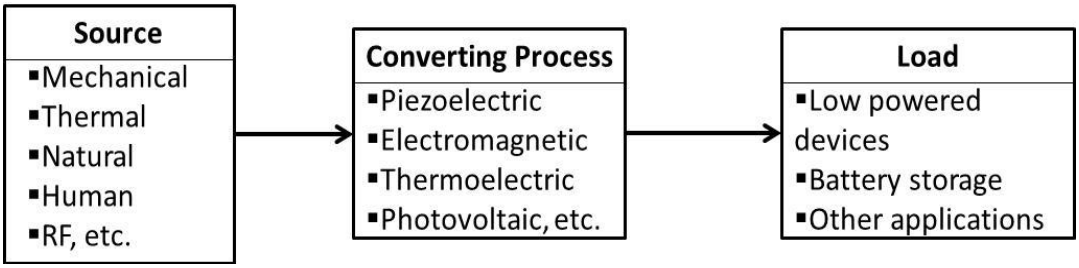

Figure 2.1: Components of Energy Harvesting Systems

In order to harvest useful electrical energy, these three basic components must be in place at all times. The following section gives a summary of common energy sources.

2.1.1 Energy Sources

The most common energy harvesting sources are natural (solar, wind, ocean, etc) energy, mechanical energy, radio frequency (RF), and human (physical) energy (20),

(21). Other types of energy sources include thermoelectricity (temperature variations) and electromagnetic energy.

Sources of natural energy include solar, wind, ocean waves, and water movements. Energy derived from these sources is mostly called renewable energy. Close to 13% (see Chapter 1) of the total electrical energy generated in the United States comes from renewable sources. Of these sources, conventional hydroelectric energy is the leading supplier or provider. The production of hydroelectricity involves using the gravitation pull of water to turn a generator powered turbine. China is currently the world's leading producer of conventional hydroelectricity followed by Canada and the United States, respectively (22).

Recently, solar and wind power are becoming popular sources of energy to harvest. Energy from light (solar power) is directly converted to electrical energy using solar cells (photovoltaic cells). Sunlight is the major source of light for most solar power generation plants. Some common smaller applications of solar power are portable hand calculators, wrist watches and street lights (23). Wind power is generated through the conversion of energy from a fast moving wind source. Wind turbines, which are typically designed with two or three blades mounted on a shaft from a rotor, capture wind energy (through a spinning action) to generate electricity (24). In order to generate large quantities of energy using this source, power companies have to mount hundreds of individual wind turbines over a widely spaced area. Places in which such mass power can be generated are called wind farms. Wind farms may be located in both onshore and offshore areas.

Mechanical energy is created by the motion or vibrations from machines, mechanical stress and strain from high-pressure motors, manufacturing machines, and other related rotational activities (25). In general, harvesting devices for vibrational sources fall in three main categories: electrostatic, piezoelectric and electromagnetic (26). Small, self-powered devices that use mechanical harvesting are known as micro-electromechanical systems (MEMS), (26), (27).

RF energy is another energy harvesting source that can be broadcast radios, public telecommunication services and other dedicated RF devices (28). The energy harvesting device (rectenna) is able to convert the RF energy into direct current (21). RF energy is inversely proportional to distance and therefore drops as the distance from a source is increased.

Humans generate energy that is a combination of mechanical and thermal energy derived from bodily activities. Running, walking, and other movements produce kinetic energy that can be converted into power. In (29) for example, energy generated from walking was used to harvest electrical energy by the piezoelectric method. In the past, hand-cranked radios and other similar devices were powered by human movement. A summary by Starner of the potential energy that can be harvested from humans is shown in Figure 2.2 (30).

Temperature differences between two points can also be used to generate electrical energy. This is commonly known as thermoelectricity. Thermoelectricity is the direct conversion of a temperature difference into electricity. The device used to generate thermoelectricity is called a thermogenerator (21). Thermoelectricity is referred to in some texts as the “Peltier-Seebeck effect” named after Thomas Seebeck who discovered

electric current flow between the junctions of two different metals at different temperatures.

Activity	*Kilocal/hr*	*Watts*
sleeping	70	81
lying quietly	80	93

carpentry	230	268
hiking, 4 mph	350	407
swimming	500	582
mountain climbing	600	698
long distance run	900	1,048
sprinting	1,400	1,630

Figure 2.2: Summary of Potential Energy That Can Be Harvested from Humans (30)

Electromagnetic fields are becoming a viable source for energy harvesting. While it is not a naturally available source of energy, it does occur around existing power distribution lines. Using Faraday's law of induction, an electromotive force (emf) is induced in an inductor (coil) placed in a magnetic field. Electricity from Faraday's principle is generated by relative movement of the inductor coil in a permanent magnetic field or an inductor placed in a changing magnetic field.

2.1.2 Converting Processes

Ambient energy exists all around us and can be transformed into a useful energy source. This section gives a brief summary of some commonly available energy harvesting methods.

Photovoltaic Harvesting

The photovoltaic (PV) effect is the process through which a photovoltaic cell (solar cell) converts light into electricity. Photons traveling to the surface of photovoltaic cells are absorbed and their energy transferred to make electricity. Solar power is the most common source of light energy harvesting due to its high power density (31). In addition to natural solar light, indoor fluorescent and tungsten lamp illuminations are also potential sources for harvestable light energy. Much less energy can be harvested from indoor environments compared to outdoor environments since less electricity can be generated by PVs with decreasing light irradiance (24).

Thermogenerator

A thermogenerator is a device that generates electricity by converting the temperature difference between two points, a process known as the thermoelectric effect. Thermogenerators are usually attached to bodies or devices which have a comparable temperature difference in relation to their surrounding environment. A good example of the thermoelectric effect is a wrist watch powered by electricity generated from body heat (32).

Piezoelectric Harvester

Quartz crystals have the ability to generate electricity when pressure is applied to them (33). This process is known as the piezoelectric effect or piezoelectricity. In principle, piezoelectricity involves the accumulation of electric charges in solid materials when mechanical stresses are applied to them. Apart from pressure, other kinetic schemes, such as strain, stress, and distortion, can also be applied to piezoelectric materials to generate electricity. Conversely, a mechanical deformation (shrinking or

expansion) is produced when an electric field is applied to piezoelectric materials. Commonly used piezoelectric materials are ceramics. Some useful applications are ceramic resonators, ceramic bandpass filters, ceramic discriminators, ceramic traps, SAW filters, and buzzers (34).

RF Energy Harvester (Rectenna)

The rectenna is the harvesting device used to scavenge power from RF energy (21). It consists of a receiving antenna and a rectifier circuit which converts RF or microwave power into useful DC power (35). The five main components of a rectenna are an antenna, input low-pass filter, rectifying diode, output filter, and resistive load (36). Design and experiments of a high-conversion-efficiency rectenna are found in (36).

Electromagnetic Harvester

From Faraday's law of induction, an induced electromotive force is generated in an inductor (conductor) placed in a magnetic field. This principle is also called electromagnetic induction. The conductor typically takes the form of a coil and electricity is generated by either the relative movement of the coil and the magnet, or via a stationary coil in a changing magnetic field. The converse of this principle is also true. Thus, a magnetic field is generated around a conductor carrying electrical current. The research proposed herein focuses on generating electrical energy by exploiting this combined principle. A magnetic field is generated around current carrying conductors in the built environment. This magnetic field is used in this research to produce electricity for the purposes of supplying energy to energy management sensors. Since the sensors are located close to the electrical nodes, the electromagnetic field generated around the current carrying conductors becomes an ideal source for energy harvesting.

2.1.3 Load

Common use of energy harvesting application is for supplying power to low powered devices. These devices are mostly low powered sensors used in remote or hazardous locations for system monitoring. Table 1.1 in Chapter 1 lists some of these sensors. In harvesting systems where power generated is not constant, battery storage systems are incorporated to store power during peak times to be used later. This is common with photovoltaic systems which typically incorporate batteries for power storage during the day to be used later at night (24). Other common applications of energy harvesting are solar powered calculators and lamps, thermal powered wrist watches, etc. The next section reviews some of the related research in electromagnetic energy harvesting which is the proposed harvesting method of this research.

2.2 Related Work

Several designs for magnetic field harvesting have been proposed in the prior art. Some of the currently available products that harvest energy from electromagnetic fields include the power donut (37) and power line sensor (38), shown in Figure 2.3.

Power donut (24) power line sensor (25)

Figure 2.3: Available Magnetic Field Harvesting Products

The majority of these designs focus on high voltage (HV) transmission lines that have currents in excess of 50A.The authors of (39) propose a microcontroller controlled electromagnetic energy harvesting system for harvesting energy from a single HV transmission line with current between 65A and 130A. The system comprises a toroid magnetic power generator setup, voltage multiplier, DC-DC boost converter and microcontroller. An adaptive algorithm is incorporated into the microcontroller to adjust the duty cycle of the converter so that it achieves maximum output power. The magnetic field energy harvesting setup is able to boost 1V AC and can store power at 58mW for 65A flowing through the HV single conductor.

In (40), D. Pimentel et al. presents power management techniques for energy harvesting systems. They introduce Harvesting Aware Power Management (HAPM) strategies for Energy Harvesting Systems (EHS) that keep devices operating in an energy neutral mode. The authors consider the advantages and disadvantages of three different methods of HAPM: Duty Cycling, Dynamic Voltage, or Frequency Scaling and Maximum Power Point Tracking. The authors conclude that dynamic or adaptive power management is the best choice for energy harvesting systems (2010).

Rohit Moghe et al. (41) study the electric and magnetic field energy harvesting for wireless sensor networks in power system applications. Their work begins with a market survey on the power consumption of a selection of wireless communication devices. Surveys on vibration, solar, and thermal based energy harvesting products are also presented along with information on energy harvesting methods in vibration, thermal, solar EM Wave and Magnetic Field Energy. Theoretical analysis of their electric-field harvesting shows a maximum harvested power of 95.2mW. Experimental testing of a

piezoelectric based energy harvesting device is also conducted revealing that up to 108.24μW can be harvested for a 1000A current carrying conductor. Experimental testing for magnetic field energy harvesting conducted by Rohit Moghe et al. for various core and winding configurations is shown in Table 2.1(41). The maximum power generated is found to be 257mW (2009).

Table 2.1: Magnetic Field Energy Harvesting for Different Core Configurations (41)

Type of Coil	No. of turns	O.C. Voltage at 200A Primary current (V)	O.C. Voltage at 1000A Primary Current (V)	Max. Harvestable Power (mW)
Rogowski Coil	18	0.03	0.16	8
28AWG wire wound on a Wooden Core	200	0.24	1.21	29.8

28AWG wire wound on a Flux Concentrator	300	0.50	2.64	257
Flux Concentrator Connected to a Transformer	300	12.5	70.6	225

Rashed H. Bhuiyan et al. propose an energy coupler for scavenging energy from current carrying conductors to power wireless sensors in electrical systems (42). Their device uses a magnetic core with an air gap in between layers. The core material presented in their work is a mu-metal of cylindrical form. Figures 2.4 and 2.5 show the diagrams for the core configuration used in their theoretical analysis (2010).

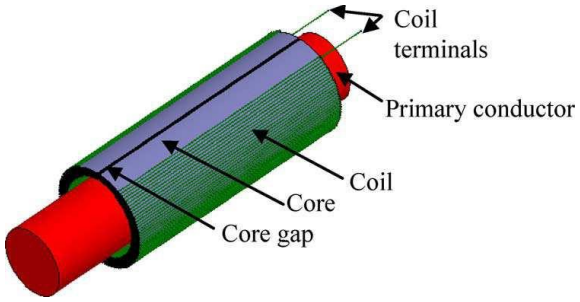

Figure 2.4: Multiturn Coil on a Magnetic Core Around A Current Carrying Conductor (42)

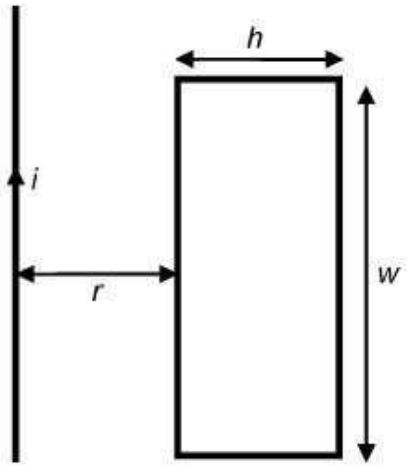

Figure 2.5: Rectangular Coil Near a Current Carrying Conductor (42)

The voltage induction equation is given as (42):

$$V = N\mu_0\mu_r wfI\ln\left(1+\frac{h}{r}\right)$$

Where N – number of turns wound around the magnetic core, μ_0 and μ_r are the permeability of free space and relative permeability of the core, *w* and *h* are the width and height of the core, *f* is the operating frequency, *r* is the distance from the current carrying conductor and *I* is the root mean square (rms) magnitude current in the current carrying conductor. A prototype of the coupler is built and tested in an experiment setup with a board consisting of eight parallel 200 W light bulbs, 120V, 60 Hz supply main (42). Multiple turns of the primary conductor are passed through the opening of the coupler each carrying 13.5A. The energy coupler is shown to be capable of producing 10mW of DC power to a 50 Ω. The authors estimated a higher power to be generated by the coupler with conductors carrying currents in excess of 1000 A (2010).

Except for the work presented in (42), no research to the author's knowledge looks at harvesting electromagnetic energy from low current drawing conductors. Moreover, the research presented in (42) uses multiple primary turns to generate an ample amount of power. The highest voltage induced was approximately 1.5V AC for 5 primary turns and 280 turns of secondary winding for 13.5A current in the primary conductors (42). However, even though the energy coupler in (42) has praiseworthy features such as its ease of use and miniature size, the low current range in the built environment (typical, 1-30A) can reduce it capacity to generate power. This is due to the fact that not enough magnetic flux can be transferred to secondary windings for power generation with the configuration of the proposed energy coupler. Figure 2.6 shows a graph of measured induced voltages from Bhuiyan et al. (42). For practical applications, a single primary turn will typically be used in the energy coupler. From the graph in Figure

2.6 it can be seen that the amount of voltage induced for a single primary turn is a little over 0.2V for 280 turns with a primary current of 13.5A. This makes the coupler presented ideal for high current drawing conductors.

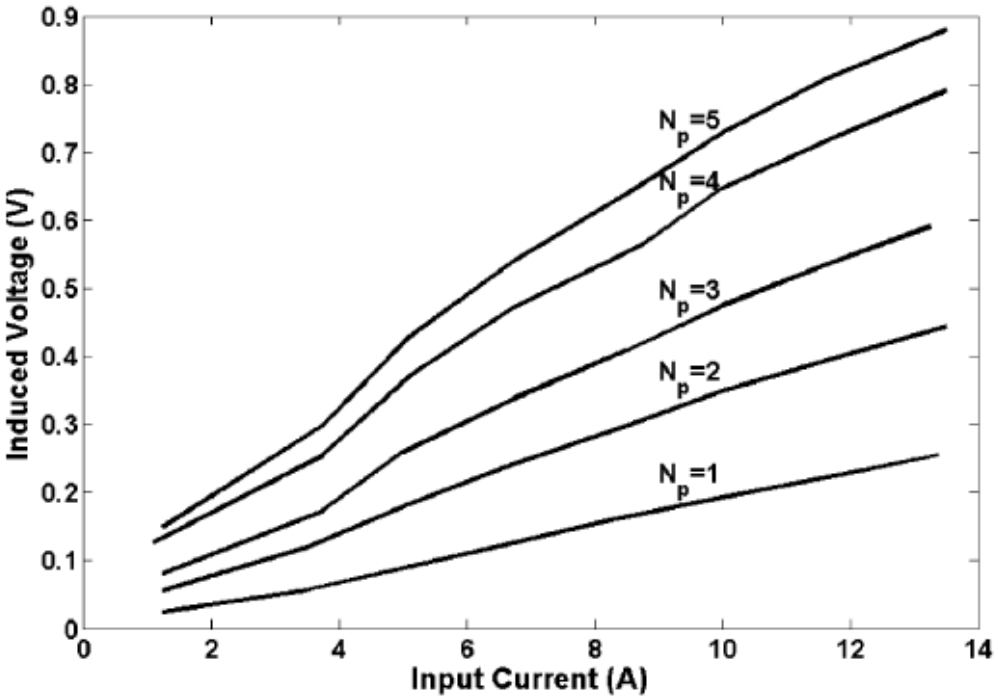

Fig. 11. Measured induced voltages versus currents (I) with number of turns (N_p) of the primary current conductor as a parameter. Parameters: $w = 50\,\mathrm{mm}$, $n = 8, T = 1.25\,\mathrm{mm}, N = 280, l_g = 1\,\mathrm{mm}, d = 0.1016\,\mathrm{mm}, f = 60\,\mathrm{Hz}$, and $\mu_r = 10^5$.

Figure 2.6: Measured Induced Voltages From (42)

The harvesting device proposed in this research uses only a single primary current carrying conductor with multiple secondary winding s from 200 to 500 turns. The core used in the research is an amorphous material designed at a reduced size to better scavenge magnetic energy. The core material has a saturation flux density of 1.56 T (43) and a rectangular cross-sectional area. Theoretical analysis used is based on design of current transformers. In order to effectively harvest ample amounts of energy, the available magnetic flux around the current carrying conductors (1-30A) in the built

environment is theoretically analyzed and simulated. The equivalent voltage that can be induced from this available magnetic flux is also analyzed and simulated for a given magnetic core. Magnetic flux and voltages induced is also simulated for various loads at electrical nodes. Simulation of the cross-sectional area of a magnetic core against the voltage induction is done with variable parameters to include the load consumed at the nodes, the current flowing through the primary conductor, and the proximity of the current carrying conductor to the core. Experimental testing is done with an already available standard amorphous core and the results are then compared with the theoretical simulation.

Since the design of the proposed energy harvesting device is based on the electrical transformer, this next chapter gives an overview of transformer basics and current transformer design.

Chapter 3

AN OVERVIEW OF ELECTROMAGNETICS & TRANSFORMERS

3.1 Introduction

Electromagnetic energy harvesting applies the theory of electromagnetism and principles of electric transformer design basics. Electric current flowing to the nodes where energy management sensors are located generates a magnetic field around the current carrying conductor. This magnetic field serves as the main energy source for the proposed electromagnetic energy harvesting device. To estimate amount of available magnetic field strength around the nodes and the equivalent amount of power that can be generated, this chapter offers a review on electromagnetics and transformer basics.

3.2 Overview of Electromagnetics

Electromagnetics involve the theory and application of electric and magnetic fields. Any electric charge in motion has an associated magnetic field. Maxwell's equations are the set of fundamental equations that govern electromagnetics (44). These equations are combination of Faraday's, Ampere's and Gauss' laws (44). For a complete presentation of electromagnetic theory and derivation of Maxwell equations, the reader is referred to references (44) and (45). To estimate the available magnetic field around current carrying conductors for energy harvesting, this section focuses on Boit-Savart law, Ampere's law and ferromagnetic materials.

3.2.1 Biot-Savart Law

Biot and Savart discovered that a conductor carrying a steady current produces a force on a magnet. They developed an equation that gives the magnetic field at some point in space in terms of the current that produces the field. Figure 3.1 shows an illustration of the Biot-Savart law. Thus for a steady current I flowing through the conductor dl, the magnetic field dH at a point P has the following properties:

- The vector *dH* is perpendicular to both *dl* and to the unit vector $\hat{R}$ directed from the element dl to the point P.
- The magnitude of *dH* is inversely proportional to R^2, where R is the distance from the element dl to the point P.
- The magnitude of *dH* is proportional to the current *I* and to the length *dl* of the element.
- The magnitude of *dH* is proportional to $sin\theta$, where θ is the angle between the vectors *dl* and $\hat{R}$.

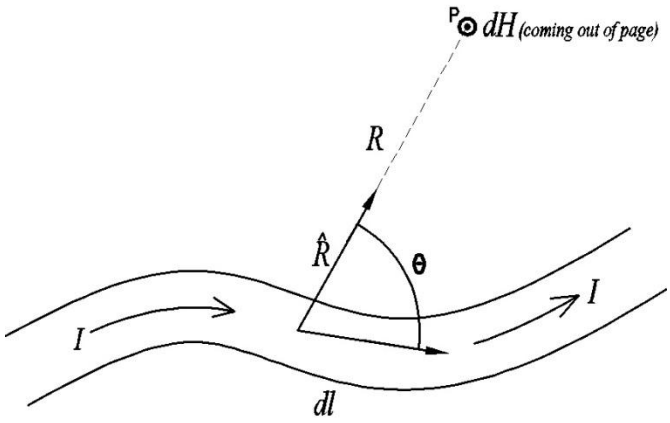

Figure 3.1: Electric Current Relationship with Magnetic Field, Biot-Savart (44)

The differential form of Biot - Savart is given by equations 1, 2:

$$dH = \frac{I}{4\pi} \cdot \frac{dl \times \hat{R}}{R^2} \qquad 1$$

The total magnetic field *H* due to a conductor of finite length *l* carrying a current *I* is,

$$H = \frac{I}{4\pi} \cdot \int_l \frac{dl \times \hat{R}}{R^2} \qquad 2$$

Derivation of magnetic field around a finite length linear conductor

Figure 3.2 shows a conductor of finite length carrying a current in the upward direction.

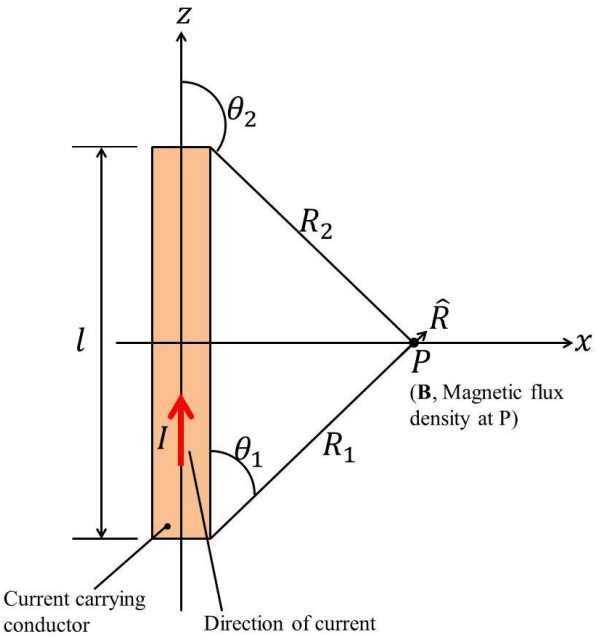

Figure 3.2: Magnetic Field Around Current Carrying Conductor of Finite Length

The integration of equation 2 for a current carrying conductor of length *l* is stated as:

$$H = \frac{I}{4\pi} \cdot \int_{-l/2}^{l/2} \frac{dl \times \hat{R}}{R^2} \qquad 3$$

$$dl = dz\hat{z} \qquad 4$$

$$dl \times \hat{R} = dz(\hat{z} \times \hat{R}) \qquad 5$$

$\hat{z} \times \hat{R} = sin\theta\ \hat{\psi}$, where$\hat{\psi}$ is the unit vector normal to the plane determined by z and R when they are drawn from a common point.

$$H = \hat{\psi}\frac{I}{4\pi}\cdot\int_{-l/2}^{l/2}\frac{sin\theta}{R^2}\,dz \qquad 6$$

Expressing R and z in terms of θ and substituting;

$$R^2 = \frac{r^2}{sin^2\theta},\ z = -r\frac{\cos\theta}{\sin\theta}, dz = \frac{r}{sin^2\theta}d\theta$$

Therefore,

$$H = \hat{\psi}\frac{I}{4\pi}\cdot\int_{\theta_1}^{\theta_2}\frac{\sin^3\theta}{r^2}\cdot\frac{r}{\sin^2\theta}d\theta = \hat{\psi}\frac{I}{4\pi}\cdot\int_{\theta_1}^{\theta_2}\frac{\sin\theta}{r}d\theta \qquad 7$$

$$H = -\frac{I}{4\pi r}(\cos\theta_2 - \cos\theta_1)\,\hat{\psi} \qquad 8$$

Expressing $z = -\frac{l}{2},\ \frac{l}{2}$ in terms of θ_1 and θ_2 ;

$$\cos\theta_1 = \frac{l/2}{\sqrt{r^2+\left(\frac{l}{2}\right)^2}},\ \cos\theta_2 = \frac{-l/2}{\sqrt{r^2+\left(\frac{l}{2}\right)^2}},$$

$$H = \frac{I}{4\pi r}\cdot\frac{2l}{\sqrt{4r^2+l^2}}\hat{\psi} = \frac{Il}{2\pi r\sqrt{4r^2+l^2}}\hat{\psi}(\mathrm{A/m}) \qquad 9$$

Biot – Savart law due to surface and volume distributions are expressed as follows (44):

$$H = \frac{I}{4\pi}\cdot\int_S\frac{J_s\times\hat{R}}{R^2}\,ds \quad \text{(for surface current)} \qquad 10$$

$$H = \frac{I}{4\pi}\cdot\int_V\frac{J\times\hat{R}}{R^2}\,dV \quad \text{(for volume current)} \qquad 11$$

Where, J_s is the surface current density (A/m) and *J* is the volume current density in (A/m^2), *R* is the distance vector between surface or volume and an observation point of interest where magnetic field is being determined (m).

3.2.2 Ampere's Law and Magnetic Flux Density

Ampere's circuital law states that the line integral of a magnetic field H, around a closed path is equal to the current traversing the surface bounded by that path (44), (45). Ampere's law in equation form is given by:

$$\oint_C H \cdot dl = I \qquad 12$$

Where C denotes the contour of close path.

The sign convention for the direction of the contour C path follows the right – hand rule. Thus if the direction of *I* is aligned with the direction of the thumb of the right hand, then the direction of the contour C should be chosen along that of the other four fingers. Therefore, given the direction of current flow in a current carrying conductor, the magnetic field close contour around the conductor will follow the right – hand rule.

The magnetic flux density *B* and field intensity *H* are related by (44), (45);

$$B = \mu H \text{ (T)} \qquad 13$$

Where, μ is the magnetic permeability property of the medium through which the field penetrates. This is usually denoted in text as $\mu_0$for most dielectric materials and metals except for ferromagnetic materials. $\mu_0 = 4\pi \times 10^{-7}$(N/A^2), (44).

For a current carrying wire conductor of finite length *l* shown in Figure 3.2, the magnetic flux density is given by:

$$B = \mu H = \mu \cdot \frac{Il}{2\pi r\sqrt{4r^2+l^2}}\hat{\psi} \text{ (T)} \qquad 14$$

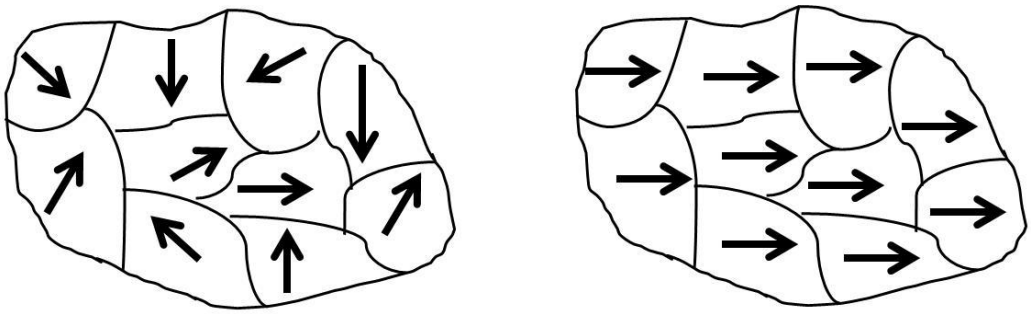
For an infinitely long wire, $l \gg r$

$$B = \frac{\mu I}{2\pi r}\hat{\psi} \text{ (T)} \qquad 15$$

3.2.3 Ferromagnetic Materials

The medium or material for transfer of electromagnetic energy for electricity should exhibit magnetic properties. These materials are called ferromagnetic materials. Ferromagnetic materials are basically materials that have the ability to attract a magnet.

Some common ferromagnetic materials are iron, nickel, cobalt, alnico and an alloy of aluminum-nickel-cobalt. From earlier discussions, the flow of electric charge has an associated magnetic field. The magnetic field comes from the motion of electrons in the atoms of these materials. In addition, each electron spins when in motion. Ferromagnetic materials exhibit a long-range ordering property at the atomic level which causes the unpaired electron spins to line up parallel with each other in a region called a domain (45). Figure 3a shows this alignment phenomenon. Magnetic field is intense in each



a. Domains with magnetic field in material but misaligned with each due to no external magnetic influence.

b. Domains aligned with each other due to external magnetic influence.

Figure 3.3: Domain Alignment in Ferromagnetic Materials

domain but the material as whole is not magnetized due to random orientations of domains (45), (50). However, an external influence of a magnetic field on a ferromagnetic material can cause the domains to line up with each other to cause magnetization. This is illustrated in Figure 3b. The magnetic field is then increased across the material by a factor called its relative permeability. Relative permeability is the ratio of permeability of a material to that of a vacuum at the same magnetic field strength (45). Table 3.1 gives the relative permeabilities of some common ferromagnetic materials.

Table 3.1: Relative Permeabilities of Common Ferromagnetic Materials (46)

Material	Relative Permeability(μ_r)
Cobalt	250
Nickel	600
Iron	6,000
Supermalloy(5%mo,79% Ni)	107
Steel (0.9 C)	100
Silicon iron (4% si)	7,000
Permalloy(78.5% Ni)	100,000
Fe3O4 (Magnetite)	100
Ferrites	5,000
Mumetal (75% Ni, 5% Cu, 2% Cr)	100,000
Permendur	5,000

Soft iron is used in electromagnetic applications like transformer cores, motors and temporary magnets. The next section is a summary on transformer basics and how electromagnetic energy is used to generate electricity.

3.3 An Overview of Electrical Transformers

This section looks at the basic working principle of transformers and the relevant equations for their design. A transformer is an electrical device that transfers energy from one circuit to another by electromagnetic induction (47). The key components of a transformer are a primary coil (winding), a secondary coil (winding) and a core material

that supports both windings. In addition, the core also acts as the medium for magnetic coupling between the primary and secondary windings. Thus, this can be said to be the medium for energy transfer. A simplified diagram of a transformer is shown in Figure 3.4.

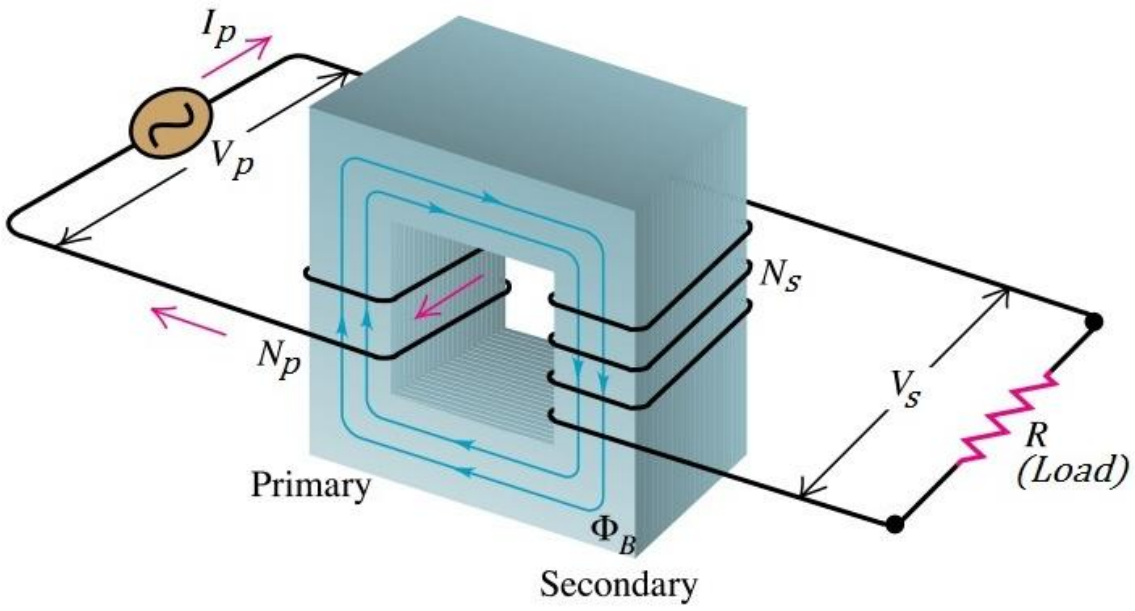


Figure 3.4: A Simplified Diagram of an Electric Transformer (5)

Faraday's law of induction is the basic law of electromagnetism relating to the operating principles of transformers. The law states that, time varying magnetic fields can produce an electric current in a closed loop (44). In other words, any coil of wire in a changing field of magnetic field will cause a voltage (electromotive force, emf) to be induced in the coil. The change can be a relative movement of either magnetic source or the coil. This is expressed in equation form as (44), (45):

$$\mathcal{E} = -N\frac{d\phi}{dt} = -N\frac{d}{dt}\int_s B \cdot ds \qquad 16$$

Where, $\mathcal{E}$ induced emf, B magnetic field strength, N number of coil turns, s surface area of the inductor and ϕ magnetic flux density.

Conventional transformers are either used to step up or down voltage from a primary side to the secondary side winding. A simple transformer circuit is shown in Figure 3.5. They are constant power devices which means, the product of the primary voltage and current is the same as the product of the secondary voltage and current. The ideal transformer equations are:

$$|Primary\ power| = I_p V_p = |Secondary\ power| = I_s V_s$$

$$\frac{V_s}{V_p} = \frac{N_s}{N_p} = \frac{I_p}{I_s} \qquad 17$$

V_p Primary side voltage, V_s Secondary Voltage, N_p Primary turns, N_s Secondary turns, I_p Primary current, I_s Secondary current.

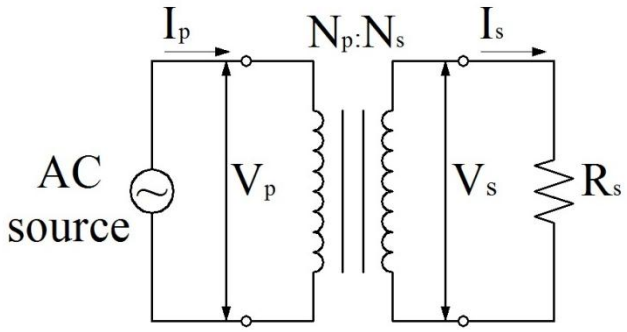

Figure 3.5: Simple Transformer Circuit

In practical transformers however, material properties of core plays an important role. The cores are selected so as not to saturate under low magnetic flux. Thus transformers are designed with cores of high permeabilities. The design principle is based on estimating the total component losses and performing an iterative process to get a balance between output performance and geometry of the core. The losses are copper

losses of the windings and losses of the core material (49). Practical transformers are designed by using equation 18 (49).

$$\frac{W_A(A_c)^{\left(\frac{2(\beta-1)}{\beta}\right)}}{(MLT)l_m^{(2/\beta)}}\left[\left(\frac{\beta}{2}\right)^{-\left(\frac{\beta}{\beta+2}\right)}+\left(\frac{\beta}{2}\right)^{\left(\frac{2}{\beta+2}\right)}\right]^{-\left(\frac{\beta+2}{\beta}\right)} = \frac{\rho\, I_{tot}^2\, \lambda_1^2\, K_{fe}^{\left(\frac{2}{\beta}\right)}}{4K_u(P_{tot})^{\left(\frac{\beta+2}{\beta}\right)}} \qquad 18$$

Where, ρ effective wire resistivity, I_{tot} total rms winding current, referred to primary, $\lambda_1$applied primary volt-sec, P_{tot} Allowed total power dissipation, K_u winding fill factor, β core loss exponent, K_{fe} core loss coefficient, A_c core cross-sectional area, W_A core window area, l_m magnetic path length, MLT mean length per turn of winding.

The terms on the left hand side of equation 18 are dependent on core geometry and that on the right hand side depend on the specifications of application (output voltage, current). Complete derivation of equation 18 and other related equations are found in (49) and (50).

3.3.1 Current Transformers (CT)

Harvesting electromagnetic flux around current carrying conductors through conventional voltage transformer design will require the current carrying conductors to be wound around transformer cores. This will involve modification of existing electrical wiring systems and also can be difficult to achieve with solid conductors. The current transformer (CT) is therefore the suitable choice to harvest energy from the magnetic flux around current carrying conductors. This section looks at the main theoretical equations used for designing current transformers.

Current transformers are used in high-power circuits where large currents are involved. They are mostly used in monitoring current of conductors or cables in AC power circuits (50). Figure 3.6 shows a circuit diagram of a simplified current transformer used to monitor line currents.

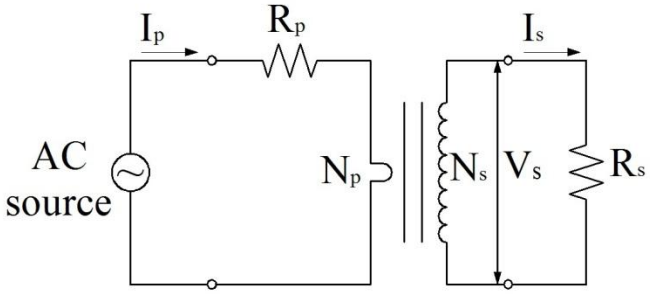

Figure 3.6: Simplified Circuit Diagram of a Current Transformer

Lists of predominant equations for designing current transformers are included below.

Application specific equations (50):

$\frac{I_p}{I_s} = \frac{N_s}{N_p}$, $N_p = 1$

$$\frac{I_p}{I_s} = N_s \quad (19)$$

$$I_s = \frac{V_s}{R_s} \text{ (A)} \quad (20)$$

I_p Primary current, I_s secondary current, N_p primary turns, N_s secondary turns, V_s secondary load voltage, R_s secondary load resistance.

For an output DC load R_o, at the secondary side, a bridge rectifier will be required to convert the secondary voltage from AC to DC voltage. Figure 3.7 shows the circuit diagram of a bridge rectifier incorporated into the secondary side of the CT.

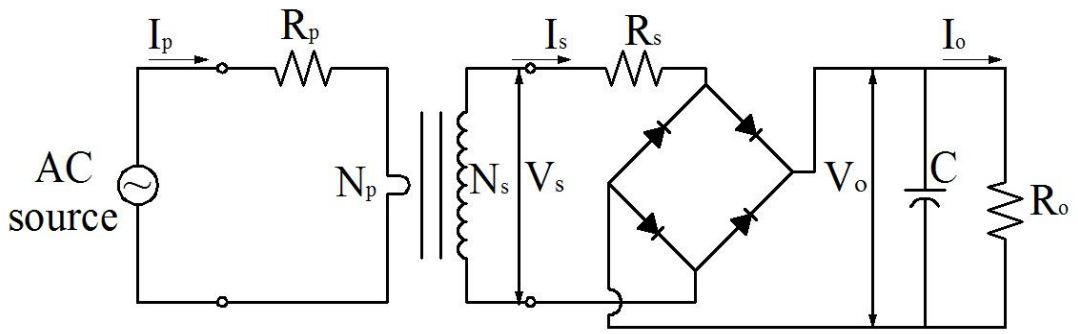

Figure 3.7: Complete Circuit Diagram of a Current Transformer with a Bridge Rectifier

Secondary winding resistance R_s

$$R_s = MLT\ (N_s)\left(\frac{\mu\Omega}{cm}\right)(10^{-6})\ (\Omega) \qquad 21$$

MLT is mean length per winding turn

and the output load voltage, V_o

$$V_o = I_o(R_o) \qquad 22$$

The Secondary voltage V_s is calculated using equation 23

$$V_s = V_o + V_d \text{ (Volts)} \qquad 23$$

Where, V_d is diode voltage drop

Total secondary output power, P_o

$$P_o = I_s V_s \text{ (watts)} \qquad 24$$

Core Geometry Equations (50):

Figure 3.8 illustrates current transformer core geometry parameters. The window area W_a is a through rectangular hole in the core material.

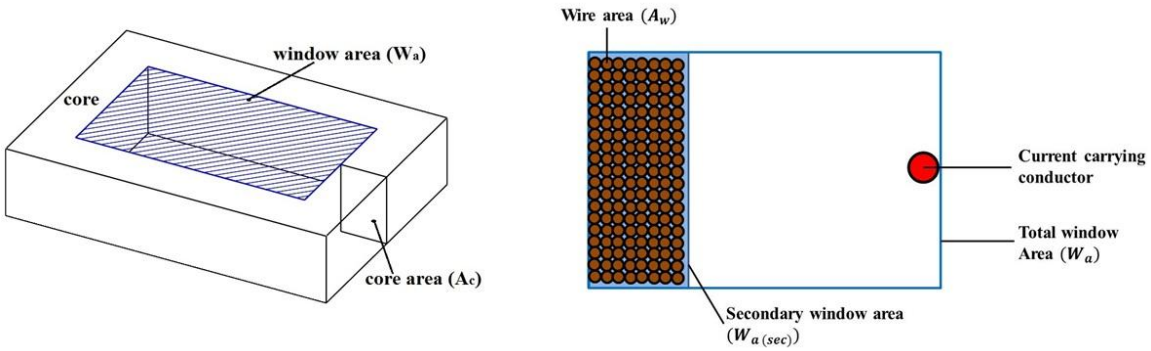

Figure 3.8: Current Transformer Core and Window Area

Core cross sectional area A_c

$$A_c = \frac{V_s(10^4)}{K_f B_{ac} f N_s} (\text{cm}^2) \quad 25$$

K_f is Waveform factor (4 for square wave and 4.44 for sinusoidal wave), (50). B_{ac} is Operating Magnetic flux density, f is Operating frequency,

Effective window area, $W_{a(eff)}$

$$W_{a(eff)} = W_a S_3 (\text{cm}^2) \quad 26$$

W_a is Core window area, S_3Effective window area constant (ratio of usable window area to window area), typical value of $S_3$is 0.873 (31).

Secondary window area, $W_{a(sec)}$

$$W_{a(sec)} = \frac{W_{a(eff)}}{2} (\text{cm}^2) \quad 27$$

Wire area, A_w

$$A_w = \frac{W_{a(sec)} S_2}{N_s} (\text{cm}^2) \quad 28$$

$S_2$is wire lay fill factor (ratio of wound area to usable window area), typical value of S_2 is 0.61 (50).

Table A.1, (50) in the appendix shows various wire areas (A_w) and corresponding AWG wire for winding. The general rule for wire selection is that when calculated, the wire area should not fall within 10% of the listed value in the wire table, otherwise the next smaller size should be selected. The design of other special CTs are found in (50).

3.3.2 Transformer Core Saturation

Transformer performance is limited by the amount of magnetic flux that can be contained in the core. Ferromagnetic cores tend to saturate after a certain level of magnetic flux. This further increase of the magnetic field flux after saturation will not result in a proportional increase in induced voltage. Saturation causes distortion of the wave shape of the primary current or voltage to secondary windings. This results in what is called harmonics in transformers. Harmonics are the distortions in wave shape of secondary side AC voltages. Common indication of harmonics in transformers is increase in temperature of during operation.

In order to avoid harmonics in transformers, material of cores should have high permeabilities. Saturation is also based on the core size, the number of coil turns, as well as the voltage and current in the windings. To improve the permeability of the cores, cut-cores are often used in most transformer applications.

The small size of the energy harvesting device requires a core material that will not saturate under the magnetic flux generated by the operating current. The typical operating current target range for this research is 1-20A. The magnetic core material

proposed for the energy harvesting device is Metglas allow 2605SA1. Metglas 2605SA1 has a high saturation flux density of 1.56 T (51) which is very high compared to the maximum magnetic flux for the target 1-20A. Simulations of magnetic flux generation from various currents are discussed in Chapter 5. The next chapter gives the objectives of this research and explains the methodology involved. The design process of the proposed energy harvesting device is illustrated in a case study.

Chapter 4

RESEARCH OBJECTIVE, METHODOLOGY, AND DESIGN

4.1 Introduction

Developing a miniature power supply that has a limited source of energy (electromagnetic field) requires in-depth design considerations. Apart from the size and source of energy being a limitation, the minimum required amount of power that can be generated also depends largely on these limitations. This minimum amount of power should be able to power the sensor to enable continual operation. Therefore, a careful design has to balance the aforementioned limitations whilst also meeting the required minimum output power. This chapter discusses the main objectives, methodology, and design considerations that must be taken into account to meet such a goal.

4.2 Research Objective and Methodology

The main objectives and methodology of the research can be summarized as follows:

[1] To develop and design a small electromagnetic energy harvesting device that will fit into the standard electrical node boxes in Figure 4.1 (52). The most common sizes of boxes used for wiring electrical nodes are 95mm by 50mm by 90mm and 100mm sq. by 38mm. Therefore, the size of the harvesting device shall meet the existing form factor of standard boxes for electrical nodes without any modification to the electrical wiring system.

Table 314.16(A) Metal Boxes

Box Trade Size			Minimum Volume		Maximum Number of Conductors* (arranged by AWG size)						
mm	in.		cm^3	$in.^3$	18	16	14	12	10	8	6

Figure 4.1: Standard Metal Boxes Used in Electrical Wiring Systems (Table 314.16 (A), NEC 2008)

Method :

- Develop a method for designing a small electric current transformer by balancing key parameters – the core size, primary energy source, and output performance. The primary source will be the magnetic field generated around a conductor carrying 1-20A in a 120V system. This will be mainly based on transformer design basics and theories.
- Propose and produce design drawings of a small current transformer for electromagnetic energy harvesting. The design drawing will be generated in CAD and shall be a shop working drawing standard.

- Coordinate with the electric transformer manufacturing company to manufacture the proposed design.

[2] Develop a method for estimating the electromagnetic field strength around the current carrying conductors and the equivalent amount of power that can be generated by the energy harvesting device using theoretical equations.

Method :

- Estimate the amount of magnetic field strength around the current carrying conductors. This will be based on the theory of electromagnetics and use MATLAB tools.
- Use theoretical equations for transformer design basics to estimate the equivalent amount of power that can be generated from the magnetic field above. This will be done with MATLAB tools.

[3] Build a prototype board made up of typical electrical nodes and run experiments with the proposed energy harvesting device. The board will have a 120V- 20A electrical distribution wiring system with an energy management sensor at the node. Typical loads such as light and plug loads will be used in the experiments.

Method:

- Design an electric distribution layout with a 120V- 20A rated conductor comprised of 5 nodes (2 lighting nodes with 2 switching nodes and 3 - 120V duplex nodes).

- Build the prototype board from the design layout. An energy management sensor will be attached to one of the nodes.
- The energy harvesting device will be mounted on the current carrying conductor at a node and hard wired to the energy management sensor. A re-chargeable battery shall be incorporated into the board for storing generated power during periods in which the sensors are idle.
- Two additional low powered devices (LED and USB power outlets) shall be mounted on the board for demonstration purposes and hard wired to the energy harvesting device.

[4] Investigate potential challenges and other useful applications. These challenges will be in relation to:

- Design limitations,
- Code violations and
- Practical implementation.

A list of other low power devices in the built environment will also be presented.

The next section explains the design process behind the creation of the energy harvesting device.

4.3 The Design Process

To illustrate design process, this section presents a case study to design the proposed energy harvesting device. The theoretical design approach is based on that of a CT. The various parameters for design and operation are given as follows:

- Sensor energy specifications (current consumption, battery voltage, average power consumption) are shown in Table 4.1.
- Energy harvesting device output voltage, 5V DC.
- Diode voltage drop is 2V DC.
- The core size specifications (height, Length, width, window size) are shown in Figure 4.2.
- Operating primary current range is 1-20A rms and a voltage of 120 V AC rms.
- Operating frequency, sine wave 60Hz.
- Operating current carrying conductor size is #12 AWG.

Table 4.1: Sensor Energy Demand Specifications

Sensor	Current Consumption			Battery Voltage	Average Power Consumption
	Transmission mode	Reception mode	Sleep mode		
XBEE Zigbee/802.15.4 Modules (15)	50mA	50mA	10 μA	2.8V-3.4V	155mW

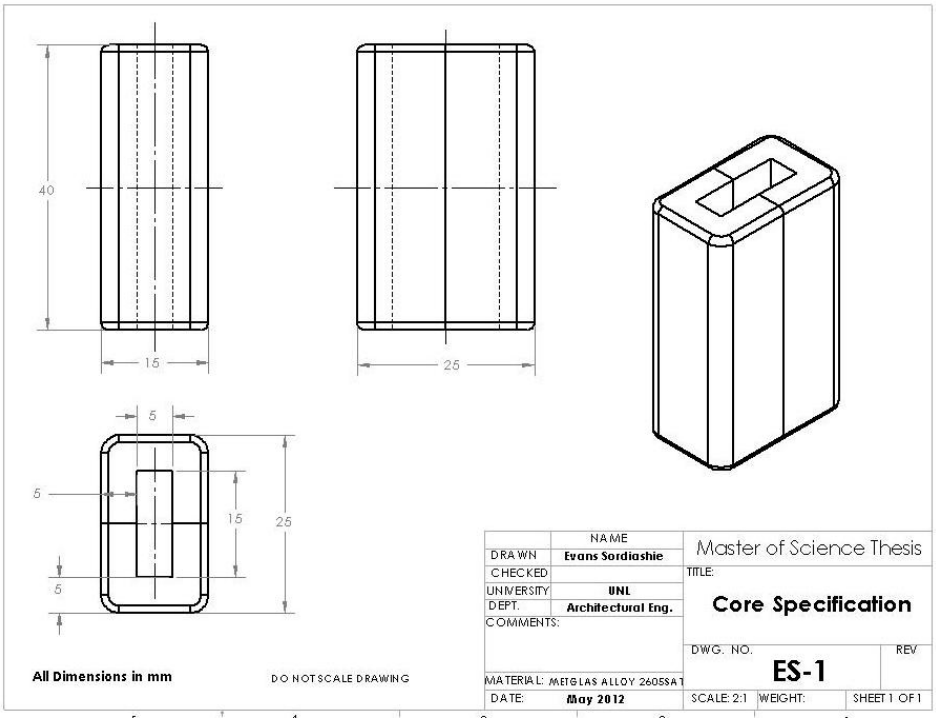

Figure 4.2: Energy Harvesting Device Core Specifications (proposed design)

4.3.1 Design Calculations

A cross sectional area of the core from equation 25 in Chapter 3 is given by;

$$A_c = \frac{V_s(10^4)}{K_f B_{ac} f N_s} \ (cm^2)$$

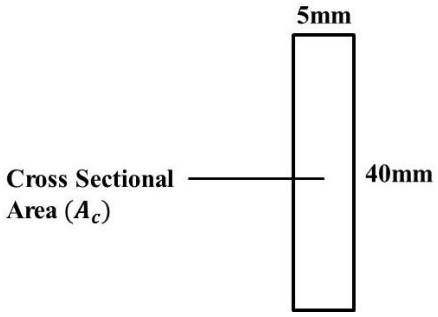

Figure 4.3: Cross-Sectional Area of the Core

From the core geometry in Figure 4.3,

Core height, $l = 40mm = 40 \times 10^{-3}\ m$

$A_c = (5 \times 40)mm^2 = 2\ cm^2$

Distance from current carrying conductor to magnetic path length r, as shown in Figure 4.4 is

$r = \left(\frac{5}{2} + 4\right) = 6.5\ mm = 6.5 \times 10^{-3}\ m$

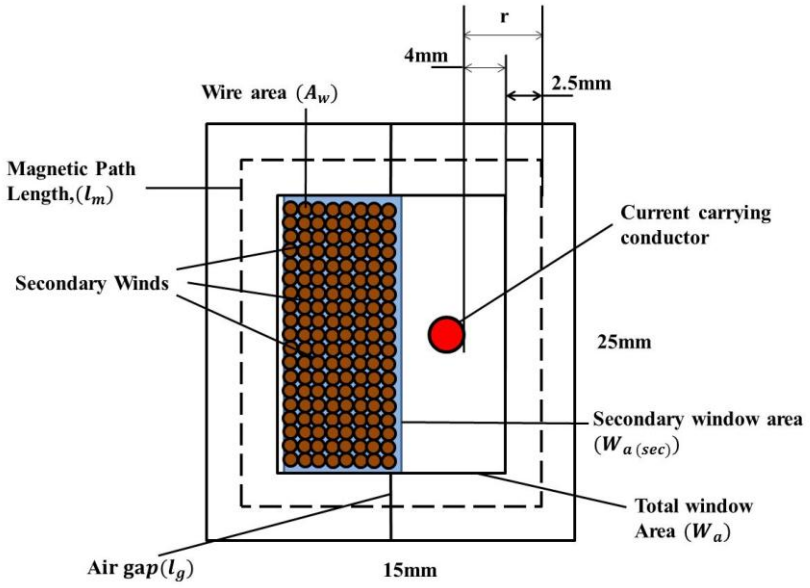

Figure 4.4: Core Window Area

Finding permeability of core

Permeability of free space $\mu_o = 4\pi\ \times 10^{-7}\ H/m$

Permeability of Metglas material, $\mu_m = 3000\ H/m$

Air gap between cut cores, $l_g = 120\ \times 10^{-6}\ m$

Magnetic path length, $l_m \cong 2\ (20 + 10) = 60 \times 10^{-3}\ m$

Overall relative permeability of Core assembly μ_r is given by (50);

$$\mu_r = \frac{\mu_m}{1 + \ \mu_m \left(\frac{l_g}{l_m}\right)}$$

$$\mu_r = \frac{3000}{1 + \ 3000 \left(\frac{120 \times 10^{-6}}{60 \times 10^{-3}}\right)} = 428.57$$

Finding magnetic field strength

Operating primary current, $I_p = 10\ A\ (rms)$

Magnetic field strength generated by *10 A* flowing through conductor is given by equation 14;

$$B_{ac} = \frac{\mu_0 \mu_r I_p l}{2\pi r \sqrt{4r^2 + l^2}}\ (T)$$

Where, $\mu = \mu_0 \mu_r$, effective permeability of core assembly.

$$B_{ac} = \frac{4\pi\ \times 10^{-7} \times 428.57 \times 10 \times (40 \times 10^{-3})}{2\pi \times 6.5 \times 10^{-3} \times \sqrt{4 \times (6.5 \times 10^{-3})^2 + (40 \times 10^{-3})^2}}\ (T)$$

$$B_{ac} = \ 0.1254\ T$$

Finding total secondary winding

Diode and secondary winding resistance voltage drop, $V_d \cong \ 3\ V$.

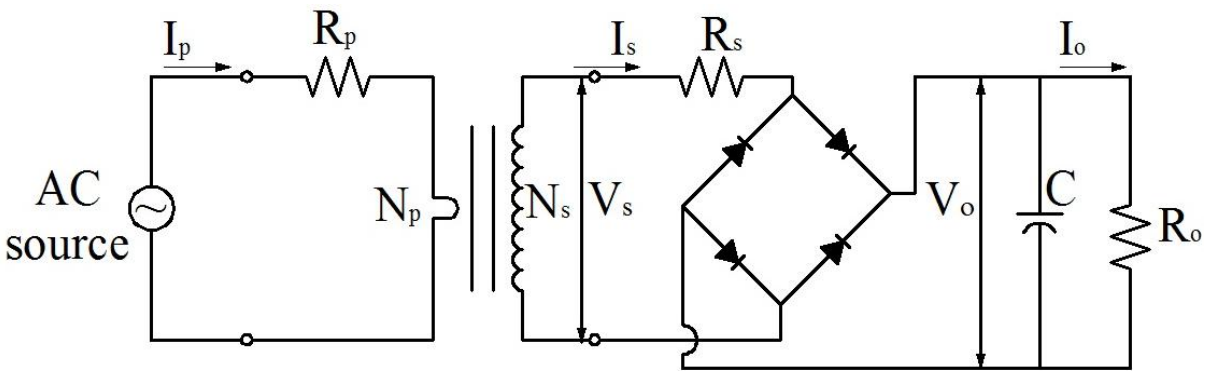

Figure 4.5: Circuit Diagram of the Energy Harvesting Device.

Expected output voltage is $V_o = 5\ V\ DC$

Output load current is$50\ mA$,

Corresponding output load resistance R_o is,

$R_o = \frac{V_L}{I_o} = \frac{3.4}{50} = 68\Omega$, V_L is actual sensor voltage requirement.

Total secondary voltage, V_s is given by;

$V_s = V_o + V_d$

$V_s = 5 + 3 = 8\ V(rms)$

Primary turns, $N_p \cong 1$

Waveform factor for sine wave, K_f = 4.44

Operating frequency, $f = 60\ Hz$

Total Secondary winding N_s, is given by;

$$N_s = \frac{V_s(10^4)}{K_f B_{ac}\, f A_c} = \frac{8 \times 10^4}{4.44 \times 0.1254 \times 60 \times 2} = 1197.3$$

$$N_s \cong 1200\ turns$$

Finding conductor size for winding

Total window area as shown in Figure 4.4 is,

$$W_a = 15 \times 5 = 75\ mm^2 = 0.75\ cm^2$$

Effective window area $W_{a(eff)}$, available for winding (both primary and secondary) is,

$W_{a(eff)} = W_a \times S_3$, S_3 is effective window area constant. Typical value of S_3 is 0.873 (50).

$$W_{a(eff)} = 0.75 \times 0.873 = .655\ cm^2$$

Secondary window area, $W_{a(sec)}$ is,

$$W_{a(sec)} = \frac{W_{a(eff)}}{2}\ (cm^2)$$

$$W_{a(sec)} = \frac{0.655}{2} = 0.327\ cm^2$$

Cross sectional area A_w of the conductor for winding is given by;

$A_w = \frac{W_{a(sec)} \times S_2}{N_s}$, S_2 is the fill factor or the wire lay, for usable window area. Typical value of S_3 is 0.61 (50).

$$A_w = \frac{0.327 \times 0.61}{1200} = 0.000166\ cm^2$$

Table A.1 (50) in appendix A shows various wire areas (A_w) and corresponding AWG wire for winding. The corresponding AWG conductor for the winding is selected to be # 36.

The corresponding winding resistance is calculated using equation 21.

$$R_s = MLT\ (N_s)\left(\frac{\mu\Omega}{cm}\right)(10^{-6})$$

MLT is the average perimeter of the cross sectional area of core before and after windings has been added. This is estimated as:

$$MLT = \frac{(40+5)\times 2 + (40+5)\times 2 \times 1.4 - 0.355}{2} \quad (mm)$$

Where, 140% is allowed for increase in perimeter for windings and 0.355mm is allowed for wrapper thickness on windings.

$$MLT = 10.8 \quad (cm)$$

$$R_s = 10.8\ (1200)(13608)(10^{-6}) = 176.36\Omega$$

The winding resistance is very high compared to the load resistance (68 Ω). To reduce this resistance, 500 turns of #25 AWG winding will be used for the secondary winding. This will also increase the current output of the harvesting device because of the constant power principle of the transformer. The new induced voltage V_s, is calculated using equation 25.

$$V_s = \frac{N_s \times K_f \times B_{ac} \times f \times A_c}{(10^4)} = 3.34\ V\ (rms)$$

The new winding resistance is,

$R_s = 10.8\,(500)(1062)(10^{-6}) = 5.73\Omega$

An AC to DC voltage doubler (multiplier) is used to boost up the new voltage. Figure 4.6 shows a circuit of the voltage doubler.

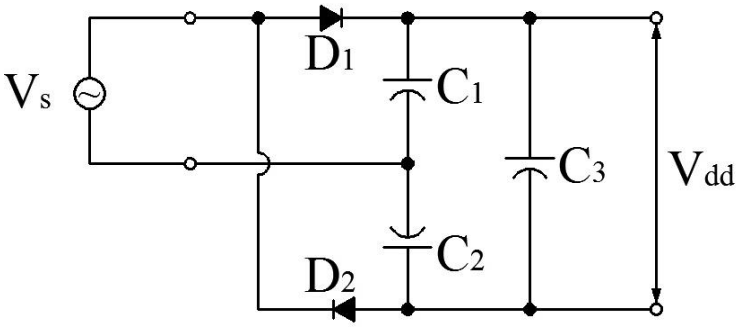

Figure 4.6: Voltage Doubler Circuit

The doubled voltage V_{dd} is calculated with equation 29

$$V_{dd} \cong 2 \times V_s\, peak = 2\sqrt{2} \times V_s\,(rms) \qquad 29$$

$$V_{dd} \cong 2\sqrt{2} \times 3.34 = 9.45\,V\,(DC)$$

To reduce and stabilize V_{dd} voltage for sensor operation voltage (2.8-3.4V DC) a voltage regulator is incorporated into the circuit. This is shown in Figure 4.7.

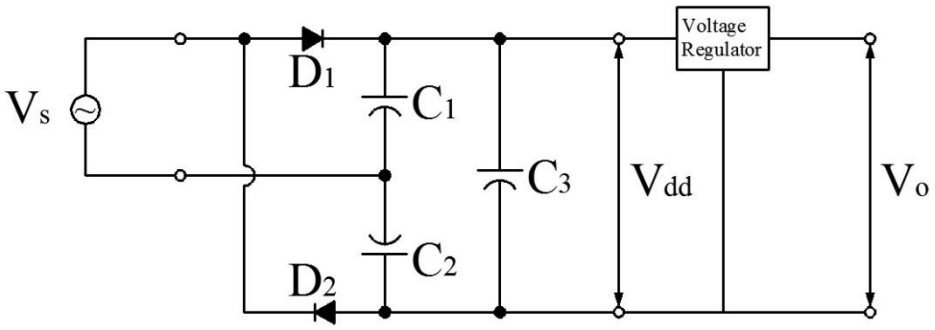

Figure 4.7: Voltage Regulator Incorporated into the Voltage Doubler Circuit

A summary of the final design specifications are as follows:

- Operating current carrying conductor, #12 AWG

- Primary turn, 1
- Average operating primary current , 10 A rms
- Operating frequency, sine wave 60Hz.
- Operating flux density, 0.1254 T
- Harvesting device size and specifications; Magnetic Material (Metglas alloy 2605SA1, High Saturation Flux Density (1.56 T)), Window area,W_a, 0.75 cm^2, Magnetic path length, $l_m \cong 6$cm, (see Figure 4.2).
- Winding conductor, # 25 AWG, 500 turns.
- Output voltage for sensor, 3.3V DC
- Output Load Resistance, ~ 68Ω
- Voltage regulator, LM2937 rated at 3.3 V DC
- Diode D_1, D_2 (IN4003), C_1 C_2 C_3 ,(1μ F rated at 100V)

This concludes the design process. The core size in Figure 4.2 is proposed core geometry for this research. The geometry will fit into typical node boxes (95mm by 50mm by 90mm or 100mm sq. by 38mm) in the built environment. In addition, management sensors can be directly mounted on the harvesting device at the node.

However, due to long manufacturing lead time for the proposed core of energy harvesting device, a smaller standard core readily available is used for prototyping and experiment. The core used is Amorphous Metal C Core #4 (AMCC-4). Detail specifications of the AMCC-4 core are provided in chapter 5.

Chapter 5

RESULTS AND DISCUSSION

5.1 Introduction

The main objective of this research is to design an electromagnetic harvesting device that will draw energy from available electromagnetic field around current carrying conductors at electrical nodes to generate power for energy management sensors. The size of this harvesting device is also a key objective as the device should fit into boxes at the electrical nodes without affecting the form factor of the boxes. To achieve these goals, it is very important to estimate the electromagnetic energy around typical current conductors in the built environment. With estimates of magnetic fields available, further estimates of equivalent voltage to be induced can be successfully done in relation to the size of the energy harvesting device core. The cross sectional area, A_c of the core needs to be carefully selected to prevent magnetic flux saturation but yet fit into typical boxes of nodes. This chapter presents simulation results and discusses the available electromagnetic energy around typical current carrying conductors in the electrical distribution system. All simulations are done with MATLAB software tools. Refer to Appendix C for the related programming codes.

The proposed core size in Figure 4.2 is not a standard core size available on the market. This means that a core must be customized for the proposed energy harvesting device. The manufacturing lead time to produce such a core is estimated to be 3 to 5 months (53). In addition, since only a few cores are needed for experiments and testing,

the initial cost will be high. To resolve this problem, a standard small size core is used in the simulations and experiments. Appendix B gives the winding specifications for the AMCC-4 core. All the results in this thesis are therefore based on the AMCC-4 core. This chapter also includes results from actual experiments conducted with an AMCC-4 core prototype energy harvesting device.

5.2 Electromagnetic Energy Around Current Carrying Conductors

Figures 5.1 and 5.2 show simulations of magnetic flux density around a current carrying conductor. Magnetic flux density reduces radially with increasing distances away from the conductor. This validates the Biot – Savart law which basically gives magnetic flux density around the conductor to be directly proportional to the current flowing through the conductor and inversely proportional to the distance of that point from the conductor.

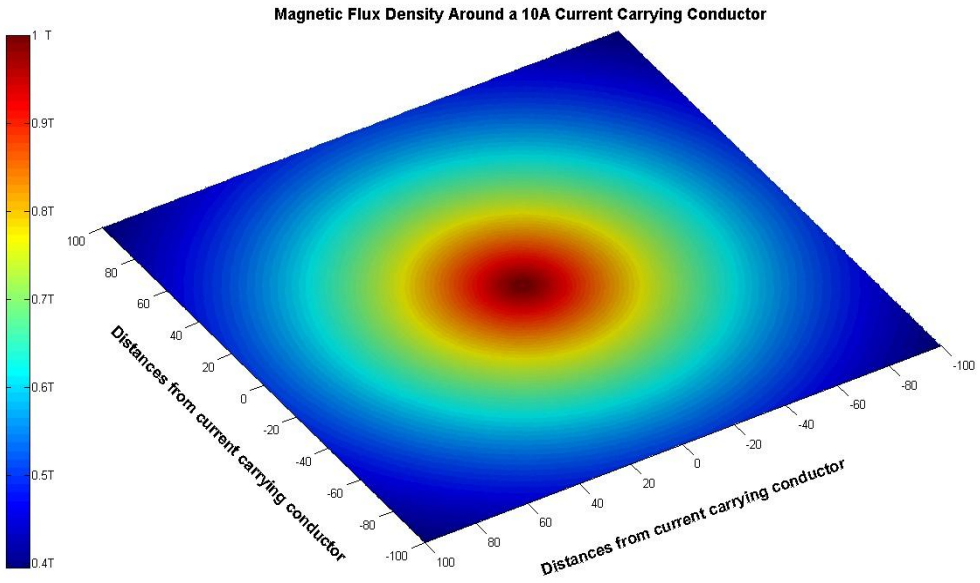

Figure 5.1: Magnetic Flux Density Around a 10 A Current Carrying Conductor

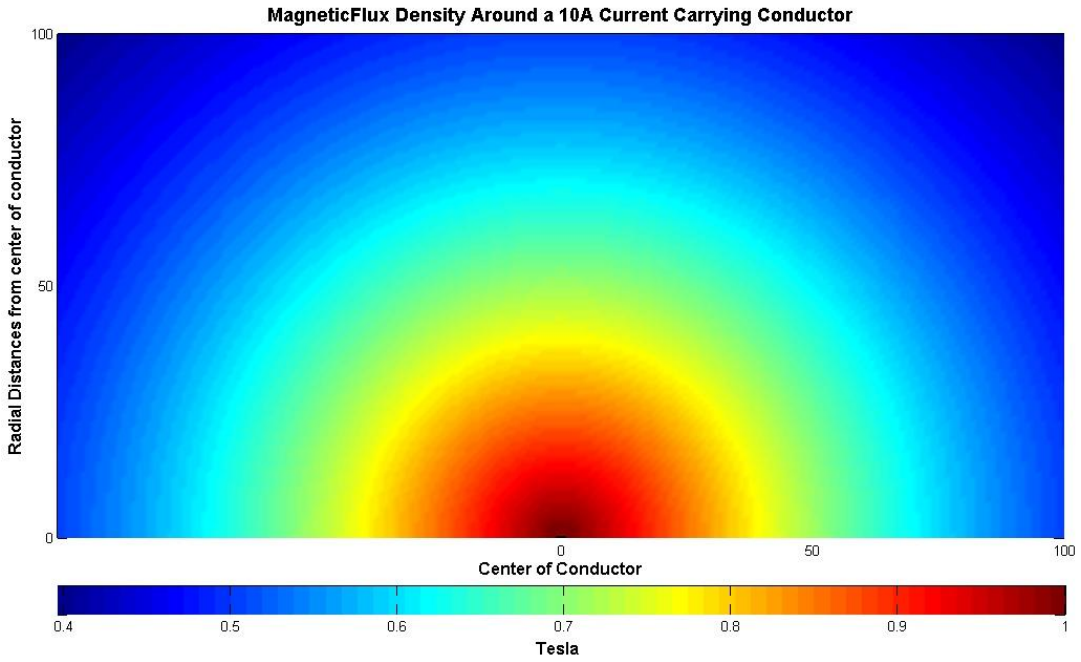

Figure 5.2: A Cut Through Section of Magnetic Flux Density Around a 10 A Current Carrying Conductor

Figure 5.3 shows theoretical result of electromagnetic flux density around a common current carrying conductor in the built environment. The conductor is #12 AWG and the current carrying capacity is 1-20A.

The magnetic flux density on the graph (see Figure 5.3) is calculated using permeability of free space ($\mu_o = 4\pi \times 10^{-7}$ H/m) and equation 14. To estimate magnetic flux that can be harvested for power generation, the relative permeability (μ_r) of the core has to be calculated as was done in the case study in chapter 4. Magnetic flux density around current carrying conductor decreases with increasing radial distances from the conductor. The simulation on the graph (see Figure 5.3) shows a radial distance of 2mm to 30mm from the current carrying conductor.

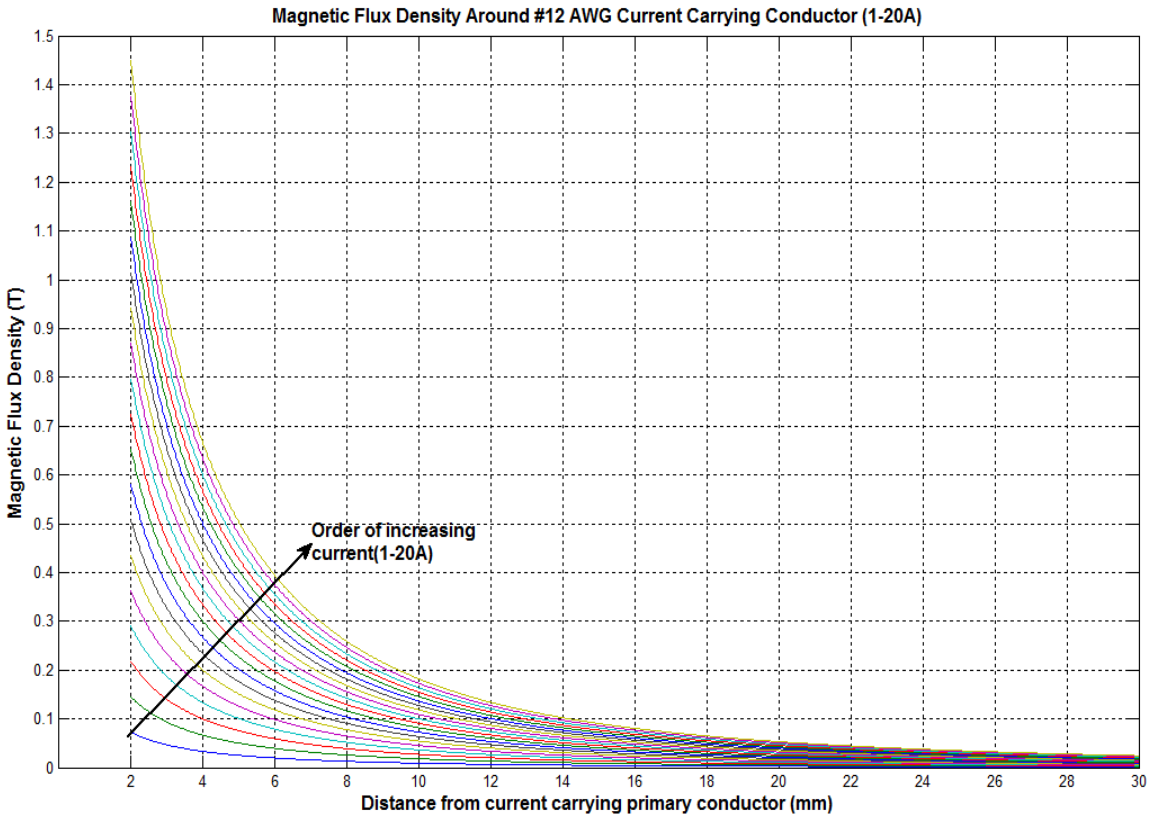

Figure 5.3: Magnetic Flux Density for Different Currents from 1-20 A

5.3 Induced and DC Output Voltages

The electric voltages that can be generated from corresponding primary load input (in watts) are shown in Figure 5.4. The voltages are generated using the AMCC-4 core. Each graph shows 5 different plots. The plots correspond to the voltages generated at radial distances from current carrying conductor to the magnetic path line (MPL, see Figure 4.4). The MPL is the length of an average magnetic field line around the interior of the core (49). The location of this field line is approximated to be at the center of the core as shown in Figure 4.4 (49). Figure 5.5 shows corresponding voltages for primary input current.

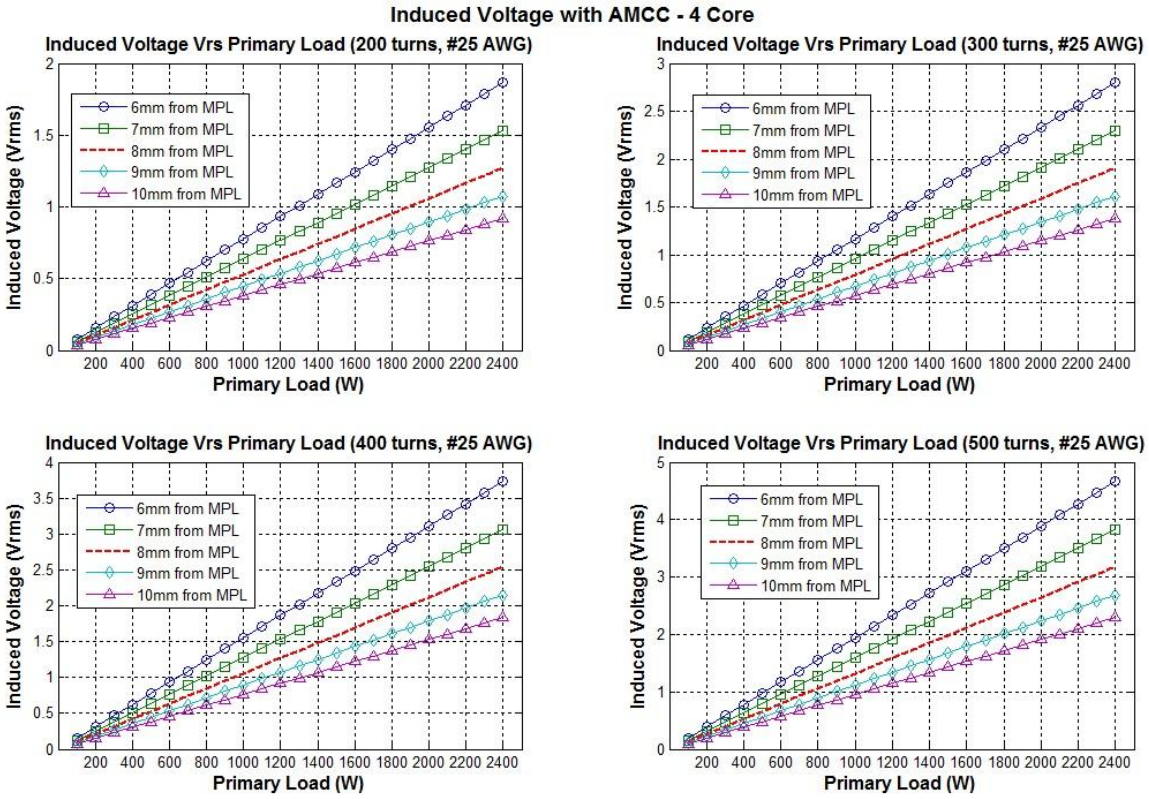

Figure 5.4: Induced Voltages per Primary Load Input (Watts)

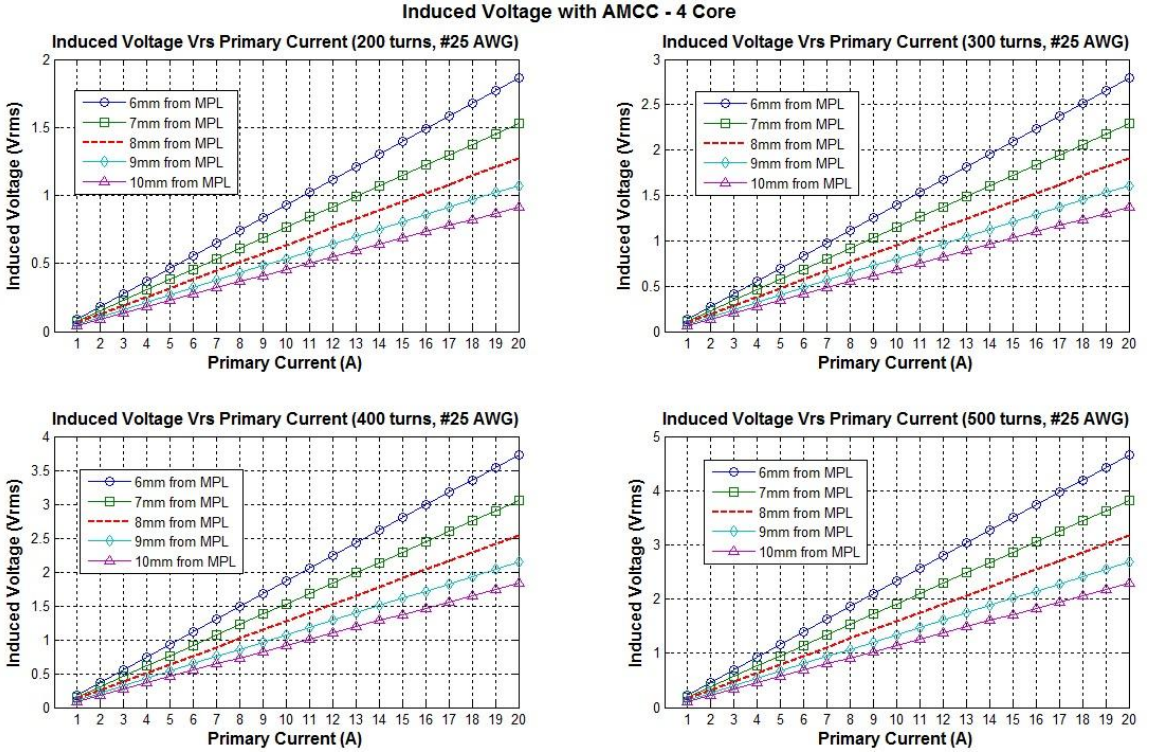

Figure 5.5: Induced Voltages per Primary Load Currents (A)

Figure 5.6 and 5.7 shows the voltages induced for a given load (watts) or current (A) and radial distances from current carrying conductor to MPL. The windings used on the AMCC-4 core for these simulations are 300 and 500 turns respectively.

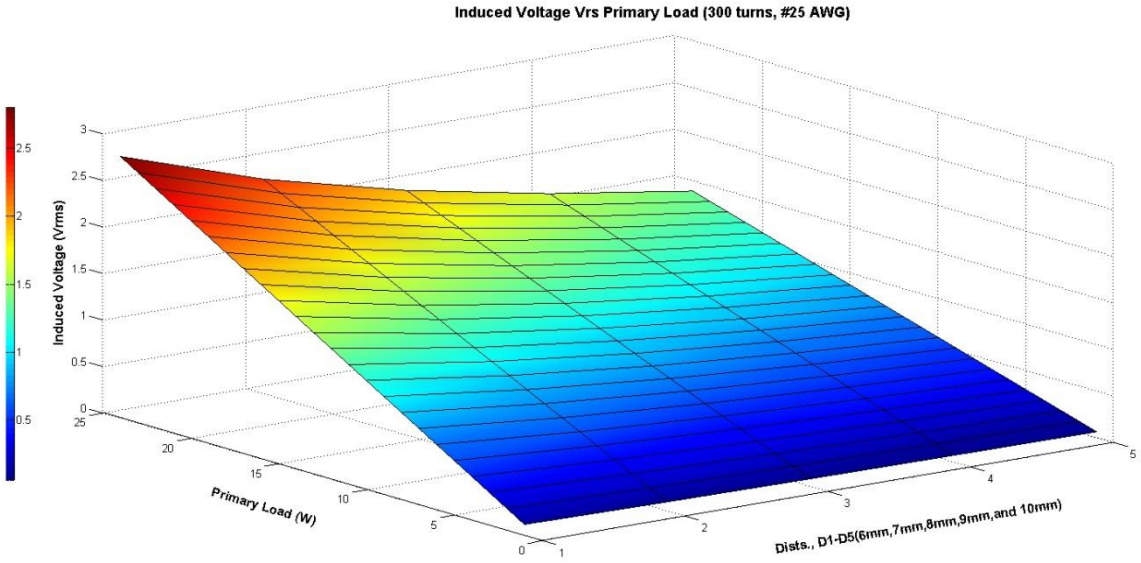

Figure 5.6: A Combination Plot of Induced Voltage Against Primary Input Load and Radial Distances from MPL (300 turns of #25 Secondary Winding)

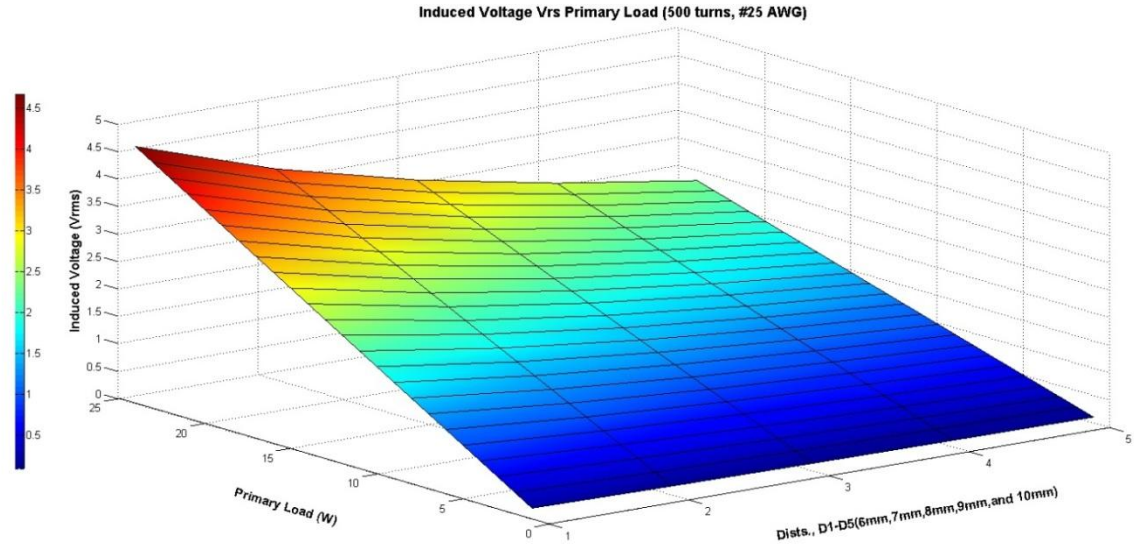

Figure 5.7: A Combination Plot of Induced Voltage Against Primary Input Load and Radial Distances from MPL (500 Turns of #25 Secondary Winding)

Most energy sensors use DC voltages during operation. Simulated voltages in Figure 5.5 are converted to DC component by incorporating an AC to DC bridge rectifier. A 0.5V voltage drop is allowed for the conversion from AC to DC. Figure 5.8 shows the DC voltage simulations.

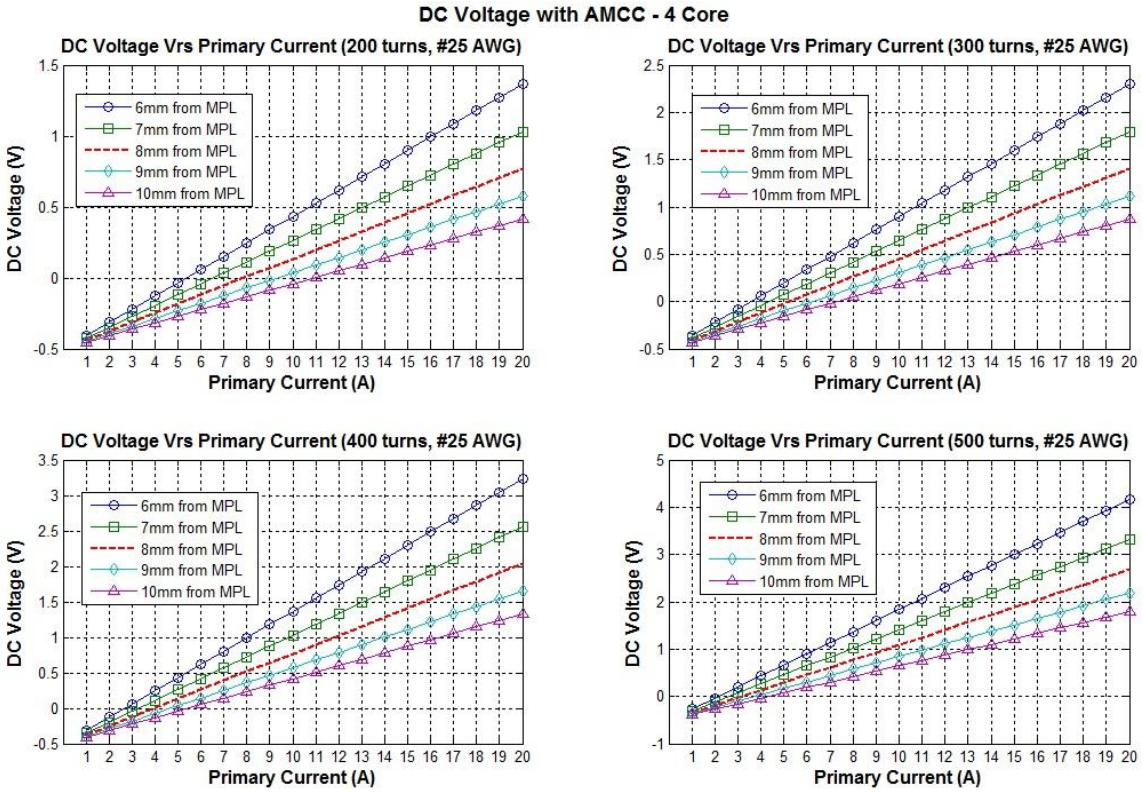

Figure 5.8: DC Output Voltages per Primary Input Load Currents

5.4 Core Size, Versus Magnetic Flux and Input Load Current

As one of the key objectives of the research, estimating the size of the core of energy harvesting device was very important. The size of the core basically translates to the cross sectional area of the core. Figure 5.9 shows a simulation of cross section estimation for a given magnetic flux density. The expected output voltages with a specific number of secondary windings on the core are also given. Corresponding graph for core cross section and primary input current is also shown in Figure 5.10.

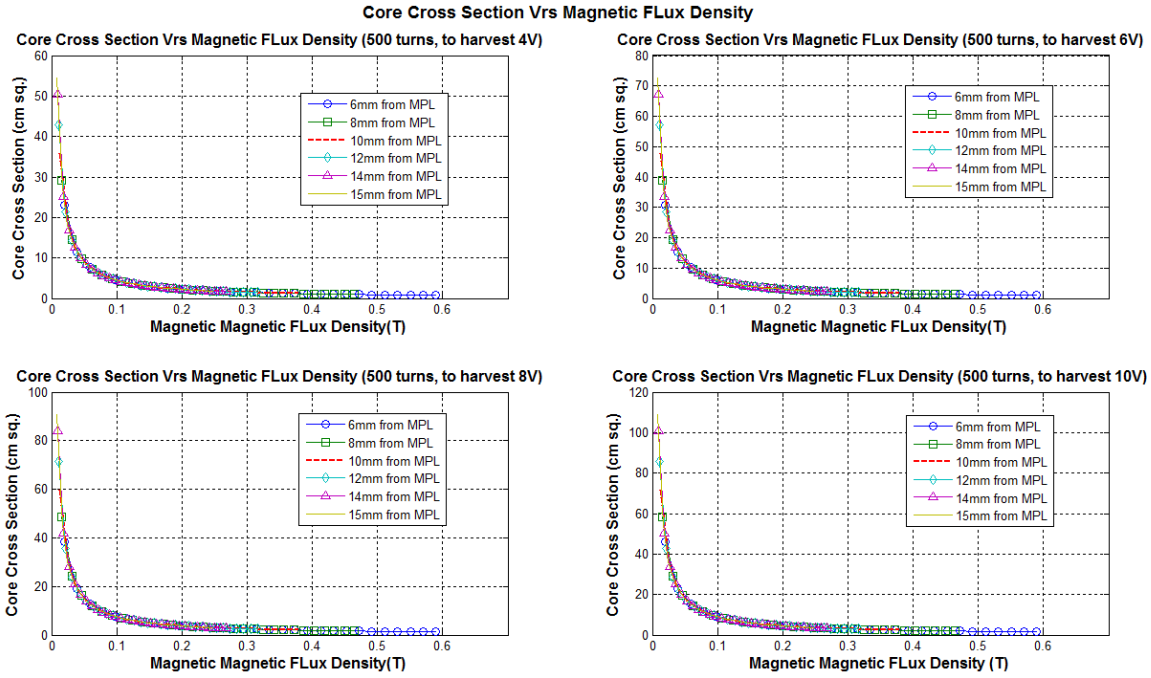

Figure 5.9: Core Cross Section vs. Available Magnetic Flux Density

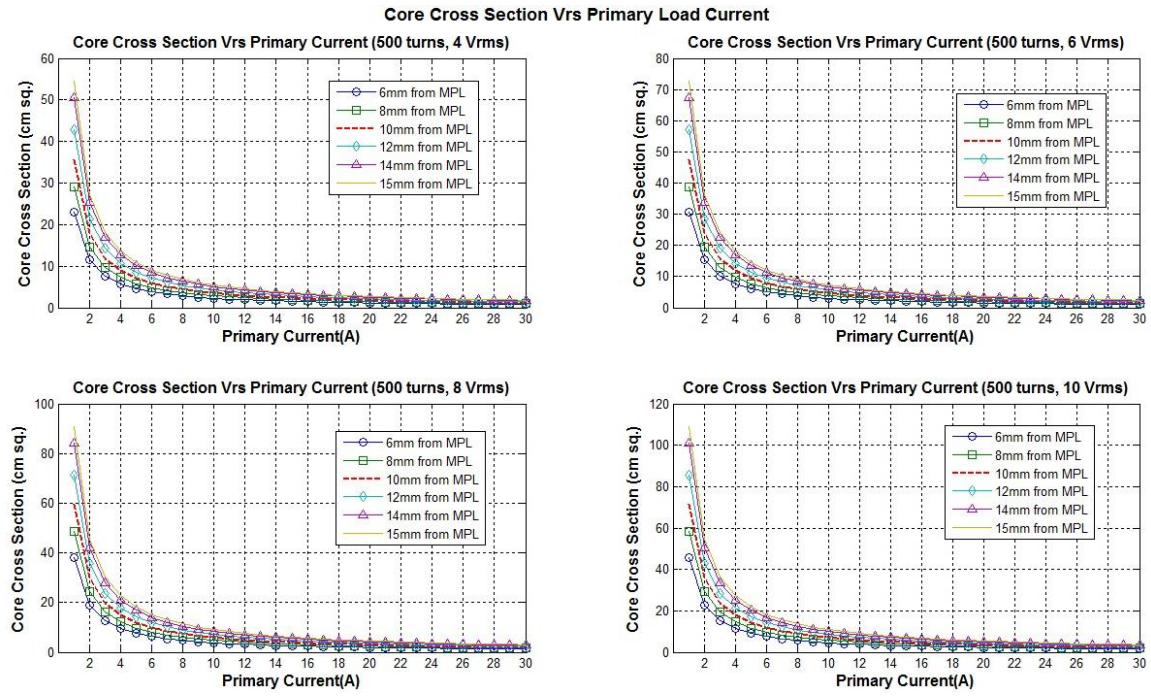

Figure 5.10: Core Cross Section Vs. Primary Input Current

To analyze how radial distances and input primary current affect the cross sectional area of the core of harvesting device, a combination plot is presented with radial distances and primary currents as inputs. This is shown in Figure 5.11.

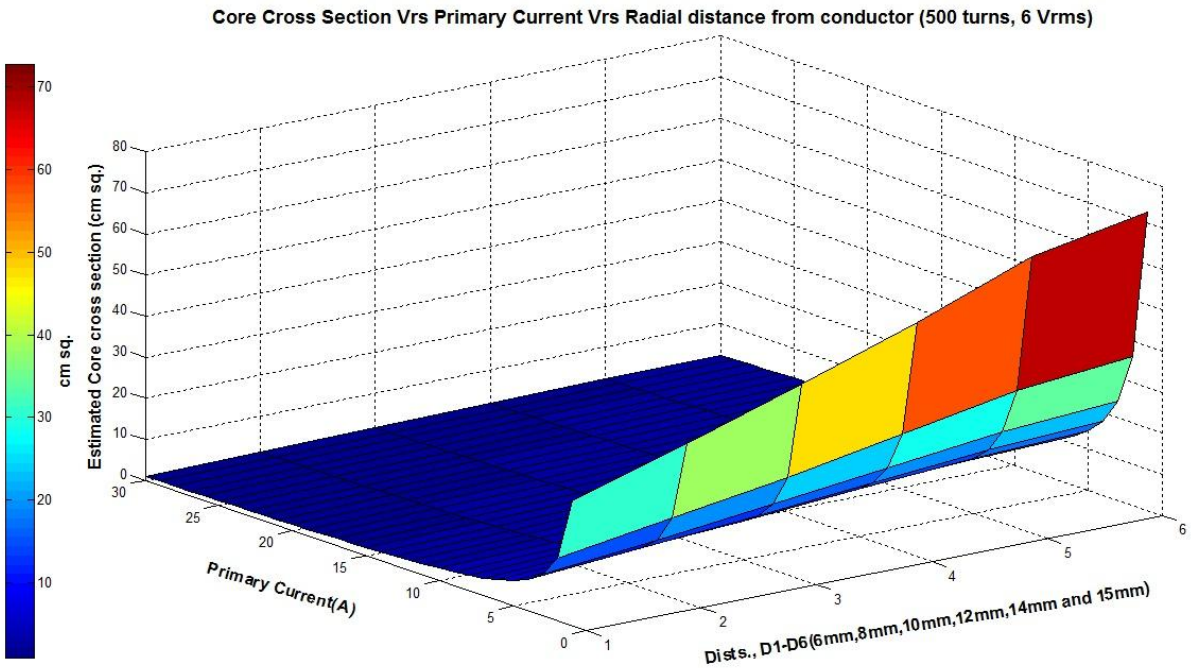

Figure 5.11: Combination Plot of Cross Sectional Area vs. Primary and Radial Distances

5.5 Experimental Results

To validate results from simulations, a prototype energy harvesting device is built with an AMCC-4 with windings, 200, 300, 400 and 500. Figure 5.12 shows an image of the AMCC-4 with the leads of the various windings. Except for the black colored, each lead corresponds to a number of windings. A circuit diagram of the windings is presented in Appendix B2.

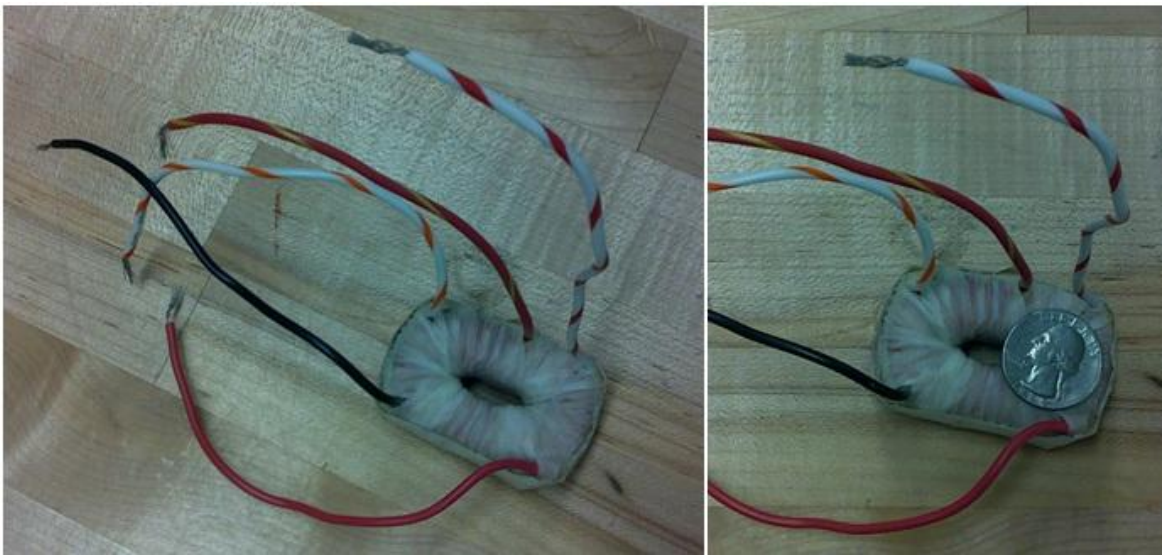

Figure 5.12 Prototype Energy Harvesting device made from AMCC-4 Core.

The board used for experiments is in Figure 5.13. The board is made up of some typical nodes in the built environments and rated for 120 V. The harvesting device is mounted on

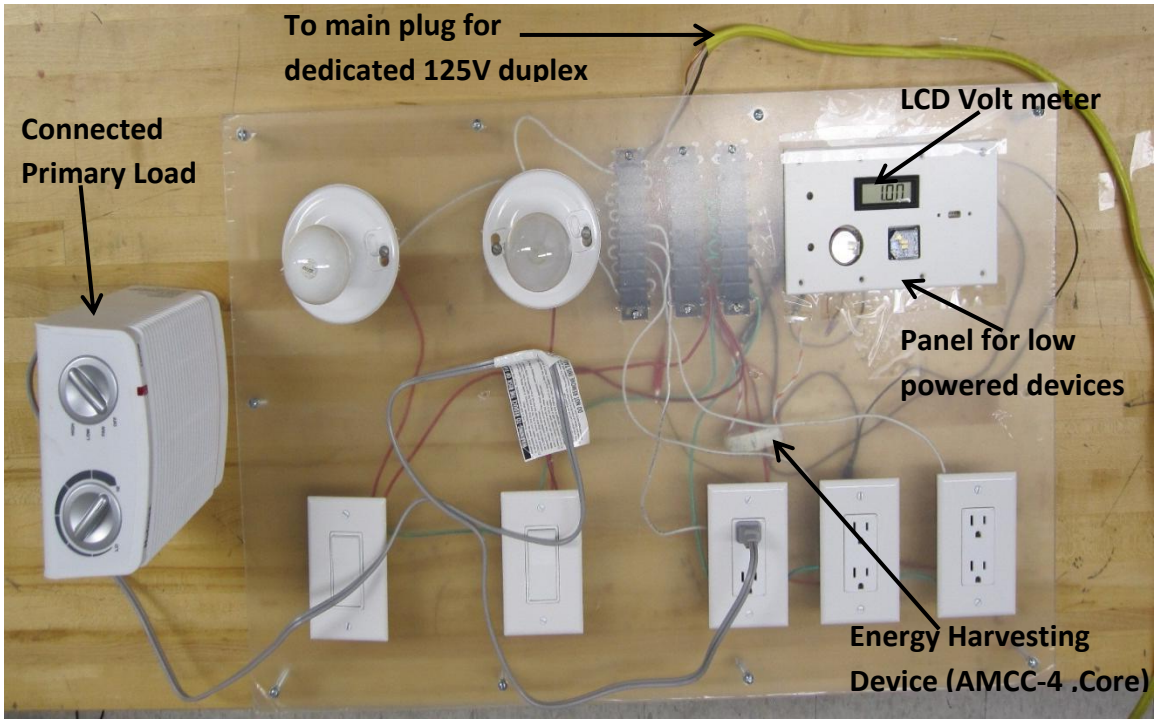

Figure 5.13: Board for Energy Harvesting Experiments

a current conductor on the board as shown in Figure 5.13. The board consists of duplex receptacles, lamp sockets and switches and low powered devices. A main plug for dedicated duplex receptacle is also included to supply power to the board.

The following are part inventory used in building the board for experiments.

1) Plastic platform
2) 3 duplex receptacles rated at 125 V.
3) 2 lamp holders rated at 120 V with connecting switches.
4) All conductors are #12 AWG (single phase, Neutral and Ground)
5) Low powered devices (energy sensors, USB outlet, LED lights, LED light)
6) DC bridge voltage multiplier (Diode D1, D2 (IN4003), C1 C2 C3 , 1μ F rated at 100V)
7) Voltage regulator, LM2937 rated at 3.3 V DC, LCD voltage display meter
8) 3V DC Chargeable Li-ion battery
9) #12 AWG main electric plug connector for a dedicated duplex receptacle rated at 125V.

Figure 5.14 shows a schematic diagram of the board used for experiment. The following steps are used to take measurements from the board.

a. The main plug is plugged into a dedicated duplex receptacle rated at 120/125V.
b. A multimeter is connected to the leads of the harvesting device installed on the current carrying conductor on the board.
c. Various sizes of loads (lamps, small size heaters, etc.) are connected to the nodes (lamp socket, receptacles) on the board.

d. The loads are turn on and induced voltage measurements are recorded from the multimeter. The sizes of the loads are also recorded. This step is repeated for various loads up to a combined total of 2400 W and also for different winding turns of the harvesting device.

e. The recorded induced voltage measurements are plotted against corresponding connected loads for the different windings on the harvesting device.

f. The main plug is disconnected from the dedicated duplex receptacle to conclude the experimental process.

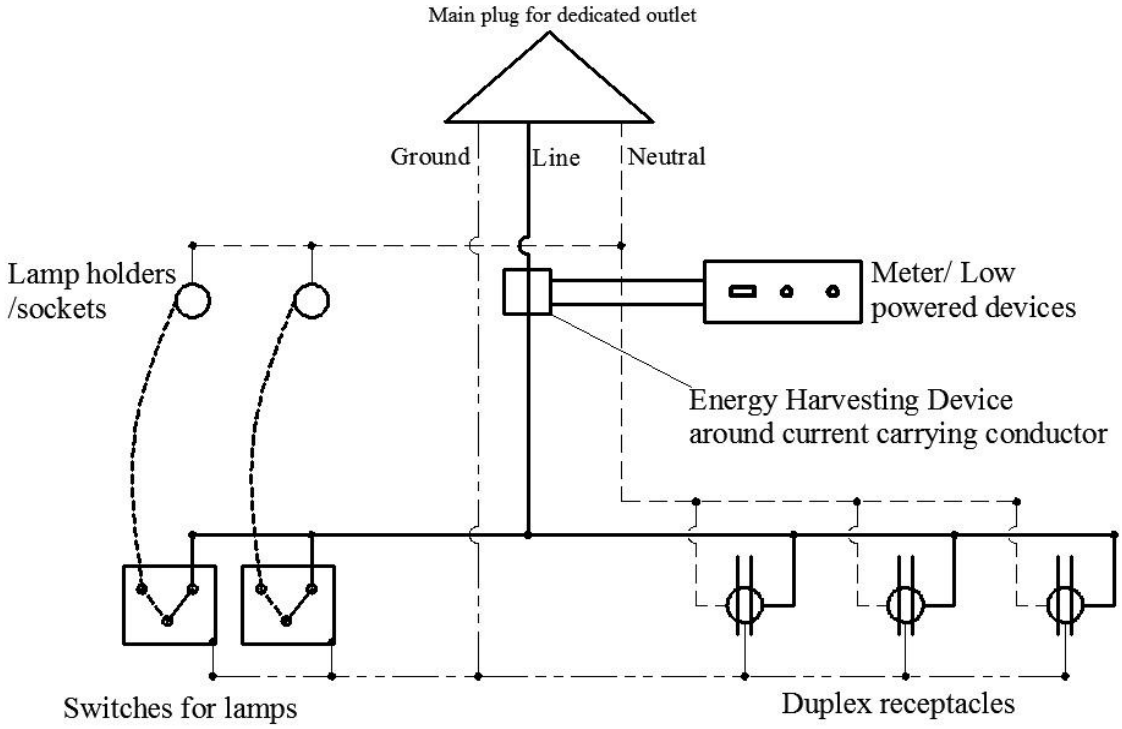

Figure 5.14: Schematic Diagram of the Experimental Board

Figure 5.15 and 5.16 show plotted measurements from experiments with different winding configurations for the AMCC-4 harvesting device.

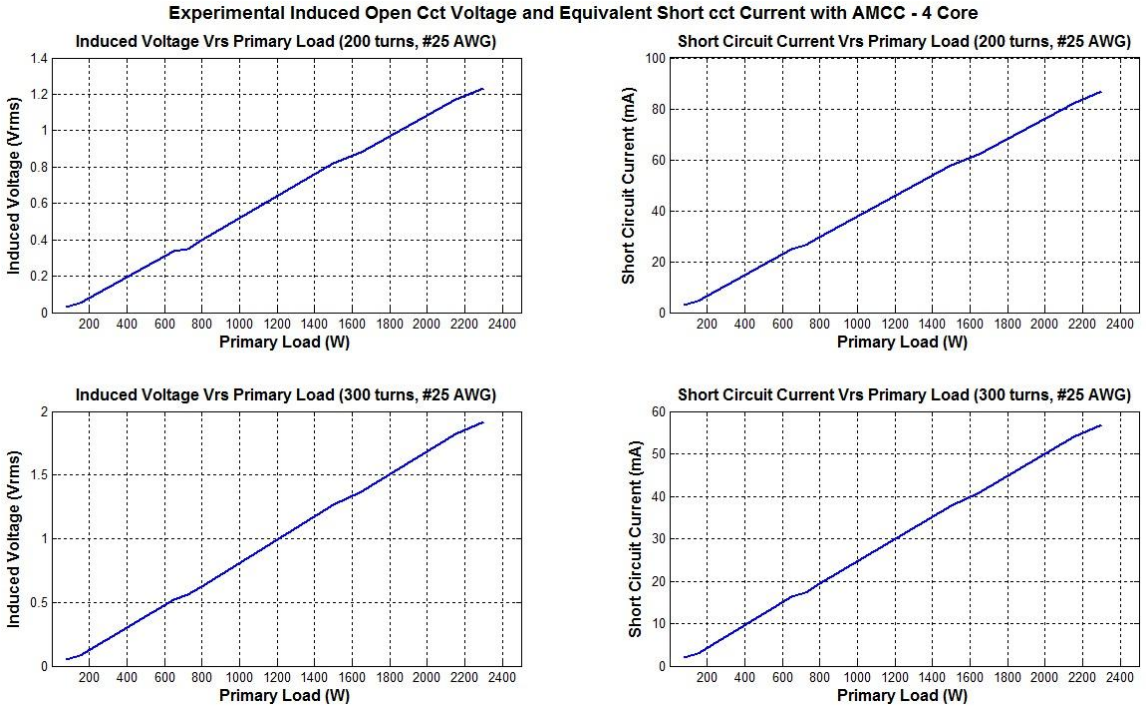

Figure 5.15: Experimental Induced Voltages with AMCC-4 Core

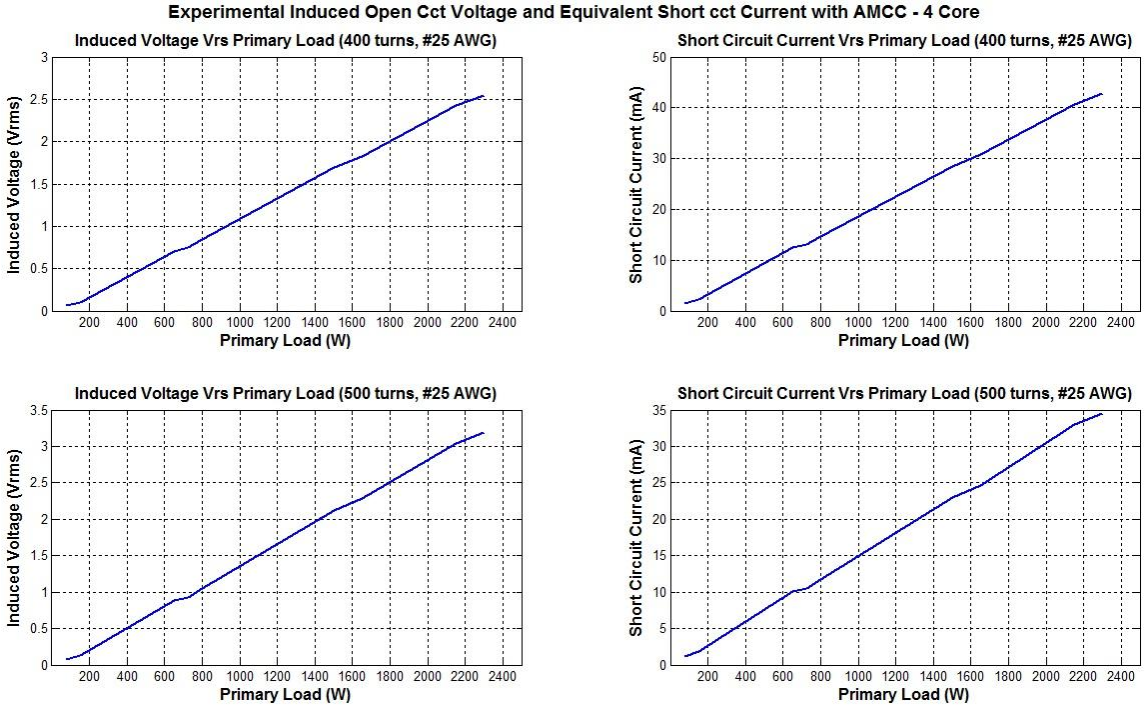

Figure 5.16: Experimental Induced Voltages with AMCC-4

5.6 Simulation vs. Experimental Results

A comparison between simulated and experimental induced voltages for various turns of secondary windings is shown in Figure 5.17. Experimental measurement are plotted with a black line and labeled on each graph.

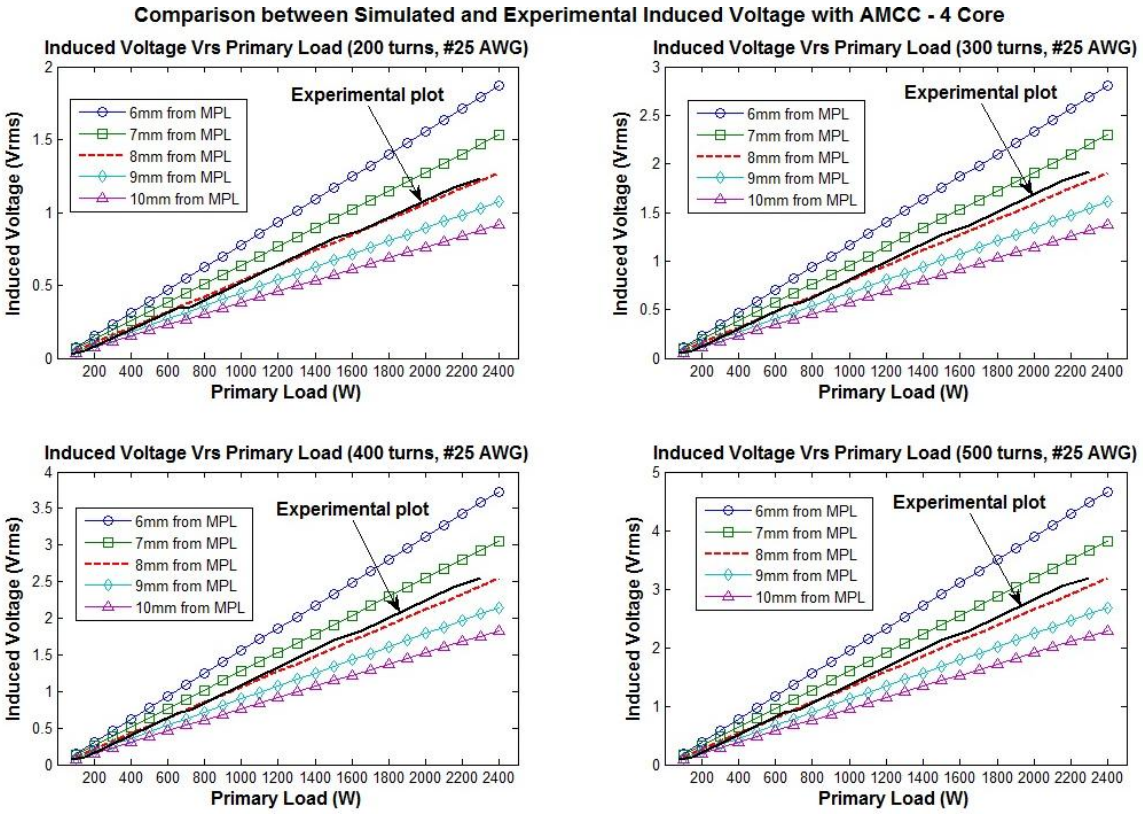

Figure 5.17: Comparison of Simulated and Experimental Induced Voltages

Table 5.1: Simulated and Experimentally Measured Induced Voltages (r = 8mm)

Primary Load (Watts)	Induced Voltages (V rms)							
	200 Turns		300 Turns		400 Turns		500 Turns	
	Simulated	Measured	Simulated	Measured	Simulated	Measured	Simulated	Measured
150	0.08	0.05	0.12	0.08	0.16	0.10	0.20	0.13
650	0.34	0.34	0.52	0.52	0.69	0.70	0.86	0.89
800	0.42	0.40	0.64	0.62	0.85	0.84	1.06	1.05
1500	0.80	0.82	1.19	1.27	1.59	1.70	1.99	2.12
1650	0.87	0.88	1.31	1.37	1.75	1.83	2.19	2.28
2150	1.14	1.17	1.71	1.82	2.28	2.43	2.85	3.04
2300	1.22	1.23	1.83	1.92	2.44	2.55	3.05	3.19

Table 5.1 shows the values of simulated and measured induced voltages from experiments. The voltages are tabulated according to the sizes of loads drawing current at the electrical nodes. Simulated and measured voltages correspond to an 8mm radial distance from the primary current carry conductor to the MPL. The measurements and simulations are also tabulated according to the number of winding turns on the AMCC-4 core.

5.7 Discussion

The objective of this research is to design an energy harvesting device to scavenge electromagnetic energy in the built environment for the purposes of supplying power to energy management sensors. The average power requirement of energy management sensors is 2V – 6 VDC and 12 – 170 mA DC. The amount of power generated depends on the proximity of the current carrying conductor to the MPL. A comparison between the simulation and experimental results indicate that the current carrying conductor is approximately 8mm in proximity from the MPL. With this proximity, simulation and experimental results show a little over 3VAC can be generated with an AMCC-4 core with 500 turns of #25 AWG. An equivalent short circuit current of 34mA AC was measured in laboratory experiments. Using a bridge voltage doubler or multiplier, the induced 3VAC can be boosted up to 6VDC to be feed into a voltage regulator and stabilized for sensor input.

The AMCC-4 was used in the simulation and experiments since it was the smallest available cut core on the market with the preferred magnetic permeability for this research.

The AMCC-4 core has a cross section of 1.11 cm^2 which is much smaller than that of the proposed core in the case study in Chapter 4. The height of the AMCC-4 core is only 15mm and hence able to enclose a much smaller length of the current carrying conductor which is very essential in the power generation process. With the proposed core in Figure 4.2 of cross sectional areas $2cm^2$ and a height of 40mm, a lot more energy can be harvested. This core size will also fit in most boxes of electrical nodes.

An estimate of the amount of the magnetic flux densities around current carrying conductors in the built environment for power generation show an average of 0.25 T can be scavenged at a radial distance of 8mm from a conductor carrying 20A. An equivalent of 3VAC can be generated from this magnetic flux density. This means that for high current drawing nodes in the building electrical system, a much higher voltage can be induced with the proposed energy harvesting device. The material property of the proposed core has a saturation flux density of 1.56 T which is much higher to prevent the core from saturating.

The prototype board used in the experiments contained a typical electrical wiring system design. The loads used for testing were incandescent lamps and small size (wattage) heaters. To utilize power generated at all times, a rechargeable battery is included in the board setup to store energy when power is not being used by the energy management sensor. This board also displays an energy management sensor alongside LEDs connected to output power from the energy harvesting device. The next chapter looks at some of the technical challenges as well as potential future applications of this research.

Chapter 6

TECHNICAL CHALLENGES, BENEFITS AND OPPORTUNITIES

6.1 Introduction

Originally, electrical node boxes were designed to contain electrical cables and splice connectors. Node boxes come in various sizes as shown in NEC table 314.6(A) in Figure 4.1. With the exception of the node boxes, most electrical distribution cables are hidden in enclosed spaces within the built environment. Even though the proposed harvesting device is intended to supply power to energy management sensors in the built environment, other low powered devices can also be supplied with similar harvested power. This chapter examines some of the technical challenges associated with the design of the harvesting device, benefits that may be derived as a result of its use, as well as related future opportunities.

6.2 Challenges

Article 314.71 of the National Electrical Code (NEC) (52) states that pull and junction boxes and handhole enclosures shall provide adequate space and dimensions for conductor installation. Installing energy harvesting devices to power the sensor devices in the boxes of the nodes will reduce the allowable space required by the NEC.

Moreover, in order to power other low powered devices that are not necessarily located at the electrical nodes, access to current carrying conductors in the conduits will

be a limitation to scavenging magnetic flux density. Another limitation is mounting of harvesting device on current carrying conductors. That is, in order to scavenge for magnetic flux, the current carrying conductor must be mounted through the opening in the harvesting device (unlike other current transformers which can be clipped on to the conductor).

In applications where the energy demand of the sensors is less than the quantity generated, energy storage devices (chargeable batteries) have to be incorporated in the installation setup. If the energy scavenged is of an amount lower than the required power, then a back-up chargeable battery must be added to supplement the power requirement. This battery can be recharged with scavenged power during periods in which the energy management sensor is idle.

6.3 Benefits

This research has the potential to create a much more sustainable built environment and thus greatly benefit society. Because the energy source (magnetic field) is in close proximity to the energy management sensor, generated power can be directly applied to the sensor at its location. The ultimate goal of replacing batteries or supplying power to the hardwired energy management sensors with free perpetual energy can be achieved. This will save money in terms of the cost of batteries and all but eliminate the labor costs associated with battery replacement. Even with the limited amount of energy harvested, rechargeable batteries can be used in place of conventional batteries. Power generated by the energy harvesting device will continuously replenish used up energy from the batteries and thus prolong life of batteries.

Furthermore, electricity usage is ultimately maximized since there is additional capture when current is drawn through existing conductors. Thus, the magnetic field located around the current carrying conductors is put to efficient use.

Finally, one of the great advantages of using this device is that it can serve as a potential energy supply for common low powered devices such as motion sensors, phone chargers and some wall clocks in the built environment. Recent power outlet technologies (54), (55), (56) that feature a USB outlet for powering low powered devices up to 5VDC can be powered from this energy harvesting device when that node is drawing power. However, in this case it should be noted that the node will have to draw current in excess of 10A. Wall clocks typically mounted on hallway corridors walls can be powered with an energy harvesting device installed on current carrying conductors powering the lamps in the hallway. In order to constantly supply power to such a clock, a rechargeable battery backup can be incorporated and replenished from time to time by the harvesting device. Motion sensors in corridor hallways that are hardwired or battery operated can also be connected in a similar configuration.

6.4 Opportunities

The proposed energy harvesting device is potentially useful in a variety of other applications than the ones stated in this thesis. For example, if the device is permanently incorporated into the node boxes of the electrical system, power can be harvested for USB outlets. These outlets are currently being integrated into some newer power outlets (57). Therefore, the proposed energy harvesting device would therefore eliminate the need to hardwire these USB outlets to the existing electrical system.

This harvesting device may also be developed into an addressable sensor. That is, the harvesting device can be integrated with a transceiver circuit which will notify a parent transceiver whenever current is drawn at a node. The transceiver integrated with the harvesting device has a unique identification code that can also be used as an alerting system.

Finally, these harvesting devices may be mounted around high current drawing conductors. The harvested power could be channeled to a battery bank to power emergency lighting systems during power outages or other emergency situations.

The final chapter summarizes the whole research and presents the conclusion and recommendations for future work.

Chapter 7

CONCLUSION AND RECOMMENDATIONS

Four objectives were accomplished in this research. First, available magnetic flux was estimated around common current carrying conductors in the built environment. The Biot-Savart law's theoretical equation for estimating the magnetic flux of a given current flowing through a conductor is used to achieve this objective. Second, a comparison of the simulated induced voltages to the experimentally measured values proved accurate Faraday's law of induction. Using theoretical equations for current transformers derived from Faraday's law of induction, an estimate for the average voltages that can be induced from the magnetic flux on the current carrying conductors is given. Third, a harvesting device is designed that is small enough to fit into typical nodes of boxes in the electrical power distribution system in the built environment. It should be noted that due to manufacturing lead time, the prototype harvesting device used for experimenting and simulation is not of the proposed design shape. Thus, the geometry of the harvesting device used for experiments will not fit into a typical node box. Finally, a board was built for the purpose of experimenting with the prototype energy harvesting device. Experimental measurements reveal that an average of 2 V - 3V rms (equivalent short circuit current , 20 mA -40mA) can be induced from magnetic flux around current conductors in the built environment.

Based on a comparison of the experimental and simulated values, it is recommended that a prototype of the proposed design of the harvesting device be built and tested.

7.1 Future Research

Electromagnetic harvesting depends on a secondary ambient source of energy. Thus in order to harvest energy through the electromagnetic converting process, a changing magnetic flux density field must first be established. In the proposed researched, this field is generated when alternating current flows through electrical conductors in the built environment. In future research, investigations will be done to find out whether the harvesting operation affects the magnitude of current flowing through the primary conductor. A further investigation will be done to see if the type of primary load (resistive, inductive, capacitive) at a node in the electrical system has any relationship with magnetic flux density generation.

Another future research will be to investigate how much energy that can be scavenged from magnetic flux density in a given space volume. This investigation will also include harvesting electromagnetic energy around metallic conduits carrying electrical conductors in the built environment.

ABSTRACT

Wideband Phased Array &

Rectenna Design and Modeling for Wireless Power Transmission.

(December 2011)

Jonathan Noel Hansen, B.S., Texas A&M University

Chair of Advisory Committee: Dr. Kai Chang

Microstrip patch antennas are the most common type of printed antenna due to a myriad of advantages which encourage use in a wide range of applications such as: wireless communication, radar, satellites, remote sensing, and biomedicine. An initial design for a stacked-patch, broadband, dual-polarized, aperture-fed antenna is tested, and some adjustments are made to improve performance. The design goal is to obtain a 3 GHz bandwidth centered at 10 GHz for each polarization.

Once the single-element design is finalized, it is used in a 4x1 array configuration. An array increases the gain, and by utilizing variable phase-shifters to each element, the pattern can be electronically steered in a desired direction. The phase-shifters are controlled by a computer running LabVIEW so that the array's steering angle can be easily adjusted. The result of this new phased array design is a wide bandwidth system with dual-polarization which can be electronically steered.

Rectennas (rectifying antennas) are used in wireless power transmission (WPT) systems to collect microwave power and convert this power into useable DC power.

They find use in many areas such as space power transmission, RFID tags, wireless sensors, and recycling ambient microwave energy.

The ability to simulate rectenna designs will allow for an easier method of analysis and tuning without the time and expense of repetitive fabrication and measurement. The most difficult part of rectenna simulation is a good diode model, and since different diodes have dissimilar properties, a model must be specific to a particular diode. Therefore, a method of modeling an individual diode is the most critical part of rectenna simulation. A diode modeling method which is based on an equivalent circuit and compatible with harmonic balance simulation is developed and presented. The equivalent circuit parameters are determined from a series of S-parameter measurements, and the final model demonstrates S-parameters in agreement with the measured data.

An aperture-coupled, high-gain, single-patch rectenna is also designed and measured. This rectenna is modeled using the presented method, and the simulation shows good agreement with the measured results. This further validates the proposed modeling technique.

ACKNOWLEDGEMENTS

I would like to express my appreciation to Dr. Kai Chang for his guidance and support throughout my graduate studies and research at Texas A&M University. I would also like to thank Dr. Michalski, Dr. Kish, and Dr. Meissner for serving on my committee and for their helpful comments.

I am grateful to Mr. Li and other members of the Electromagnetic and Microwaves Laboratory at Texas A&M University for their invaluable technical assistance. I also want to extend my gratitude for the generous support of Raytheon and the guidance of Dr. James McSpadden throughout the phased array project.

Lastly, I would like to thank my family, especially my father, who has been a continuing source of guidance, support, and encouragement.

1. INTRODUCTION

This dissertation is divided into two main topics. The first topic covers the design of a patch antenna and the subsequent development of this antenna into a phased array system. The second topic discusses rectenna theory, design, and modeling.

Section 2 discusses the design of a stacked-patch, broadband, dual-polarized, aperture-fed antenna. Background on patch antennas and the utilized design features are given, and reasons for all design decisions are addressed. Design goals, fabrication techniques, and measurement results which characterize the final design are also discussed.

Section 3 presents background information on array theory. Advantages of phased arrays are first discussed, followed by a brief mathematical description of how they operate. A few characteristics of phased arrays are addressed, and finally a discussion of design choices which will affect these characteristics is given.

Section 4 discusses the development of a phased array system which utilizes the single-element antenna designed in Section 2. A 4x1 array configuration is created which requires a power divider to be designed and fabricated to properly distribute power to each of the antenna elements. Phase-shifters must also be integrated into the system in order to control the phased array, and these phase-shifters are controlled by using LabVIEW to control a Data Acquisition (DAQ) device which is linked to a

---

This dissertation follows the style of *IEEE Transactions on Microwave Theory and Techniques*.

connector box and a logic-conversion circuit. The phased array is integrated into a useable system, calibrated, and measured for various settings. The results are then analyzed and discussed.

Section 5 gives a history of rectennas and their use in wireless power transmission systems. A definition for the term "rectenna" is first given, and some typical applications of rectennas are listed. A chronological history of rectenna development is then provided, starting with Hertz and Tesla in the 1800's and concluding with today's interest in a space solar-power satellite.

Section 6 provides a theoretical discussion of rectenna and wireless power transmission technology. The wireless power transmission system as a whole is first discussed, and the rectenna is then described in more detail. A rectenna is analogous to a half-wave rectifier, so a mathematical explanation of this is provided. An analytical model of rectenna efficiency is also derived and presented. The section concludes with a discussion on the effect of input power and diode selection.

Section 7 discusses rectenna simulation and its impact on rectenna design. A rectenna model is then proposed which will aid in simulation and simplify rectenna analysis and tuning. The model is based on a series of S-parameter measurements which allow the extraction of equivalent circuit model parameters. The final model is analyzed for usability and its match to the measurements on which it is based.

Section 8 proposes a new rectenna design and discusses its design, fabrication, and measurement. The new design is also modeled using the method proposed in

Section 7, and the simulation results are compared to the measured results to further validate the proposed rectenna model.

Section 9 concludes this dissertation with a summary, a discussion of accomplishments, and recommendations for future work.

The appendices provide LabVIEW and Matlab code developed to aid in the work presented here.

2. SINGLE-ELEMENT ANTENNA DEVELOPMENT

A. Background

The microstrip patch antenna is widely used because of its many advantages and is "often described as one of the most exciting developments in antenna and electromagnetic history [1]." These advantages include: lightweight, small size, conformability, easy fabrication, low cost, efficiency, and simple integration with microwave integrated circuits. However, there are some disadvantages which include: narrow impedance bandwidth, low gain, and the excitation of surface waves (decreases efficiency) [1]-[4]. A thorough history can be found in [1].

Radiation of the microstrip patch antenna is determined from the electromagnetic field distribution between the patch and the ground plane. The radiation can also be described in terms of the surface currents which exist on the patch [2]. Radiation arises from discontinuities at the patch edges, and resonance is created when the patch length is approximately a half-wavelength. However, some of the field extends outside the bounds of the physical patch. This is called the fringing effect, and it causes the patch to behave slightly larger than its physical dimensions. The length of the patch can be approximated as [5]

$$L \approx 0.49\lambda_d = 0.49\frac{\lambda_0}{\sqrt{\varepsilon_r}} \tag{2.1}$$

where λ_d is the wavelength in the dielectric, λ_0 is the free space wavelength, and ε_r is the relative permittivity of the dielectric.

Stacked patches can be used to increase the bandwidth. By stacking a parasitic patch (of different size) on top of the fed patch, two resonant frequencies will now exist as a result of the two different sized patches. This will effectively widen the bandwidth [6].

The most common methods of feeding early microstrip antennas were by means of a microstrip line contacting the patch edge or a coaxial probe extending through the ground plane and contacting the patch. However, microstrip feeds promote spurious radiation which limits bandwidth [4], and coaxial probes require long probes which increase spurious radiation from the probe, amplify surface waves, and increase feed inductance [2]. Microstrip feeds and coaxial probes also produce cross-polarized radiation due to inherent asymmetries which produce higher order modes [4]. Alternatively, an aperture-coupled feed electromagnetically couples from a microstrip line on the lower substrate to the patch through an aperture in the ground plane. This method isolates the feedline from the patch so that the feedline does not interfere with the radiating element (due to the shielding effect of the ground plane). This also has the benefit of increasing polarization purity. Coupling and bandwidth can be improved by adjusting the shape and size of the aperture, the feedline dimensions, and the stub length [2]. It has been shown that the best coupling is achieved when the aperture is in the shape of a bowtie [7].

Substrate choice is an important design decision. In general, substrates with a lower dielectric constant will give higher efficiency and a larger bandwidth. Also, as substrate thickness is increased, bandwidth tends to increase while efficiency decreases [8]. Therefore, tradeoffs must be made in selecting a suitable substrate.

Polarization of a wave is described by the direction of the electric field as time advances. If the electric field is oriented in a single direction then the wave is linearly polarized; if it rotates as time advances then the wave is circularly or elliptically polarized [3]-[4]. Dual linear polarization indicates that the wave is composed of two independent orthogonal linear polarizations. An antenna with dual-polarization allows two separate signals to be transmitted or received on the same antenna. Since both polarizations should operate at the same frequency bandwidth, both dimensions of the patch should be the same length. This has a negative effect on the bandwidth of the antenna since unequal dimensions of a patch can be used to increase bandwidth [9].

B. Initial Design

The design goals are to create a flat-panel, dual-polarized antenna which is centered at 10 GHz and has a 3 GHz bandwidth. A high cross-polarization isolation of greater than 20 dB is also desirable.

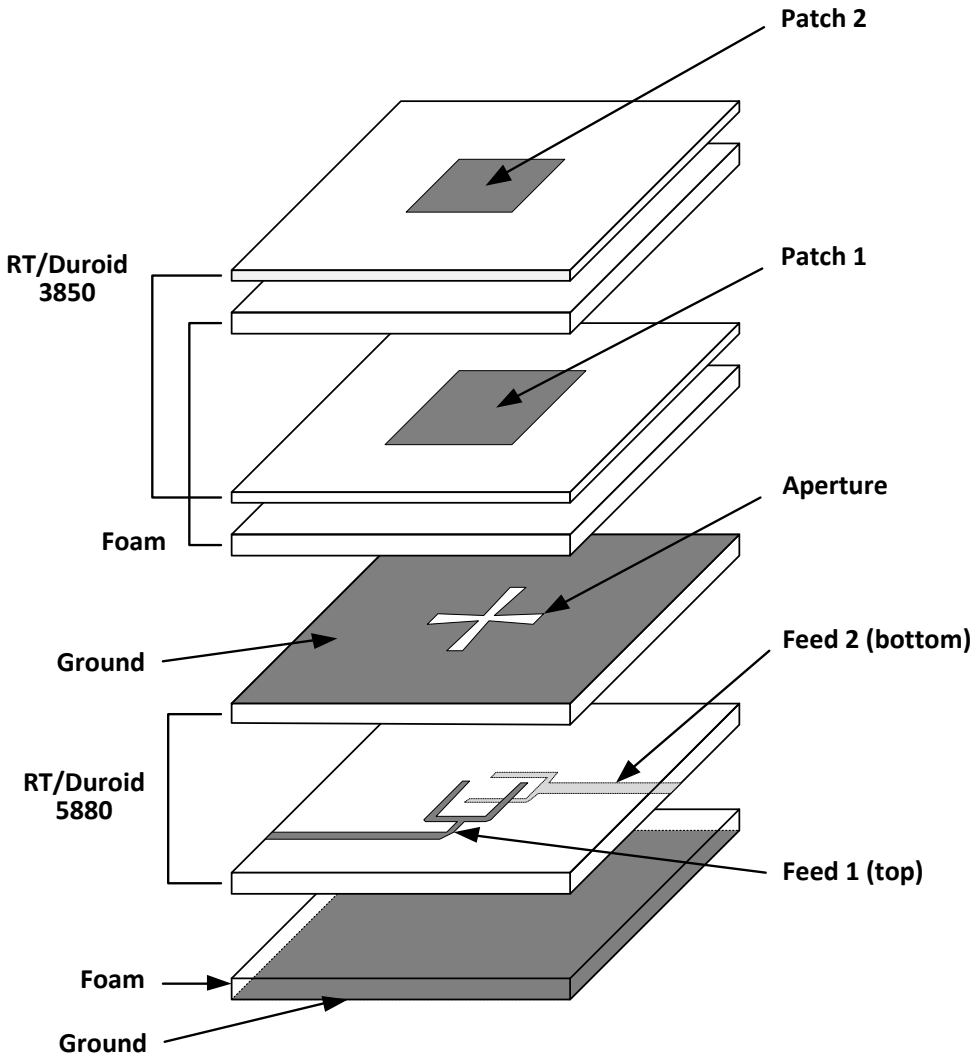

Figure 2.1. Single-element design (stacked-patch, aperture-fed, dual-polarized stripline).

The initial design of the single-element antenna [10] is a stacked-patch, aperture-fed, dual-polarized stripline design which is illustrated in Fig. 2.1. The patches are etched on 2 mil RT/Duroid 3850 substrate with a dielectric constant of 2.9. The top patch is supported by a 1.6 mm thick layer of lightweight foam, and the bottom patch is supported by a 3.2 mm thick layer of the same foam. This foam (Cuming C-FOAM PF-4/PSA) is specially made for microwave applications and has a low dielectric constant of 1.06. The apertured-ground plane and the feedlines are etched on 20 mil RT/Duroid 5880 substrate with a dielectric constant of 2.2. This places the top feed 20 mil from the apertured-ground plane and the bottom feed 40 mil from the apertured-ground plane.

There is also a second ground plane for the stripline design which is separated from the bottom feed by a 4.8 mm thick layer of the previously mentioned foam. The stripline scheme provides ground planes on both sides of the feedlines thereby shielding them from outside influences. The stripline structure also confines all of the electromagnetic field to the dielectric which allows it to support TEM waves and higher order TM/TE modes. This is in contrast to the microstrip design which has only one ground plane; this permits some of its field to exist in the air surrounding the dielectric which prevents the microstrip line from supporting pure TEM waves [11]. The downside to the stripline scheme is that since the field is distributed between two ground planes, the coupling through the aperture is reduced. However, by separating the second ground plane from the feedlines by a thick 4.8 mm layer of foam, most of the field is distributed toward the apertured-ground plane. This retains some of the benefit of a stripline feed while still maintaining good coupling through the aperture.

Dual-offset feedlines are used to improve impedance matching and decrease coupling between the feeds which reduces cross-polarization [9]. This feeding method also allows both feeds to share a single aperture. The feeding design can be seen in Fig. 2.2. It uses a simple two-way power divider with a mitered junction to split the power between the two feeds. The single input is a 50 Ω line which is split into two 100 Ω lines. Rather than extending straight to the edge of the structure as feed 2 does, feed 1 makes a 90° turn so that it exits the structure on the opposite side from feed 1. This is to ease its use in an array in which the feeds must exit on opposite sides.

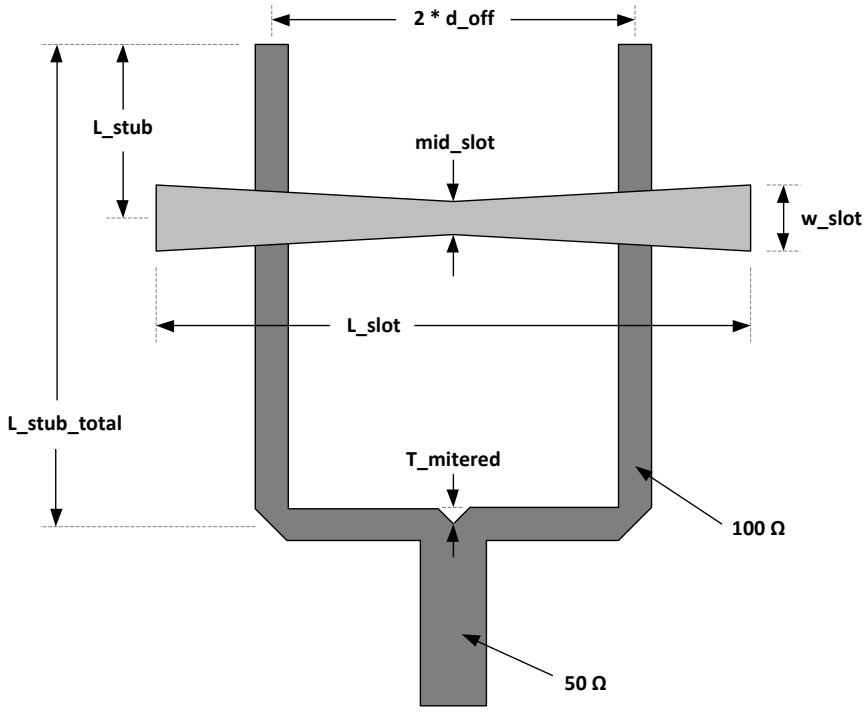

Figure 2.2. Dual-offset feedline with a bowtie aperture.

The design is tuned for a center frequency of 10 GHz and wide bandwidth. The dimensions of this design are given in Table 2.1.

Table 2.1. Initial antenna design parameters.

Variable	**Value**	**Variable**	**Value**
Height of feed 1 (top) substrate (h_feed1)	0.508 mm	Feed 1 (top) matching stub length (L_stub1)	1.98 mm
Height of feed 2 (bottom) substrate (h_feed2)	0.508 mm	Feed 2 (bottom) matching stub length (L_stub2)	2.07 mm
Height of patch 1 (bottom) foam (h_ant1)	3.2 mm	Feed 1 (top) total matching stub length (L_stub_total1)	8.6215 mm
Height of patch 2 (top) foam (h_ant2)	1.6 mm	Feed 2 (bottom) total matching stub length (L_stub_total2)	9.0165 mm
Feed 1 (top) width (100 Ω) (f1w_100)	0.403 mm	Aperture 1 length (L_slot1)	9.75 mm
Feed 1 (top) width (50 Ω) (f1w_50)	1.578 mm	Aperture 1 end-width (w_slot1)	1 mm
Feed 2 (bottom) width (100 Ω) (f2w_100)	1.013 mm	Aperture 1 mid-width (mid_slot1)	0.6 mm
Feed 2 (bottom) width (50 Ω) (f2w_50)	3.3 mm	Aperture 2 length (L_slot2)	10 mm
Offset feed 1 (top) separation (d_off1)	2.5 mm	Aperture 2 end-width (w_slot2)	1 mm
Offset feed 2 (bottom) separation (d_off2)	2.5 mm	Aperture 2 mid-width (mid_slot2)	0.6 mm
Mitered T-Junction Feed 1(top) (T1_mitered)	0.2015 mm	Patch 1 (bottom) length (L_p1)	11.3 mm
Mitered T-Junction Feed 2 (bottom) (T2_mitered)	0.5065 mm	Patch 2 (top) length (L_p2)	10.2 mm
Height of bottom foam (h_foam)	4.8 mm		

This design shows good simulation results using IE3D [12] as seen in Fig. 2.3. Using a standard VSWR cutoff value of 2.0, feed 1 shows a VSWR bandwidth of 42% (7.9 – 12.1 GHz) (f_0 = 10.0 GHz), and feed 2 shows a VSWR bandwidth of 44% (7.7 – 12.0 GHz) (f_0 = 9.85 GHz). The isolation between the two feeds is greater than 20 dB throughout the VSWR bandwidth.

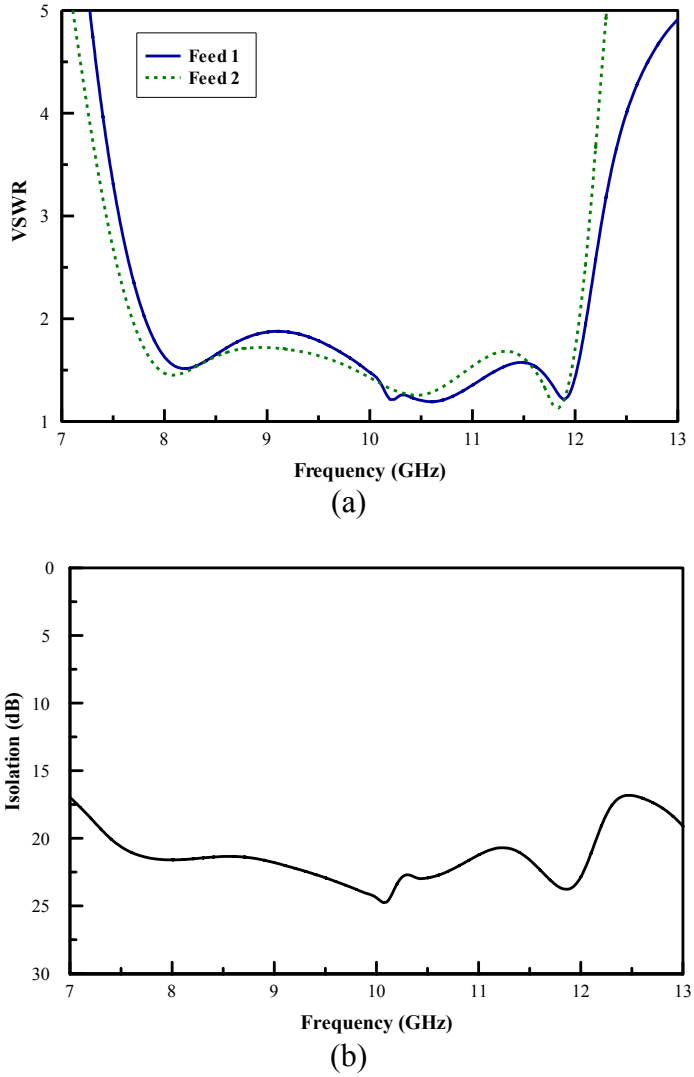

Figure 2.3. Simulation of the original single-element design. (a) VSWR and (b) isolation.

C. Fabrication of Initial Design

For optimal performance, the patches would be floating in the air or etched on top of the foam. Since this is not practical, a very thin substrate (2 mil) is placed on top of the foam layers. All patches, apertures, and feeds are etched using a photolithography process in which ultraviolet light and etching chemicals are used to remove specified areas of copper from the substrates.

All substrate and foam layers are cut as precisely as possible to the same dimensions as the ground planes (26 oz. zinc-plated steel is used as the bottom ground plane). The layers are then aligned and fixed together using 3M Super 77 Multipurpose Spray Adhesive. SMA connectors must also be soldered to the feedlines and both ground planes. Precise alignment is difficult, and care must be taken during this step since the alignment has a dramatic impact on performance of the antenna. A photograph of the fabricated antenna can be seen in Fig. 2.4.

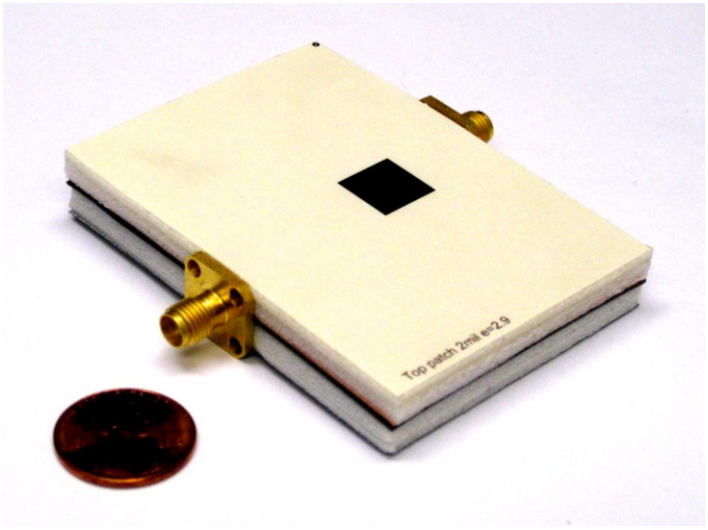

Figure 2.4. Photograph of the single-element antenna.

S-parameter measurements of the antenna can be seen in Fig. 2.5. Ignoring a small overrun in feed 2's VSWR, feed 1 has a measured bandwidth of 35% (7.8 – 11.1 GHz) (f_0 = 9.45 GHz), and feed 2 has a measured VSWR bandwidth of 37% (7.6 – 11.0 GHz) (f_0 = 9.3 GHz). The isolation between the two feeds is measured to be greater than 17 dB throughout the VSWR bandwidth. The measured results show a decrease in performance from the simulated values which is to be expected due to fabrication errors and extreme alignment difficulty. There is, however, one particularly troubling deviation from simulated data. The bandwidth's upper cutoff frequency is reduced by 1 GHz. For comparison, a number of devices were fabricated using the same procedure, and they all showed the same trend.

As a check on the IE3D [12] simulation results, another simulator, HFSS [13] was used to verify the solution. IE3D uses a method-of-moments analysis while HFSS uses a 3D finite element method. The simulated results from HFSS were very similar to the results from IE3D as can be seen in Fig. 2.6. Hence, comparable results were obtained from two different types of simulations, so simulator problems cannot explain the deviation in measured results.

As an attempt to increase alignment accuracy and possibly reduce any air gap errors in fabrication, a new fabrication method was tested in which feed 1 is etched on the bottom side of the apertured-ground plane substrate rather than on the top side of the feed 2 substrate. Several devices using this method were fabricated and compared to the previous method. This new method did show more consistent results, but the results were similar to the previous method, and the frequency-shifting problem still persisted.

Adhesive effects on multi-layer antenna performance have been analyzed in [14]-[15], and an explanation for the type of fabrication error appearing here is presented in the analysis. The authors theorize that the lossy adhesive used to bond the layers is the cause of the VSWR bandwidth's upper frequency shift. As an attempt to avoid adhesive losses, antennas were fabricated using double-sided tape to bond the layers instead of spray adhesive. The tape was strategically placed to avoid the areas where electromagnetic waves are coupling between layers. Measurements showed that this did not correct the problem, and the results were less consistent. This is probably due to air gaps introduced by the taping method.

D. Redesign (Dimension Adjustment) (Final Design)

Since a fabrication method to correct the problem could not be found, the antenna was redesigned to give a higher upper frequency cutoff. The main change was a reduction in patch size which raised the resonant frequency. Some other parameters were then altered to fine tune the new design. The dimensions of the new design are given in Table 2.2.

Table 2.2. Final antenna design parameters.

Variable	**Value**	**Variable**	**Value**
Height of feed 1 (top) substrate (h_feed1)	0.508 mm	Feed 1 (top) matching stub length (L_stub1)	1.96 mm
Height of feed 2 (bottom) substrate (h_feed2)	0.508 mm	Feed 2 (bottom) matching stub length (L_stub2)	2.07 mm
Height of patch 1 (bottom) foam (h_ant1)	3.2 mm	Feed 1 (top) total matching stub length (L_stub_total1)	8.6015 mm
Height of patch 2 (top) foam (h_ant2)	1.6 mm	Feed 2 (bottom) total matching stub length (L_stub_total2)	9.0165 mm
Feed 1 (top) width (100 Ω) (f1w_100)	0.403 mm	Aperture 1 length (L_slot1)	9.7 mm
Feed 1 (top) width (50 Ω) (f1w_50)	1.578 mm	Aperture 1 end-width (w_slot1)	1 mm
Feed 2 (bottom) width (100 Ω) (f2w_100)	1.013 mm	Aperture 1 mid-width (mid_slot1)	0.6 mm
Feed 2 (bottom) width (50 Ω) (f2w_50)	3.3 mm	Aperture 2 length (L_slot2)	9.6 mm
Offset feed 1 (top) separation (d_off1)	2.5 mm	Aperture 2 end-width (w_slot2)	1 mm
Offset feed 2 (bottom) separation (d_off2)	2.5 mm	Aperture 2 mid-width (mid_slot2)	0.6 mm
Mitered T-Junction Feed 1(top) (T1_mitered)	0.2015 mm	Patch 1 (bottom) length (L_p1)	10.9 mm
Mitered T-Junction Feed 2 (bottom) (T2_mitered)	0.5065 mm	Patch 2 (top) length (L_p2)	9.5 mm
Height of bottom foam (h_foam)	4.8 mm		

S-parameter simulation results and measurements of the new antenna design can be seen in Fig. 2.7. For the simulation, using a standard VSWR cutoff value of 2.0, feed 1 shows a VSWR bandwidth of 47% (7.9 – 12.7 GHz) (f_0 = 10.3 GHz), and feed 2 shows a VSWR bandwidth of 45% (8.0 – 12.6 GHz) (f_0 = 10.3 GHz). The isolation between the two feeds is greater than 20 dB throughout the VSWR bandwidth.

Ignoring a small overrun in feed 2's VSWR, feed 1 has a measured bandwidth of 42% (7.9 – 12.1 GHz) (f_0 = 10.0 GHz), and feed 2 has a measured VSWR bandwidth of 38% (8.2 – 12.0 GHz) (f_0 = 10.1 GHz). The isolation between the two feeds is measured to be greater than 17 dB throughout the VSWR bandwidth. The measured results still show a shift in the bandwidth's upper cutoff frequency, but now that shift is accounted for, so the measured center frequencies for feeds 1 and 2 are 10.0 GHz and 10.1 GHz, respectively. This dimension adjustment has corrected the fabricated antenna and shifted the bandwidth to the desired location.

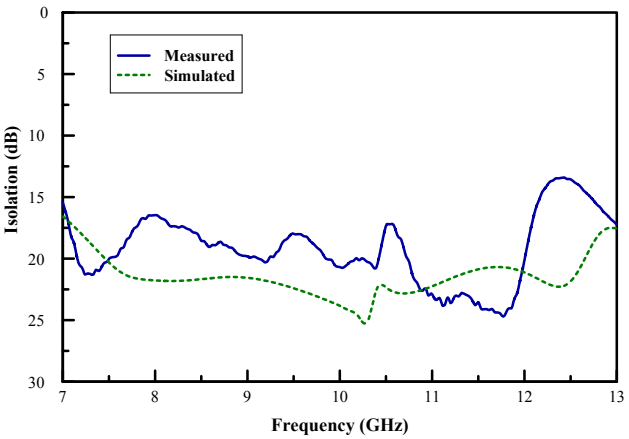
(b)



(c)

Figure 2.7. Measured and simulated VSWR and isolation of the redesigned (final) single-element with new dimensions.

E. Radiation Pattern Measurement

The radiation pattern of the redesigned (final) antenna was measured in an anechoic chamber. Each feed is measured separately, and when one feed is being measured, the other is terminated with a 50 Ω load to prevent reflections. Also, during measurement it is important to cover the antenna's connectors with absorber to prevent reflections. If this is not done, results similar to Fig. 2.8 will be obtained.

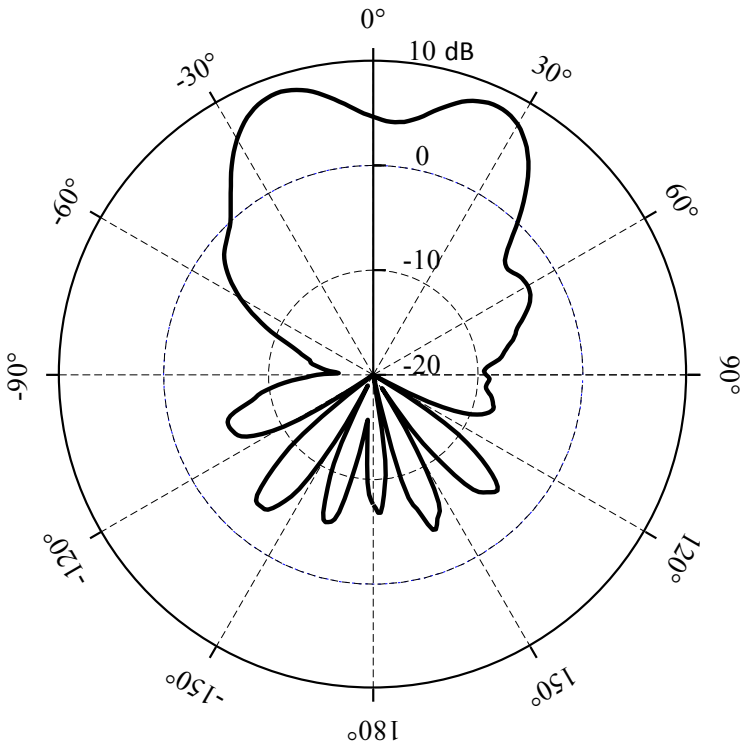


Figure 2.8. Radiation pattern with no absorber (10 GHz / Port 1 / co-pol E-plane).

After a complete set of antenna measurements was taken, a comparison was made to simulated results (Fig. 2.9), and it was noticed that the absorber covering the connectors might be disturbing some of the measured pattern at larger measurement angles and artificially reducing the beamwidth of the antenna. This was corrected by fabricating a new antenna with a larger ground plane (Fig. 2.10). This placed the connectors farther away from the patch so that when they are covered with absorber, it does not interfere with the pattern measurement. This adds approximately 15-25° of beamwidth to the measured pattern. This is illustrated in Fig. 2.11.

Measured radiation patterns of the antenna are displayed in Fig. 2.12 for 8.5, 10, and 11.5 GHz. The patterns are well behaved, and the cross-polarization isolation is greater than 20 dB for all cases. Also, graphs of gain and half-power beamwidth (HPBW) versus frequency are displayed in Figs. 2.13-2.14. The measured gain ranges from 5 - 8 dBi, and the measured HPBW is 50 - 70° for the E-plane and 70 - 90° for the H-plane. Accounting for measurement error and alignment difficulties during fabrication, these results match well to the simulation.

F. Conclusion

S-parameter measurements of the initial single-element design showed a shift in the VSWR bandwidth's upper frequency cutoff which shifted the bandwidth out of the desired range of 8.5 – 11.5 GHz. Some adjustments to the antenna dimensions corrected for this unavoidable shift, and the new design was shown to perform well in the target bandwidth and beyond. The VSWR bandwidth of feed 1 was measured as 42% with f_0=10.0 GHz, and the VSWR bandwidth of feed 2 was measured as 38% with f_0=10.1 GHz. S-parameter isolation between the feeds was measured to be greater than 17 dB, and gain measurements showed a cross-polarization isolation of greater than 20 dB. Gain was measured to be 5 – 8 dBi throughout the target bandwidth, and HPBW was measured to be 50 – 90°. Measurements and simulation of the antenna show a good match, and the antenna should work well in a phased array application.

3. ARRAY THEORY

A. Introduction

Single-element antennas have two significant drawbacks: a large beamwidth and a fixed beam direction. This can be overcome with an array of antenna elements which is able to focus energy in a desired direction to narrow the beam and increase range. In order to increase the directivity, the electrical size of an antenna must be increased, and creating an array of elements is a simple and effective way of doing this [4]. An antenna can be mechanically steered, but this is slow and prone to breakage [16]. Alternatively, an antenna array can be fitted with phase shifting devices which will allow the real-time adjustment of individual elements so that the elements will interfere constructively in the desired direction and interfere destructively in all other directions.

Phased arrays were first used in the 1930s for communications between the United States and England. It was, however, the radar and radioastronomy communities that were responsible for the large advances in phased array technology [17]. Since a phased array radar steers without movement and inertia, it has the ability to pause scans to check detections, track multiple targets by switching back and forth, and simultaneously survey and track [16].

B. Array Factor

An *N*-element linear array can be formed by aligning *N* identical antenna elements along the z-axis with each element separated by a distance *d* and phase β. This *N*-element array will form a plane wave whose direction is determined by the progressive phase shift between elements [3]. This is illustrated in Fig. 3.1 where each element has a phase-shifter with a shifting value of β degrees greater than the previous element. This phase shift offset will align the phases to form a wave front and create a plane wave traveling at an angle θ_0 with respect to the array's broadside. The angle θ is with respect to the z-axis on which the elements are positioned.

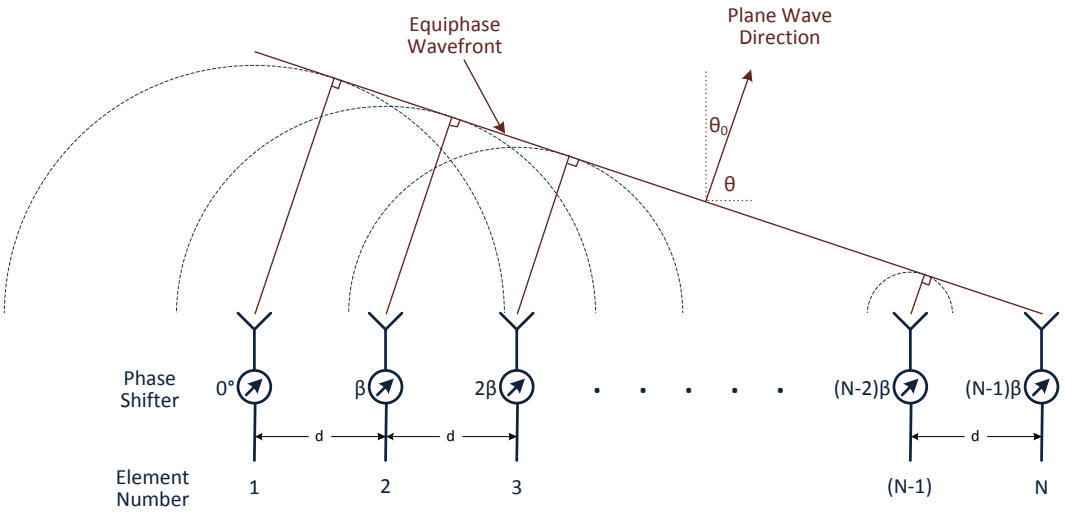

Figure 3.1. An *N*-element linear array with each element separated by a distance *d* and phase β.

The total radiated field from an array of identical single-elements can be calculated as the sum of all the individual elements. The far-field approximation [4][3]:

$$\theta_1 = \theta_2 = \ldots = \theta_N = \theta \tag{3.1}$$

$$\left.\begin{aligned} r_1 &= r \\ r_2 &= r + d\cos\theta \\ &\vdots \\ r_N &= r + (N-1)d\cos\theta \end{aligned}\right\} \text{ for phase variation} \tag{3.2}$$

$$r_1 = r_2 = \ldots = r_N = r \qquad \text{for amplitude variation} \tag{3.3}$$

can be applied in order to express the total field from the array as

$$E_{\text{total}} = E_{\text{single-element}} \times AF \tag{3.4}$$

where $E_{\text{single-element}}$ is the electric field of the single-element at the reference point and AF is the array factor. For an array of uniform amplitude and spacing, the array factor can be expressed as [4]

$$AF = \sum_{n=1}^{N} e^{j(n-1)\psi} \tag{3.5}$$

$$\text{where} \qquad \psi = kd\cos\theta + \beta \ . \tag{3.6}$$

The parameter *k* is the wave number, *d* is the distance between elements, and β is the progressive phase shift between elements. By setting the reference point to the center of the array, applying complex exponential identities, and normalizing [4], the array factor can also be expressed as

$$AF = \frac{1}{N}\left[\frac{\sin\left(\frac{N}{2}\psi\right)}{\sin\left(\frac{1}{2}\psi\right)}\right] \quad . \tag{3.7}$$

As described in Fig. 3.1, the progressive phase shift β produces a wave front moving in the direction of the angle θ_0 (where $\theta_0 = 90° - \theta$). The array can then be steered by adjusting β. As seen in (3.5), the array factor (*AF)* is maximum when ψ=0, so the array's scan angle can be calculated by

$$\beta = -kd\cos\theta = -kd\sin\theta_0 . \tag{3.8}$$

For an N-element array with elements separated by half-wavelengths, the half-power (3 dB) beamwidth can be estimated [3] as

$$\theta_{HPBW} \approx \frac{100}{\sqrt{N}} \tag{3.9}$$

where θ_{HPBW} is in degrees. It should also be mentioned that the AF's beamwidth increases some with increasing scan angles.

C. Grating Lobes

Since the array factor is a periodic function, it is possible for constant phase wave fronts to form by constructive interference in more than one direction. The additional wave fronts which appear are known as grating lobes which occur when the array factor's exponential in (3.5) is equal to a multiple of 2π, so grating lobes appear when

$$\psi = \pm 2\pi m \quad , \quad \text{m} = 0, 1, 2, \ldots \tag{3.10}$$

Then to scan to an angle θ_0, the condition in (3.8) must hold, so (3.6) and (3.10) can be equated and (3.8) substituted for β resulting in the condition

$$\psi = kd\cos\theta - kd\sin\theta_0 = \pm 2\pi m \quad . \tag{3.11}$$

Next, the observation angle θ (relative to the z-axis) will be changed to an angle relative to broadside and identified as the grating lobe angle such that $\theta_g = 90° - \theta$. Then the condition for grating lobes becomes

$$kd(\sin\theta_g - \sin\theta_0) = \pm 2\pi m \quad , \tag{3.12}$$

and since $k=2\pi/\lambda$,

$$\frac{d}{\lambda}\left(\sin\theta_g - \sin\theta_0\right) = \pm m \ . \tag{3.13}$$

Then the grating lobe angles can be found from

$$\sin\theta_g = \pm m\frac{\lambda}{d} + \sin\theta_0 \quad , \tag{3.14}$$

and the condition for avoiding grating lobes in all of real space is

$$\left|\sin\theta_0 \pm \frac{\lambda}{d}\right| > 1 \tag{3.15}$$

which is satisfied if

$$\frac{\lambda}{d} > 1 + \sin\theta_0 \tag{3.16}$$

which can be rewritten as

$$\frac{d}{\lambda} < \frac{1}{1+\sin\theta_0} \quad . \tag{3.17}$$

Since the maximum scan is 90°, the condition to avoid grating lobes (in all visible space) for all scan angles is

$$d < \lambda/2 \quad . \tag{3.18}$$

It should be noted that the θ in (3.8) and the θ in (3.11) represent observation angles for different pattern features. The θ in (3.8) denotes the scan angle, and the θ in (3.11) denotes grating lobe angles. Both θs are with respect to the z-axis.

D. Non-Uniform Amplitude

Non-uniform amplitude distributions can be used to adjust the beamwidth and sidelobe levels of a phased array. The equation for the array factor in (3.5) can be modified to include the effect of element amplitudes a_n as

$$AF = \sum_{n=1}^{N} a_n e^{j(n-1)\psi} \quad . \tag{3.19}$$

By setting the reference point to the center of the array, applying complex exponential identities, and normalizing [4], the array factor can also be expressed as

$$(AF)_{2M}(\text{even}) = \sum_{n=1}^{M} a_n \cos\left[(2n-1)u\right] \tag{3.20}$$

$$(AF)_{2M+1}(\text{odd}) = \sum_{n=1}^{M+1} a_n \cos\left[2(n-1)u\right] \tag{3.21}$$

$$\text{where} \qquad u = \frac{\pi d}{\lambda}\cos\theta \ . \tag{3.22}$$

In these equations, the total number of elements for an even array is $2M$ and for an odd array is $2M+1$. Also, the amplitude excitation of the center element for an odd numbered array as described in (3.21) is $2a_1$.

Amplitude coefficients for each element can then be chosen and used in (3.19)-(3.22) to determine the array factor. Two of the most popular amplitude distributions are discussed here, but there are many others.

Binomial Distribution

A binomial distribution [4] can be found by expanding the function $(1\text{-}x)^{m-1}$ using a binomial expansion as

$$(1+x)^{m-1} = 1 + (m-1)x + \frac{(m-1)(m-2)}{2!}x^2 + \frac{(m-1)(m-2)(m-3)}{3!}x^3 + \cdots \qquad (3.23)$$

The positive coefficients of the series can then be used as amplitude coefficients for an array of *m* elements. These coefficients for increasing values of *m* form a Pascal triangle as:

m = 1							1							
m = 2						1		1						
m = 3					1		2		1					
m = 4				1		3		3		1				
m = 5			1		4		6		4		1			
m = 6		1		5		10		10		5		1		
m = 7	1		6		15		20		15		6		1	
m = 8	1		7		21		35		35		21		7	1

(3.24)

Dolph-Tschebyscheff Distribution

The Dolph-Tschebyscheff distribution [4] is formed from the Tschebyscheff polynomials and is a compromise between a uniform and a binomial distribution. Its amplitude coefficients can be chosen to create sidelobes of any desired level, and when a Dolph-Tschebyscheff array with no sidelobes is chosen, it reduces to a binomial array. The Dolph-Tschebyscheff polynomial [18] is defined as

$$T_m(z) = \cos\left[m\cos^{-1}(z)\right], \qquad -1 \le z \le 1 \tag{3.25}$$

$$T_m(z) = \cosh\left[m\cosh^{-1}(z)\right], \qquad |z| > 1 \quad . \tag{3.26}$$

The method of finding the Dolph-Tschebyscheff coefficients involves expanding (3.25)-(3.26) and the array factor to be of the same form and equating the coefficients. The complete procedure is explained in detail in [4] and [18]. The Dolph-Tschebyscheff coefficients will give an array with all sidelobes at a level specified in the design procedure. However, decreasing the sidelobe level increases the beamwidth and the difference in coefficient magnitudes.

E. Phase Quantization

Most recent phased array systems use digital phase-shifters to control the phase of each element. This effectively quantizes the phase so that the realized phase is only an approximation of the ideal phase. For an *N*-bit phase-shifter, the phase states are separated by the least significant phase ϕ_0 which is given by

$$\phi_0 = \frac{2\pi}{2^N} \quad . \tag{3.27}$$

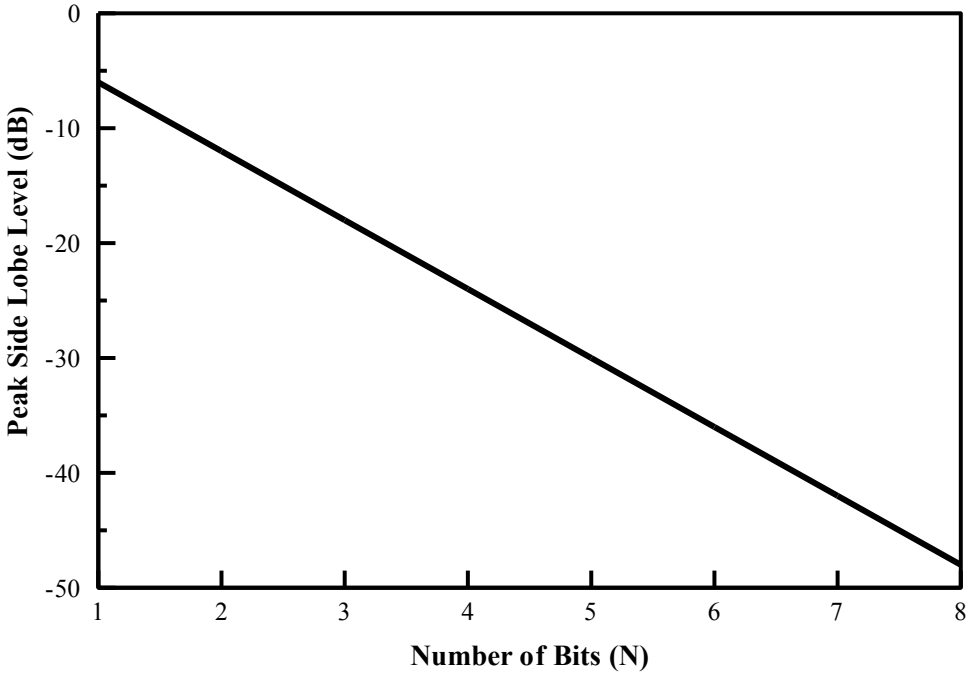
This phase approximation creates phase quantization grating lobes, and the first detailed analysis of this effect was performed by Miller [19]-[20]. He evaluated the level of the first grating lobe by assuming that the array current distribution is continuous (i.e., there is not a discrete number of elements). From this analysis, the level of the first phase quantization lobe can be expressed as

$$P_{QL} = \frac{1}{2^{2N}} \approx -6N \text{ (dB)} . \tag{3.28}$$

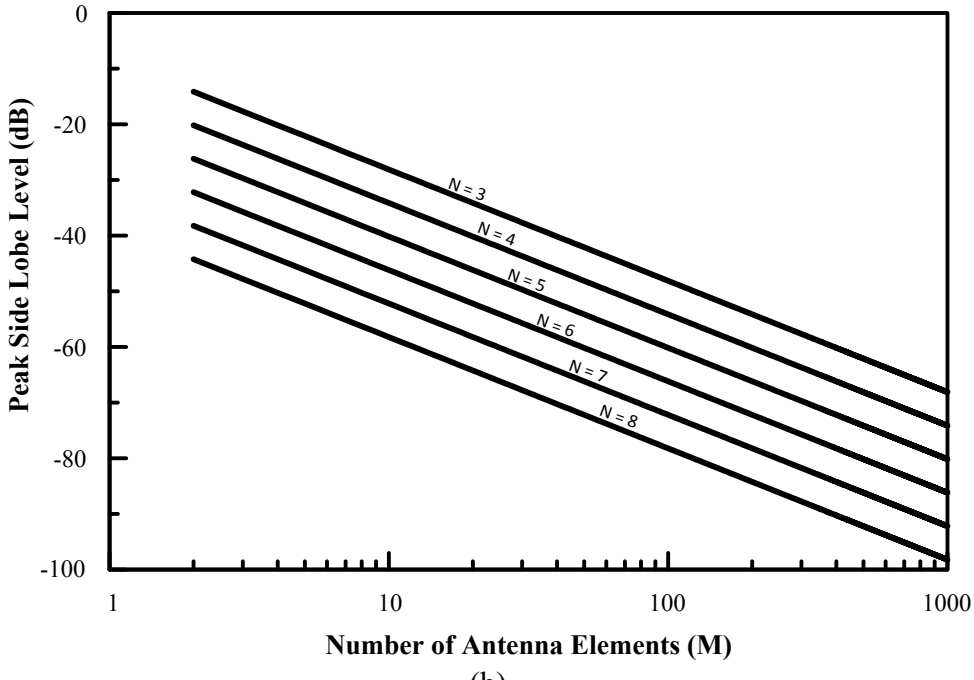
The continuous array approximation used by Miller led to an underestimation of the actual peak phase quantization lobes [21]. More accurate equations have been given by various authors including Hansen [22] and Mailloux [23]. Mailloux gives an estimate for the upper bound on the phase quantization sidelobe level as

$$P_{QL} < -20\log M + 9.94 - 6.02N \text{ (dB)} \quad \text{for } M \geq 2 \text{ and } N \geq 3 \tag{3.29}$$

where N is still the number of bits and M is the number of array elements. The equations for phase quantization sidelobe levels as proposed by Miller (3.28) and Mailloux (3.29) are plotted in Fig. 3.2.



(a)



(b)

Figure 3.2. Maximum phase quantization sidelobe levels as proposed by (a) Miller and (b) Mailloux.

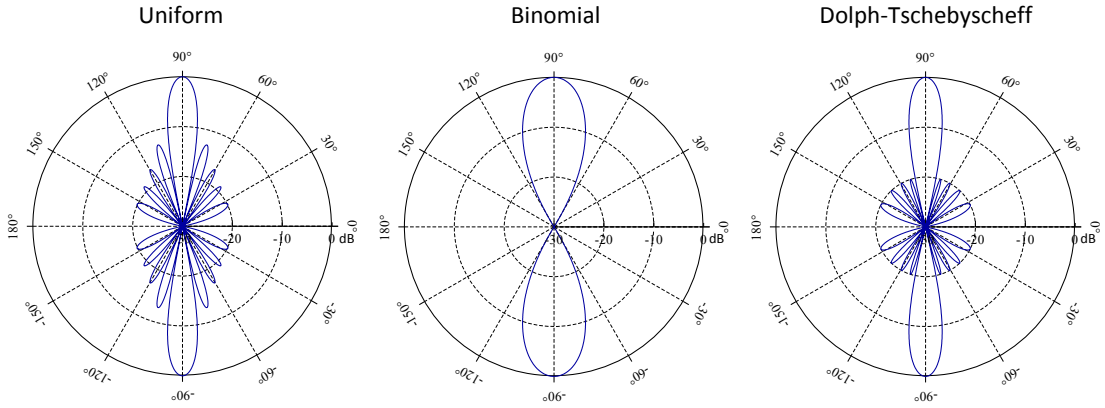
F. Design Choices

When designing a phased array, decisions must be made which balance the tradeoffs between performance and cost/complexity. Assuming that the single-element is already designed, these decisions involve the amplitude distribution, the number of elements, element spacing, and the number of phase-shifter bits.

Amplitude Distribution

As previously mentioned, there are many choices for an array's amplitude distribution, of which the most popular are: uniform, binomial, and Dolph-Tschebyscheff. Examples of these are illustrated in Fig. 3.3. One of the uniform distribution's advantages is that it has a beamwidth which is narrower than the other distributions. The downside is that the sidelobes are relatively large. The uniform distribution is also simple to implement; since all of the elements' amplitudes are equal, there is no need for an amplifier or attenuator for each feed. For non-uniform distributions, individual element amplitudes must be controlled, which leads to increased system complexity and cost.

The binomial distribution eliminates sidelobes, but it does this at the expense of a wide beamwidth. Also, the difference in element amplitudes is quite large, and this can be difficult to implement in a practical system.



N = 10 d = λ/2

	Uniform	Binomial	Dolph-Tschebyscheff
	1	1	1
	1	9	1.67
	1	36	2.60
	1	84	3.41
Amplitude	1	126	3.88
Distribution	1	126	3.88
	1	84	3.41
	1	36	2.60
	1	9	1.67
	1	1	1
HPBW	10.2°	20.2°	11.2°

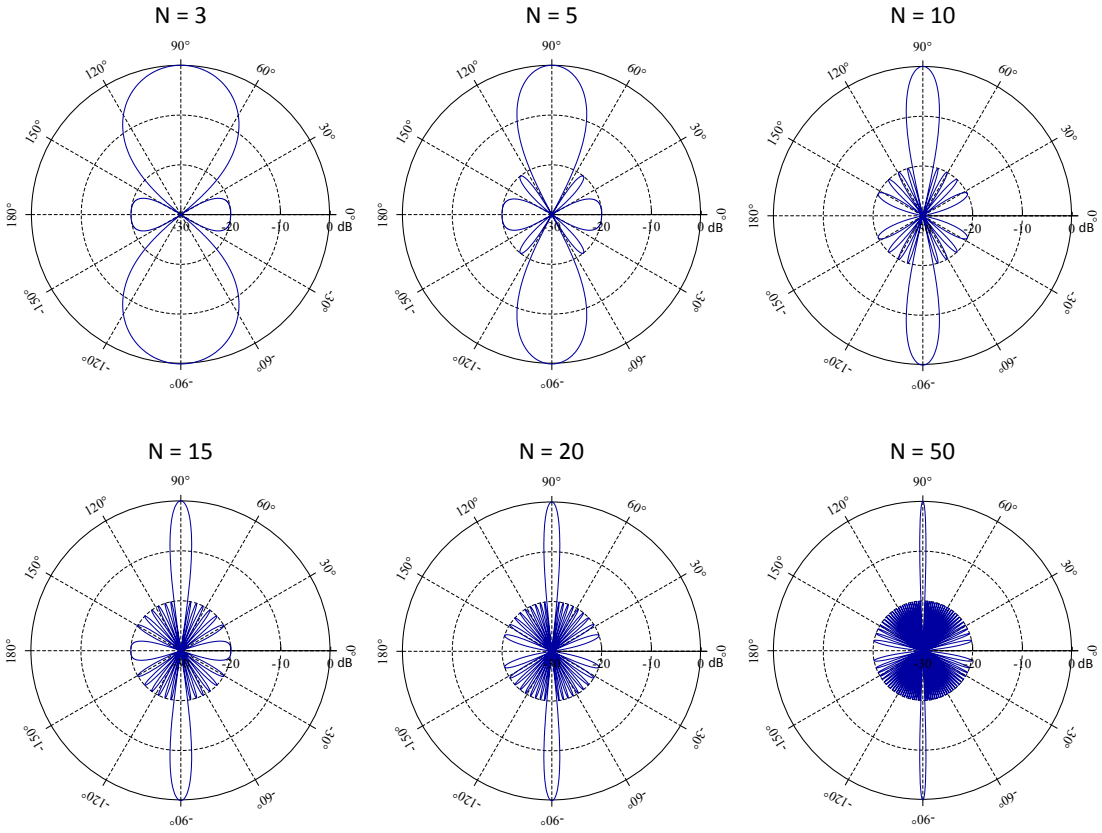
Figure 3.3. AF for different amplitude distributions: uniform, binomial, and Dolph-Tschebyscheff (20 dB SLL). An array with $N = 10$ elements and element spacing $d = \lambda/2$ is used. The amplitude distribution and half-power beamwidth (HPBW) are also given for each distribution.

The Dolph-Tschebyscheff distribution is somewhat of a compromise between the uniform and binomial distribution. When implementing this distribution, the SLL (sidelobe level) is specified, and when the sidelobes are eliminated, it reduces to a binomial distribution. When using this distribution, all sidelobes are at a constant level as opposed to the uniform distribution where the SLL decreases for lobes farther from the main beam. Specifying lower sidelobes widens the beamwidth and increases the disparity between individual element amplitudes. Therefore, the Dolph-Tschebyscheff distribution allows a compromise to be chosen between SLL, beamwidth, and amplitude disparity.

Number of Elements

The number of elements greatly affects a phased array's performance and cost. Adding elements to an array reduces its beamwidth, and an array with a large number of elements can produce a very narrow beamwidth. This is illustrated in Fig. 3.4.

However, more elements means that the system will be larger and more expensive. Phase-shifters can be quite expensive, and since each element must have its own phase-shifter and controlling mechanism, the expense can add up very quickly.



Dolph-Tschebyscheff d = λ/2

N	3	5	10	15	20	50
HPBW	**40.4°**	**23.6°**	**11.2°**	**7.2°**	**5.4°**	**2.1°**

Figure 3.4. Illustration of the effect of N (number of elements) on the AF's beamwidth. A Dolph-Tschebyscheff (20 dB SLL) array with element spacing $d = \lambda/2$ is used for comparison.

Element Spacing

As previously mentioned, close element spacing will delay the onset of grating lobes as illustrated in Fig. 3.5; and (3.17) can be used to find the maximum element spacing (for a given scan angle) which will prevent grating lobes.

The tradeoff is that closer element spacing will also increase the beamwidth as illustrated in Fig. 3.6. Therefore close element spacing is desired to eliminate grating lobes, but large element spacing is desirable for a narrow beamwidth. Also, the element spacing is expressed as a function of wavelength, so if the array is to operate at multiple frequencies, the effective element separation will be different for each frequency. This effect should be taken into consideration in the design.

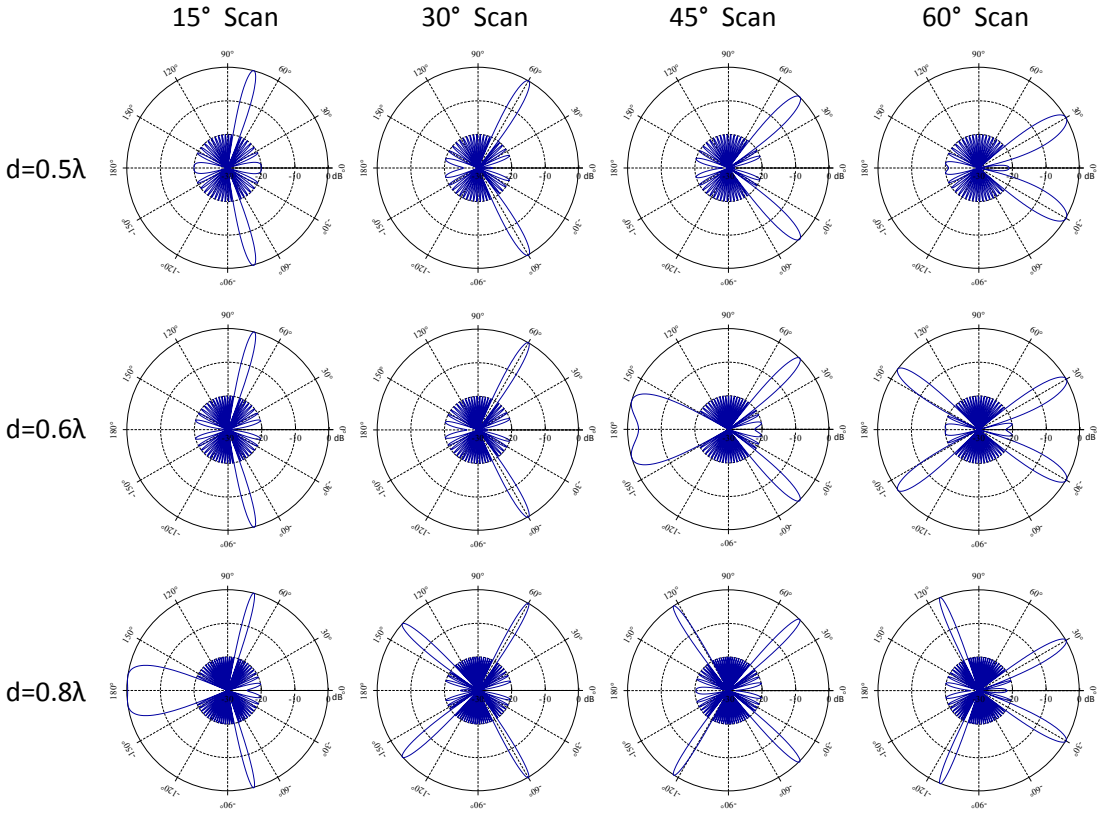


Figure 3.5. Illustration of the effect of d (element spacing) on grating lobes in the AF. A Dolph-Tschebyscheff (20 dB SLL) array with $N = 20$ elements is used for comparison.

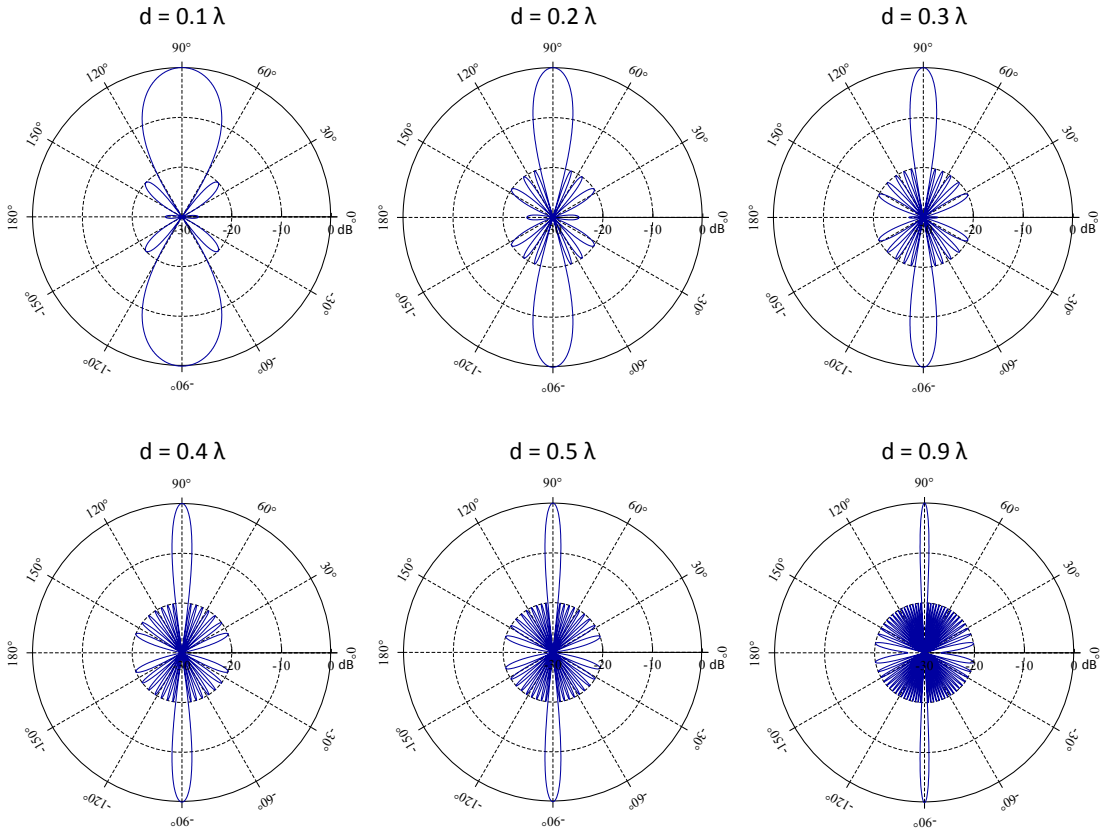

Figure 3.6. Illustration of the effect of *d* (element spacing) on AF beamwidth. A Dolph-Tschebyscheff (20 dB SLL) array with $N = 20$ elements is used for comparison.

Phase-Shifter Bits

The effect that the number of phase-shifter bits has on phase quantization grating lobes has been previously discussed and quantified in (3.28)-(3.29) and graphed in Fig. 3.2. A phase-shifter with many bits reduces the size of the quantization lobes, but it is in general more expensive than one with fewer bits. Increasing the number of bits also increases control complexity and cost.

Scan Range Considerations

The AF's gain is constant across all scan angles. However, since practical antennas are not isotropic, the single-element antenna's gain will decrease as the observation angle diverges from broadside. Since the array pattern is determined by the product of the array factor and the single-element pattern, the array's gain will decrease with increasing scan angles. If AF beamwidth is wide, the AF gain at angles which are lower than the intended scan angle can be large enough that when multiplied by the larger single-element gain, the array's gain will actually be larger at smaller angles than it is at the intended scan angle. This will effectively create a smaller scan angle than intended and can decrease the array's maximum scan angle.

Fig. 3.7 illustrates this by showing different scan angles for arrays of various sizes. The AF and single-element pattern are illustrated in thin red and blue, respectively. The product of these gives the array pattern which is shown in thick black. For a 4-element array, a 30° scan works well, but already the array points to an angle slightly less than 30°. For a 45° scan, the array points to an angle slightly larger than

30°, and for a 75° scan, the sidelobes have exceeded the magnitude of the main beam. The 8-element array scans significantly better, and the 16-element array only starts to lose angle at the 75° scan angle.

It has been shown that the number of elements in an array has a significant impact on the array's maximum scan angle and performance. Hence, the required scan angle and beamwidth should be taken into account when designing a phased array.

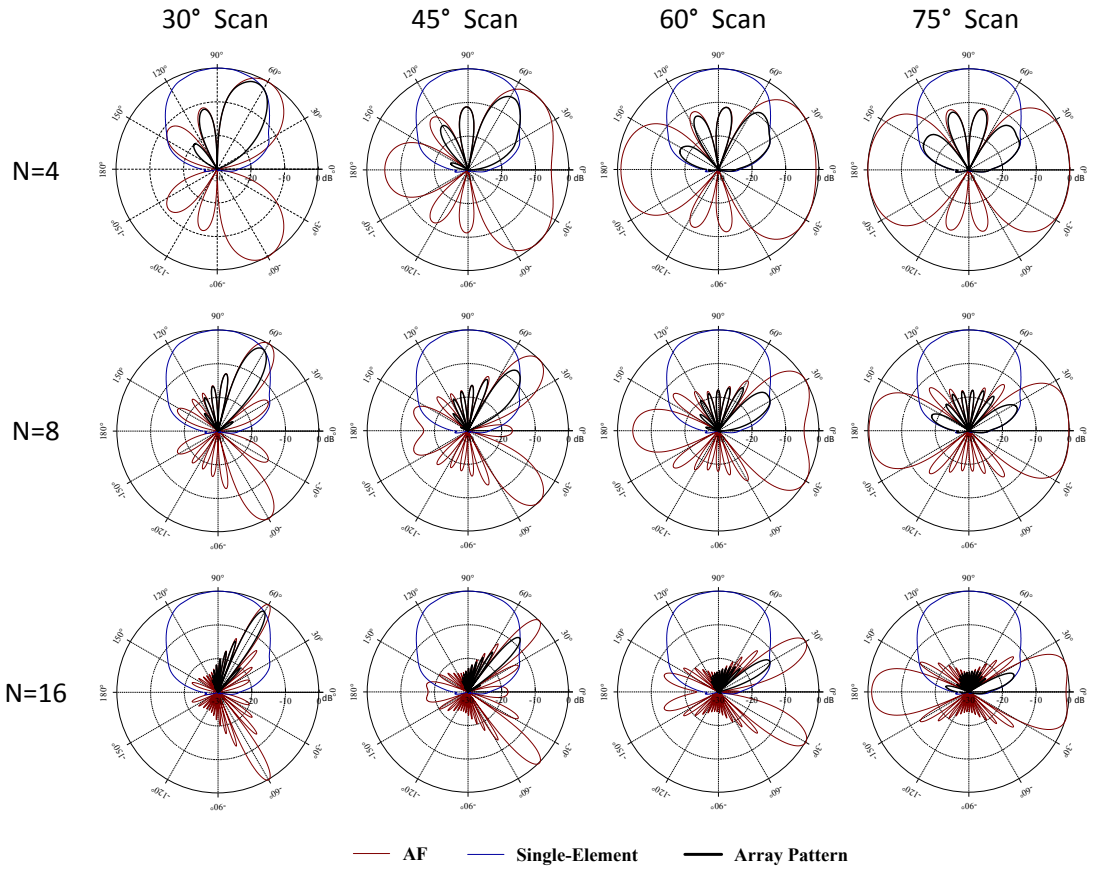

Figure 3.7. Illustration of the effect of N (number of elements) on scan angle. The AF and Single-Element patterns are shown in red and blue, respectively. The Array Pattern is the product of these two and is shown in black. The measured single-element E-plane pattern from the previous section (for Feed 1 at 10 GHz) and a uniform array with $d = \lambda/2$ are used to generate the plots.

4. PHASED ARRAY DEVELOPMENT

A. Antenna Array

The previously designed single-element antenna is to be used in a 4x1 array configuration. A uniform amplitude arrangement is chosen at this stage to simplify the design and avoid the need for amplifiers or attenuators. At a later date, computer-controlled amplifiers can be incorporated in the design to allow various amplitude schemes to be easily realized. The element spacing is chosen as 0.5λ at 10 GHz (1.5 cm) to minimize the effect of grating lobes while still maintaining a reasonably narrow beamwidth. This equates to 0.425λ at 8.5 GHz and 0.575λ at 11.5 GHz. A diagram of the array configuration can be seen in Fig. 4.1.

The array is fabricated in a manner similar to the method previously described for the single-element, with care being taken to ensure proper alignment; the fabricated array can be seen in Fig. 4.2. The four feeds on one side of the array will be combined into port 1, and the four feeds on the other side will be combined into port 2. The port numbering is defined from the numbering paradigm set by the single-element feed numbering (i.e., port 1 is created from the top feeds and port 2 is created from the bottom feeds).

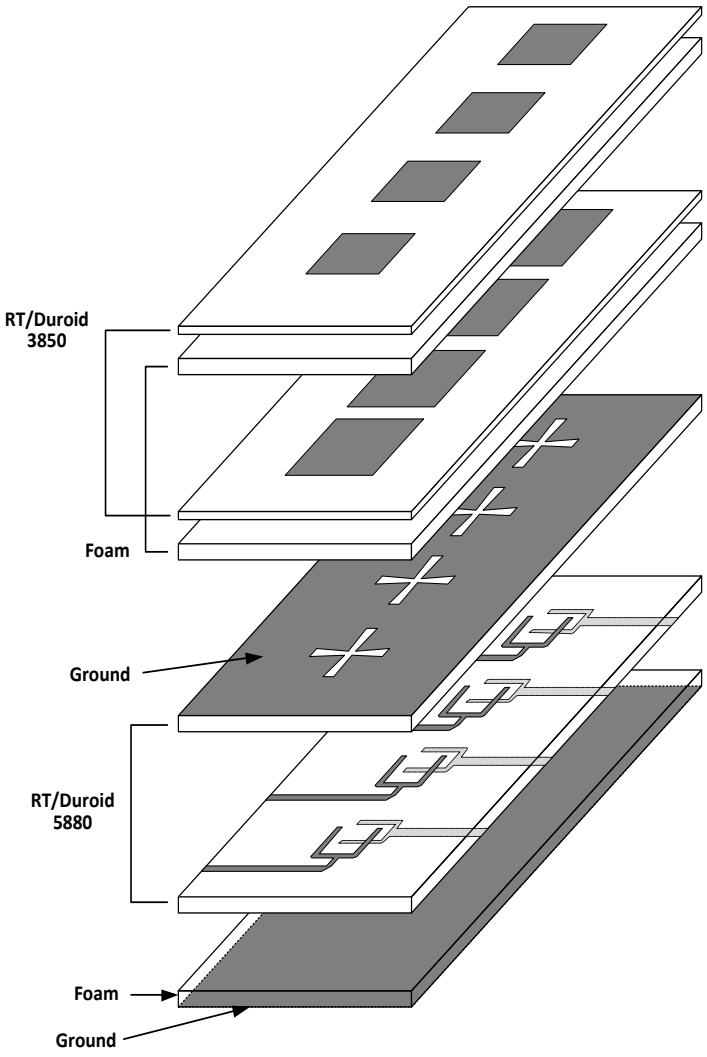

Figure 4.1. 4-element array design (stacked-patch, aperture-fed, dual-polarized stripline).

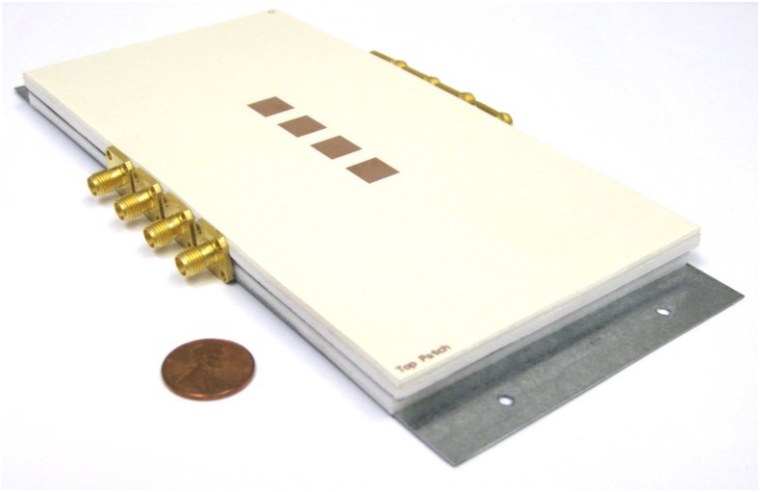

Figure 4.2. Photograph of the antenna array.

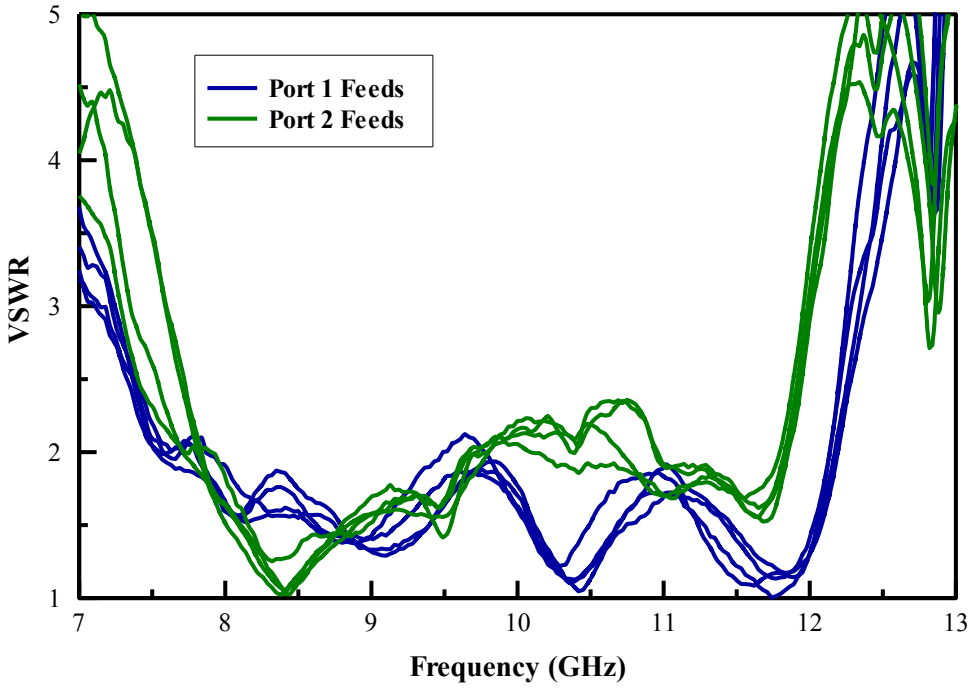
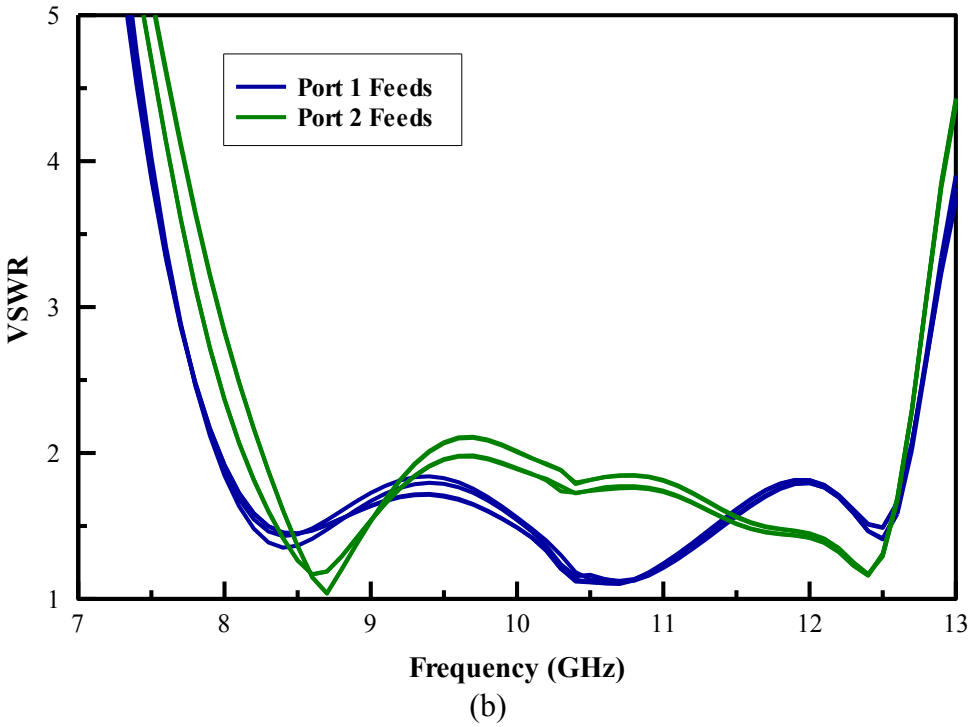
An Agilent 8510C network analyzer was used to measure the VSWR of the feeds as well as the isolation between the feeds. These measured values as well as simulated values can be seen in Figs. 4.3-4.4. Ignoring some small overruns, port 1's feeds have a simulated VSWR bandwidth of 45% (8 – 12.7 GHz) (f_0 = 10.4 GHz) and a measured VSWR bandwidth of 43% (7.9 – 12.2 GHz) (f_0 = 10.1 GHz). Port 2's feeds have a simulated VSWR bandwidth of 42% (8.3 – 12.7 GHz) (f_0 = 10.5 GHz) and a measured VSWR bandwidth of 41% (7.8 – 11.8 GHz) (f_0 = 9.8 GHz). This shift in bandwidth between simulated and measured values is similar to what was seen with the single-element and is the reason for the redesign. This places the center frequency close to 10 GHz. The simulated isolation between the ports' feeds is greater than 20 dB, and the measured isolation is greater than 18 dB throughout the VSWR bandwidth.

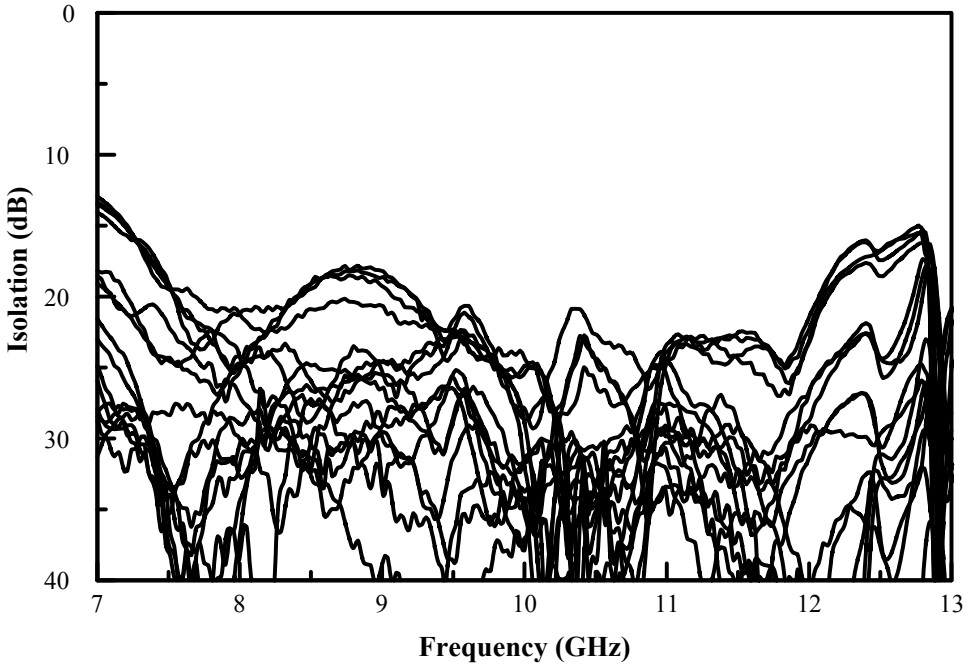


(a)

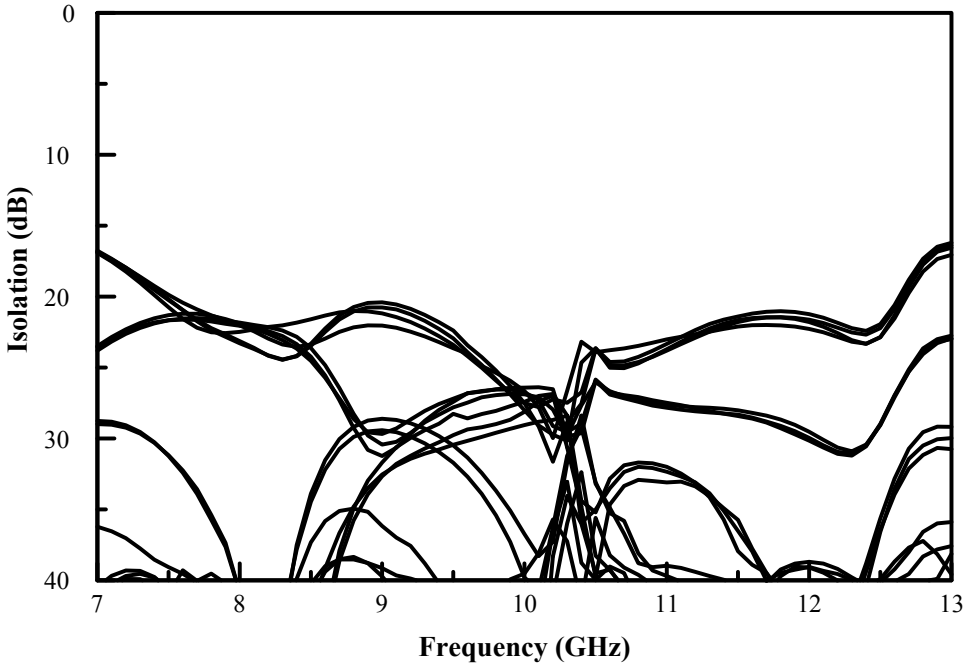


(b)

Figure 4.3. VSWR of the array feeds. (a) Measured and (b) simulated.



(a)



(b)

Figure 4.4. Isolation of the array feeds. (a) Measured and (b) simulated.

B. Power Divider

A 1-to-4 power divider must be used to evenly divide power between the four feeds of each port. Ideally, each output of the power divider will have the same amplitude and phase shift. However, the phase-shifters can be used to adjust for any difference in phase, but since variable amplifiers (or attenuators) are not used in this design, there is no way to adjust for an amplitude variation.

A corporate feed [24] arrangement is used to divide power since this can support a wide bandwidth. In this arrangement, a mitered T-junction [25] will be used to split the power into two, and then mitered T-junctions will be used to split that power again.

In addition to splitting power, the mitered T-junction will change the impedance from Z_0 at the input to $2*Z_0$ at the two outputs. This change in impedance must be accounted for with a transformer. The transformer will be placed before the T-junction rather than after it so that it changes the impedance from 50 to 25 Ω rather than from 100 to 50 Ω. This will prevent the use of high impedance lines which are narrow and sensitive to fabrication errors. It will also reduce the number of required transformers from six to three.

A single quarter-wave transformer can only support a narrow bandwidth, so it is better to use a multi-section transformer to increase the bandwidth. A two section transformer is sufficient and can be designed from a simple algorithm using a uniform geometric progression as presented in [26]. The characteristic impedance Z_0 is 50 Ω, and the load resistance R_L, which is the required impedance before the T-junction, is 25 Ω. The number of sections N will be 2. The impedance will be transformed into

intermediary impedances before finally reaching the final value. The step between these intermediary impedances is defined as:

$$Step = \left(\frac{R_L}{Z_0}\right)^{1/N} = \left(\frac{25}{50}\right)^{1/2} = 0.7071 \quad . \tag{4.1}$$

Then the intermediary impedances are defined as:

$$Z_i(1) = Step \text{ x } Z_0 = 35.6\ \Omega \tag{4.2}$$

$$Z_i(2) = Step \text{ x } Z_i(1) = 25\ \Omega \quad . \tag{4.3}$$

Finally, the characteristic impedance of each quarter-wave section can be defined as:

$$Z(1) = \sqrt{Z_i(0)Z_i(1)} = 42.04\ \Omega \tag{4.4}$$

$$Z(2) = \sqrt{Z_i(1)Z_i(2)} = 29.73\ \Omega \quad . \tag{4.5}$$

The power divider design can be seen in Fig. 4.5, and a photograph can be seen in Fig. 4.6. Note that there is not a 25 Ω line in the design because the input to the mitered T-junction is placed immediately following the conversion to 25 Ω.

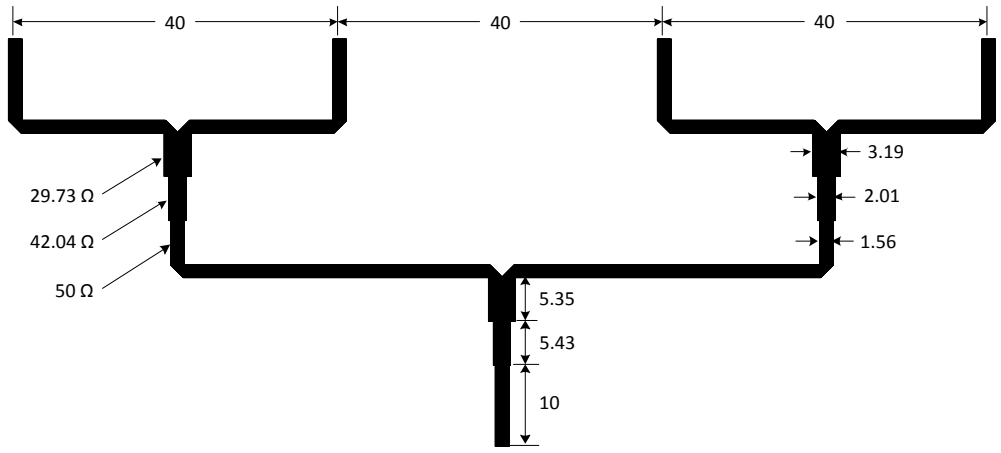


Figure 4.5. Schematic of the power divider (all units in mm).

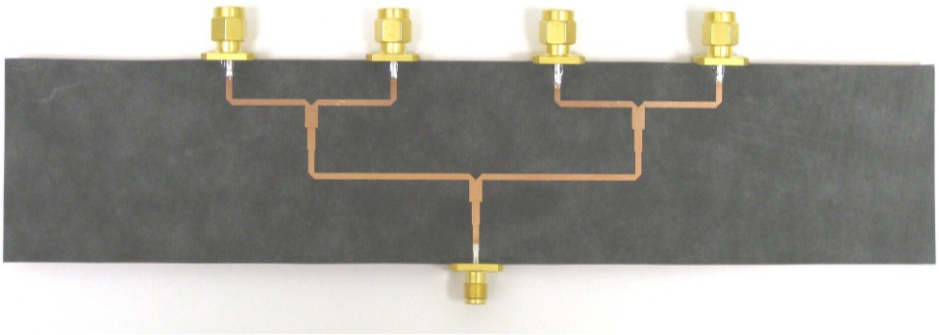

Figure 4.6. Photograph of the power divider.

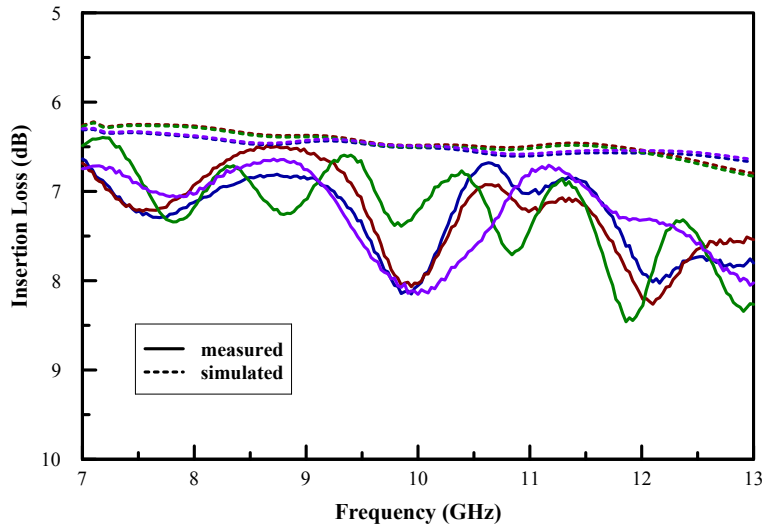
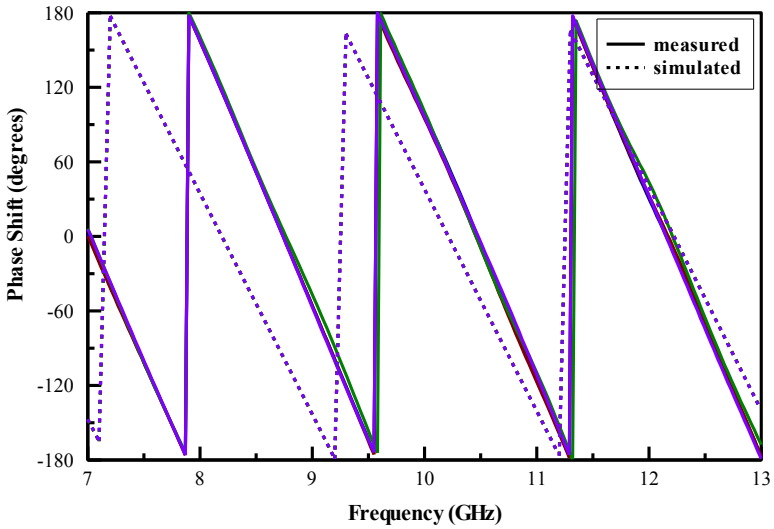
The insertion loss of the power divider is measured with a network analyzer, and the results are displayed in Fig. 4.7. These are plots of the insertion loss and phase shift from the input to each of the outputs, so ideally the insertion loss and phase shift of all the outputs would be equal to one another. The simulation shows that, at every frequency, the insertion loss of any two outputs differ by less than 0.19 dB, and the phase shifts differ by less than 1°. The measurements show that the insertion losses

differ by less than 1.16 dB, and the phase shifts differ by less than 14°. This error in measured values is most likely due to fabrication errors, namely connector inconsistencies.



(a)



(b)

Figure 4.7. Measured and simulated (a) insertion loss and (b) phase shift of the power divider.

C. Phase-Shifters

Four digital phase-shifters are needed to control the phased array (one shifter for each element), and there are a number of varieties and options available on the market. Some of the phase-shifters are packaged as a sealed unit in a hardened case which is durable but also large and expensive. The other option is a monolithic microwave integrated circuit (MMIC) which is much cheaper and smaller. They are typically a few square millimeters and can be directly integrated into the antenna array. Using MMIC phase-shifters would allow the entire phased array (antenna, phase-shifters, and power divider) to be fabricated together and be very compact. The downside to the MMIC is that they can be very fragile, and if an integrated phase-shifter breaks then the whole array assembly must be discarded and rebuilt. The other downside is that special equipment is required to mount and connect MMICs, and unfortunately this lab does not have access to that equipment.

There is another option for using MMIC phase-shifters which overcomes this lab's inability to mount them. The companies which manufacture MMICs usually also make an evaluation board with the MMIC already mounted on a board and attached to external connections. Using evaluation boards would sacrifice some of the MMICs advantages since it would no longer be possible to fabricate the entire phased array together, and they are more expensive than the standalone MMICs. However, the evaluation boards are still smaller and less expensive than the sealed units. For these reasons, MMIC evaluation boards will be used in the system.

The Hittite HMC543LC4B phase-shifter is chosen for use in this system mainly for its price. It is a 4-bit digital phase-shifter which operates from 8 – 12 GHz. It has 360° coverage, so 4-bits means that the smallest possible adjustment is 22.5°. A photograph of the HMC543LC4B phase-shifter evaluation board can be seen in Fig. 4.8.

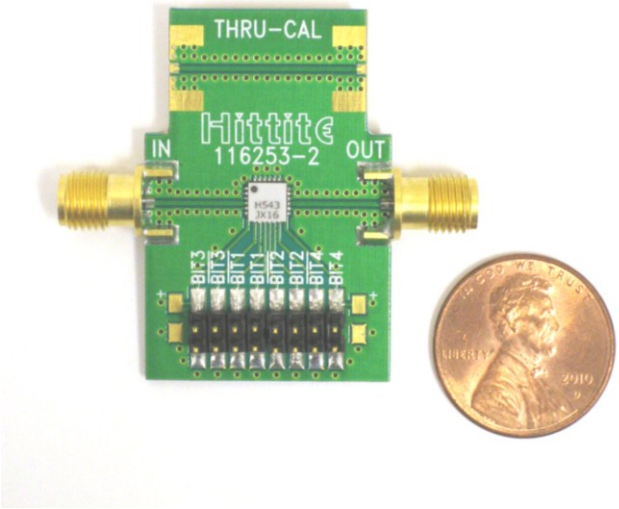


Figure 4.8. Photograph of the Hittite HMC543LC4B phase-shifter evaluation board.

The S-parameters of the phase-shifter are measured with a network analyzer, and the results can be seen in Figs. 4.9-4.10. Each line in the graphs represents a different phase setting. The insertion loss for each phase setting (Fig. 4.9) ranges from 6.3 – 8.3 dB which is a range of 2 dB. However, at any given frequency, the insertion loss varies by less than 1.6 dB, and at 10 GHz it varies by less than 0.6 dB. The variation in insertion loss increases for frequencies farther away from the center frequency of 10 GHz. This insertion loss variation will create a deviation from the

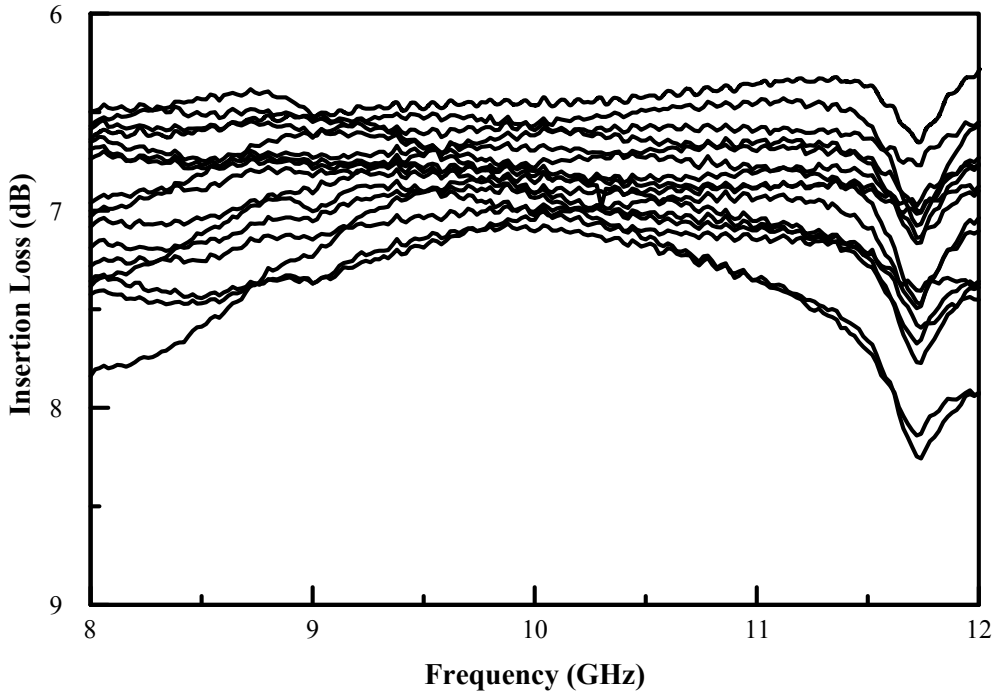

Figure 4.9. Measured insertion loss of the phase-shifter at all phase settings.

planned uniform amplitude distribution, and if variable amplifiers were included in the design, this variation could be accounted for.

Fig. 4.10a illustrates the relative phase shift of each setting where each setting is relative to the 0° state. Ideally each setting would be 22.5° from the previous setting, but some deviation exists. This deviation can be seen in Fig. 4.10b which illustrates the amount that each setting deviates, and it can be seen that there is a maximum deviation of 12°. This phase deviation can be corrected in the calibration. However, the phase shift error of each state is not consistent for all frequencies, and it can vary by as much as 18° (as a function of frequency) for some states. Hence, if the system is calibrated at

one frequency, there will be some phase error introduced at other frequencies by the inconsistencies of the phase-shifter. Of course this can be corrected by recalibrating at other frequencies and using different settings for different frequencies, but if the system is to be used in a broadband application, a single setting should be used.

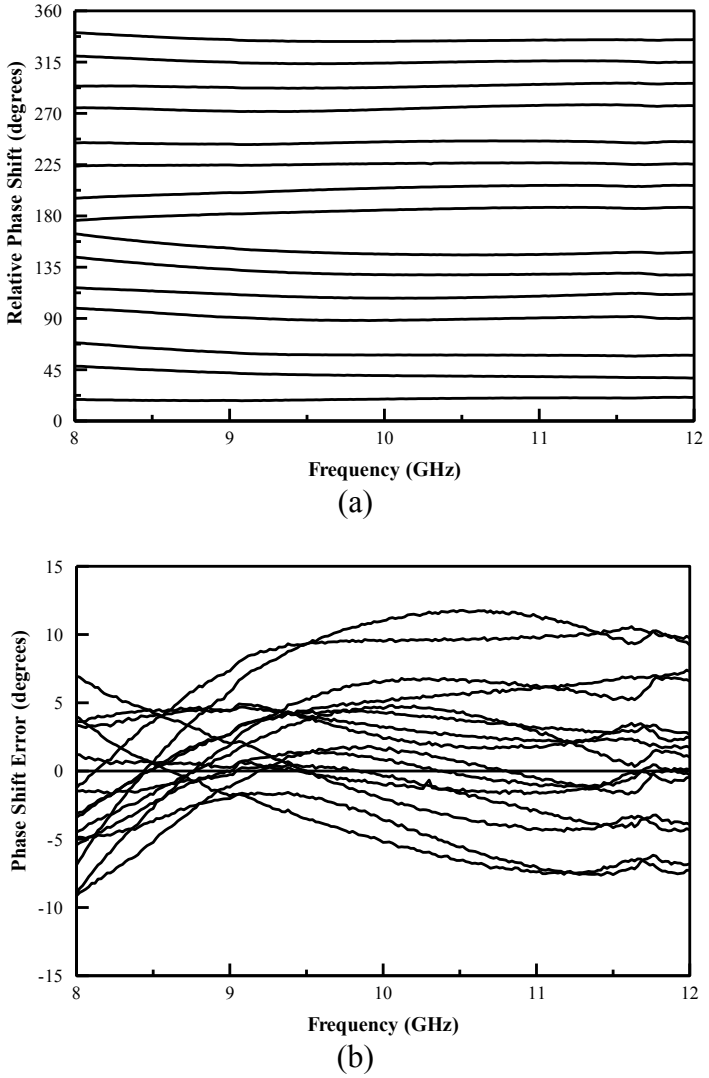

Figure 4.10. Measured (a) relative phase shift of the phase-shifter at all phase settings and (b) phase shift error.

D. Phase-Shifter Control

To steer the phased array, the phase-shifters must be digitally controlled by a computer. There are four 4-bit shifters, so 16 bits of information are required. LabVIEW [27] can be used in conjunction with a Data Acquisition (DAQ) device to provide the 16 bits. An NI USB-6509 Digital I/O device will serve as the DAQ with an NI CB-50 connector box providing the connection terminals. This DAQ provides 96 channels (operating on the 5 V TTL/CMOS standard) which will allow room for the array to grow at a later date. Photographs of the DAQ and connector box can be seen in Fig. 4.11.

(a) (b)

Figure 4.11. Photographs of (a) the NI USB-6509 DAQ and (b) the NI CB-50 connector box.

LabVIEW can be used to convert the desired phase to a 4-bit representation which can be sent to the phase-shifter. The conversion procedure is as follows:

1.) Shift phase to the range 0 - 360° [phase modulo 360]

2.) Convert phase to a 4-bit representation [round(phase/22.5)]

3.) If the result is 16, change this to 0 (16 is an overflow)

Outputs are sent in packets of 8 bits, so two phases should be combined into one 8-bit output as follows:

1.) (4-bit phase 1) + (4-bit phase 2) x 16

where the least significant bits (LSBs) are for shifter 1 and the most significant bits (MSBs) are for shifter 2. This procedure is used to develop an easy to use LabVIEW interface (Fig. 4.12), and the details of the implementation can be seen in the appendix.

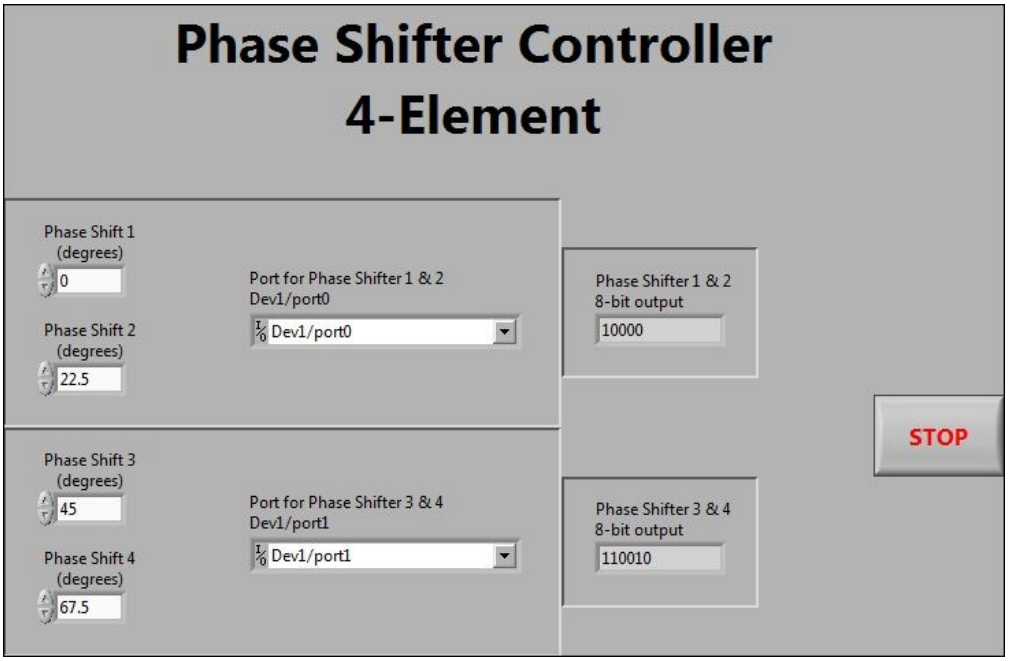

Figure 4.12. LabVIEW interface for controlling four 4-bit phase-shifters.

E. Phase-Shifter Logic Conversion

LabVIEW and the DAQ provide the standard 5 V TTL/CMOS logic, but unfortunately the phase-shifters require a complementary logic of 0/-3V. In this logic scheme, each bit of information requires two control lines (one with 0 V and the other with -3 V). A converting circuit must be designed to convert all 16 control bits into 32 bits of this 0/-3V complementary logic. A circuit design [28] as seen in Fig. 4.13 can be used to convert each bit.

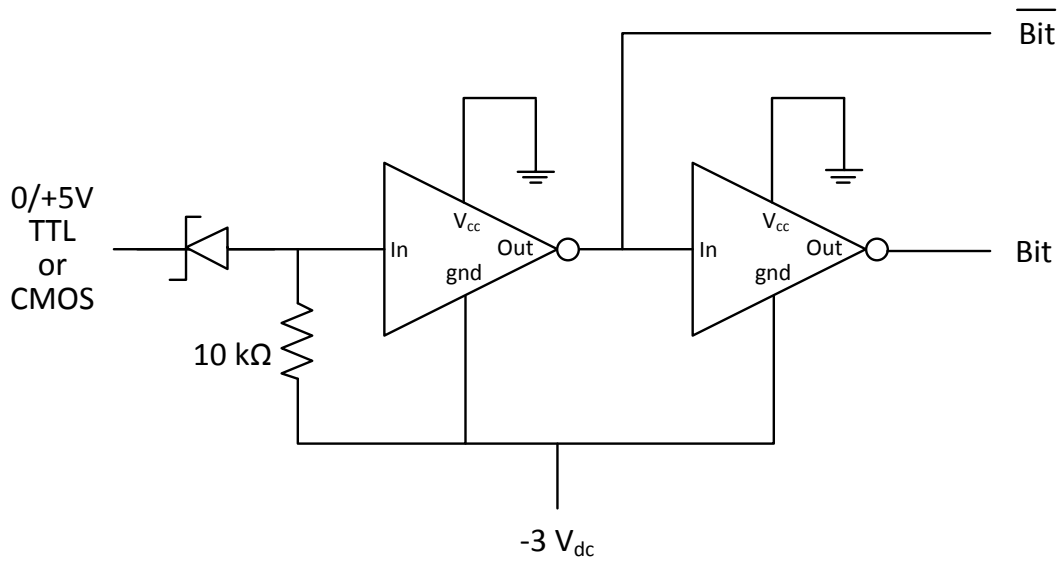

Figure 4.13. Circuit to convert 5 V TTL/CMOS logic to 0/-3V complementary logic.

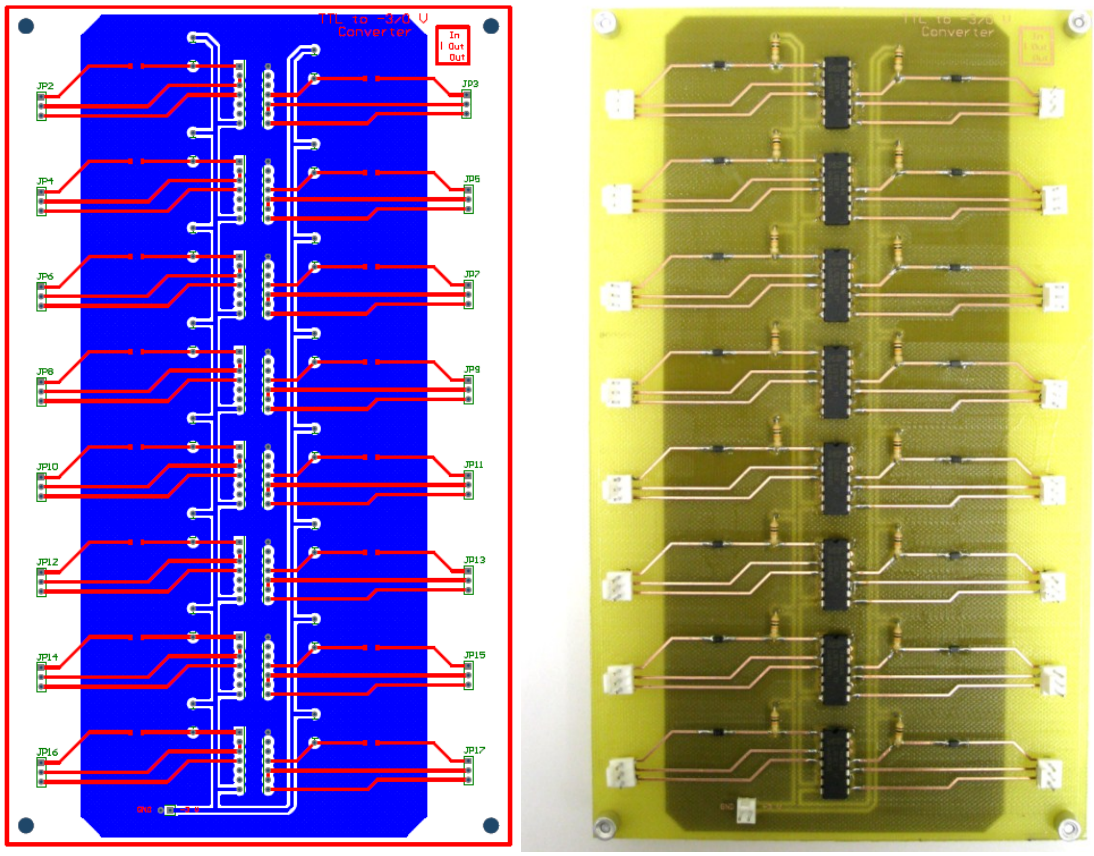
This circuit contains two inverters (Philips Semiconductors 74HC04), a 10 kΩ resistor, and a zener diode (ON Semiconductor MMSZ4689T1, V_z = 5.1 V, I_{zt} = 50 μA). When the input is 5 V, the diode will conduct, and the 5 V zener voltage drop will cause 0 V to appear at the input of the first inverter. This will cause the inverter to connect its

gnd (which is connected to -3 V) to its output. Then -3 V will appear at the output $\overline{Bit}$, and the second inverter will connect its V_{cc} (which is connected to ground) to its output which is the output *Bit*. This will make $\overline{Bit}$ = -3 V and *Bit* = 0 V. When the input is 0 V, the diode will not conduct, and -3 V will appear at the input to the first inverter. This will cause the inverter to connect its V_{cc} (which is connected to ground) to its output. Then 0 V will appear at the output $\overline{Bit}$, and the second inverter will connect its *gnd* (which is connected to -3 V) to its output which is the output *Bit*. This will make $\overline{Bit}$ = 0 V and *Bit* = -3 V.

This circuit must be implemented 16 times in order to convert all of the bits. The most clean and efficient way to do this is with a Printed Circuit Board (PCB) which can be designed using Protel DXP 2004 [29]. The input and outputs for each bit are grouped together and placed on the left and right sides of the PCB. A connection for ground and a -3 V_{dc} source are placed at the bottom, and the inverter DIPs run down the center. The grounds and the -3 V_{dc} leads are connected on the backside of the board. The DXP schematic and a photograph of the assembled PCB can be seen in Fig. 4.14.



(a) (b)

Figure 4.14. PCB to convert 5 V TTL/CMOS logic to 0/-3V complementary logic. (a) Schematic and (b) photograph.

F. Phased Array Assembly

The antenna array, phase-shifters, and power divider are connected and fixed together using a bracket as illustrated in Fig. 4.15. Each polarization will be measured separately with the feeds for the other polarization terminated with 50 Ω loads as shown in the photograph. Three-inch coaxial cables (Mini-Circuits Hand-Flex 086-3SM+) are used to connect the antenna array to the phase-shifters since they can easily be formed to the necessary shape, and the phase-shifters and power divider are directly connected with SMA connectors.

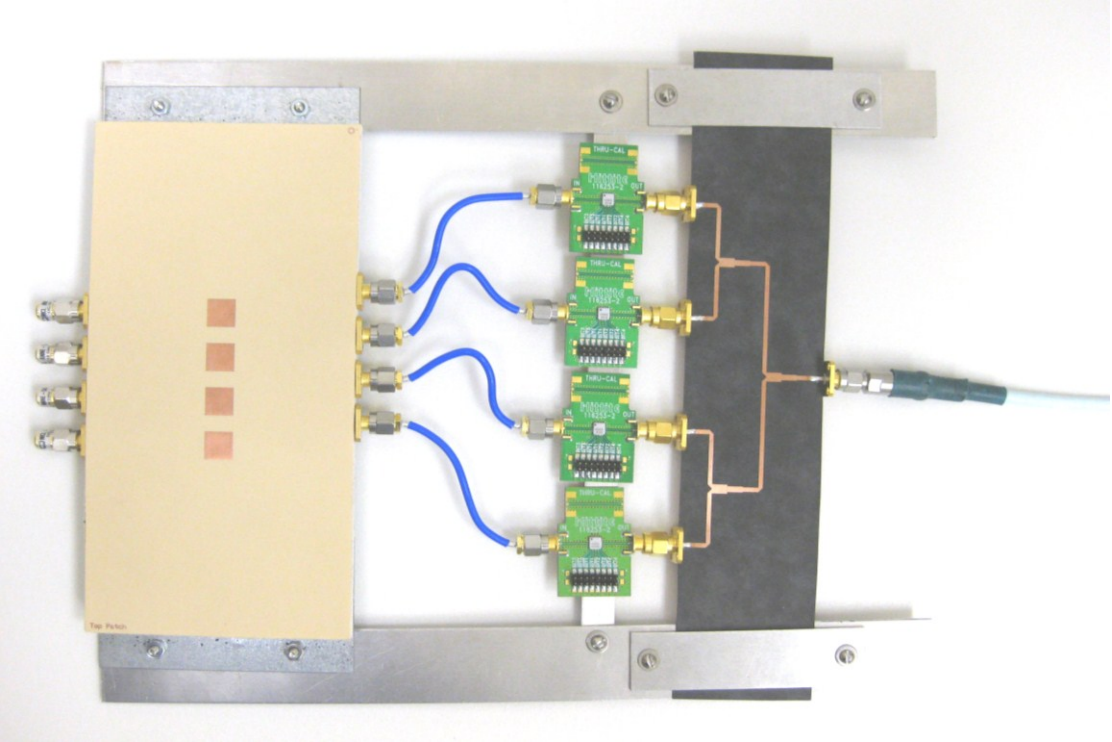


Figure 4.15. Photograph of the array assembly (antenna array, phase-shifters, and power divider) fixed together by a bracket.

The phase-shifters must be wired to the logic converter circuit and the LabVIEW DAQ. Due to the fragility of the phase-shifters, a protective shield is built to protect them from harmful external disturbances as shown in Fig. 4.16. The array assembly is surrounded by absorber to prevent reflections; this is done by placing the assembly in a large hollowed out chunk of absorber and then covering it with layers of absorber as shown in Fig. 4.17.

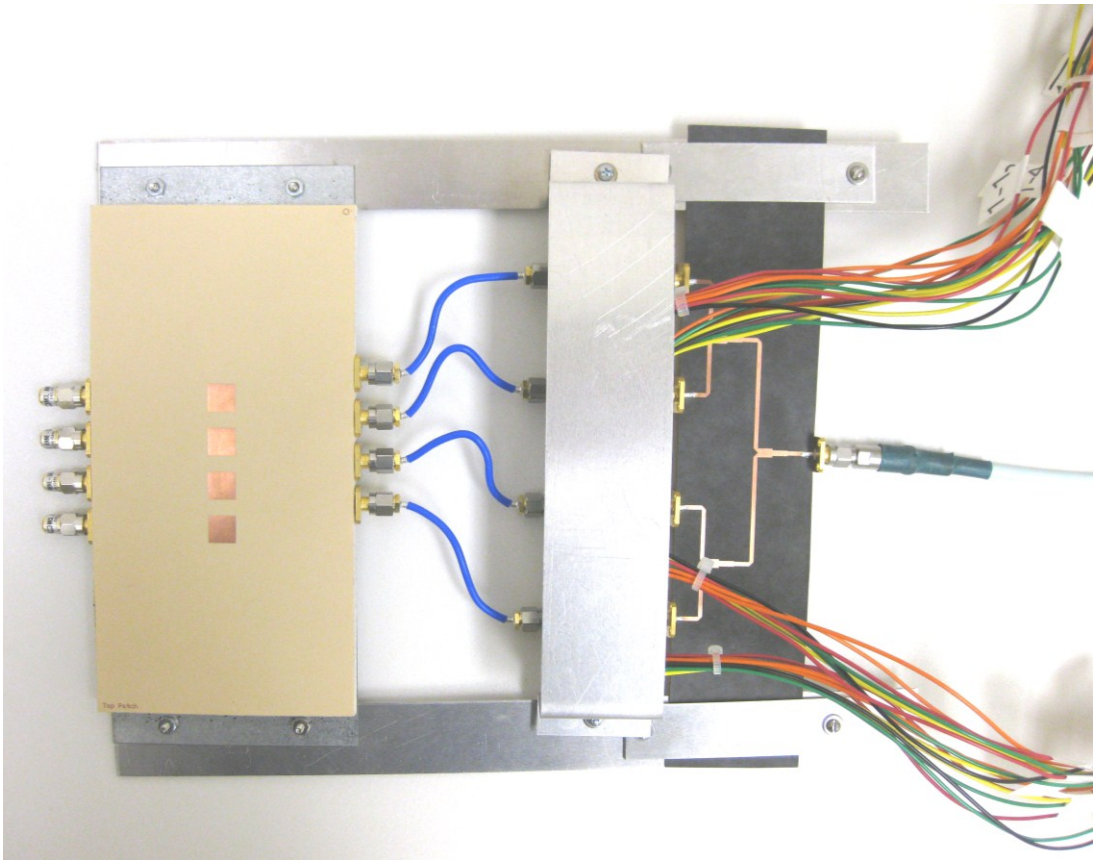

Figure 4.16. Photograph of the array assembly with a protective shield over the phase-shifters.

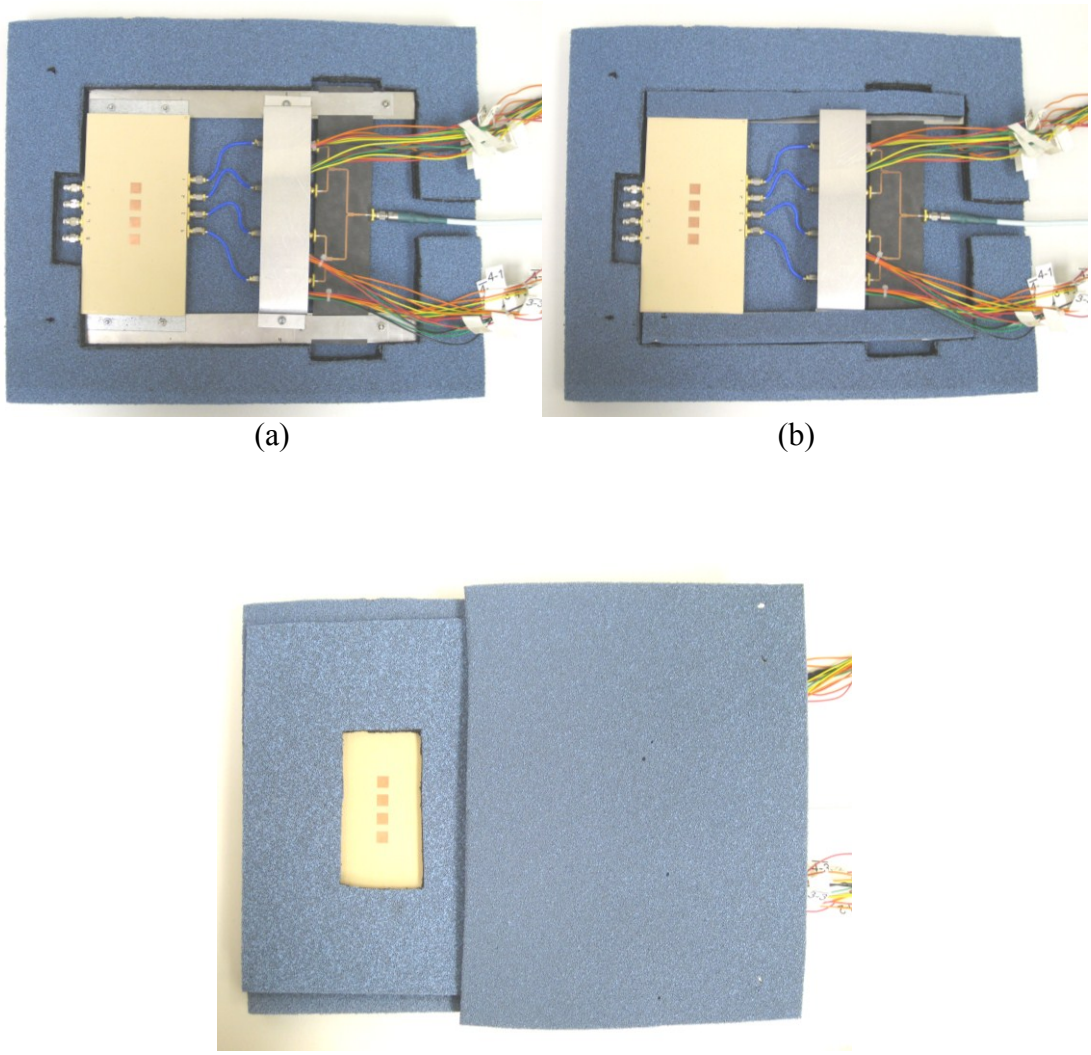

(a) (b)

(c)

Figure 4.17. Photograph of the array assembly. (a) Placed in a hollowed out chunk of absorber, (b) protected by pieces of absorber, and (c) covered with layers of absorber.

To operate the phased array and take measurements in the anechoic chamber, the array assembly (Fig. 4.17) is mounted inside the chamber, and the wires controlling the phase-shifters are run under the chamber door so that the phase-shifter controlling equipment does not disturb the measurements. These wires are connected to the logic converter circuit which is connected to the connector box which is connected to the DAQ which is connected to a computer running LabVIEW. This arrangement is illustrated in Fig. 4.18, and a photograph can be seen in Fig. 4.19.

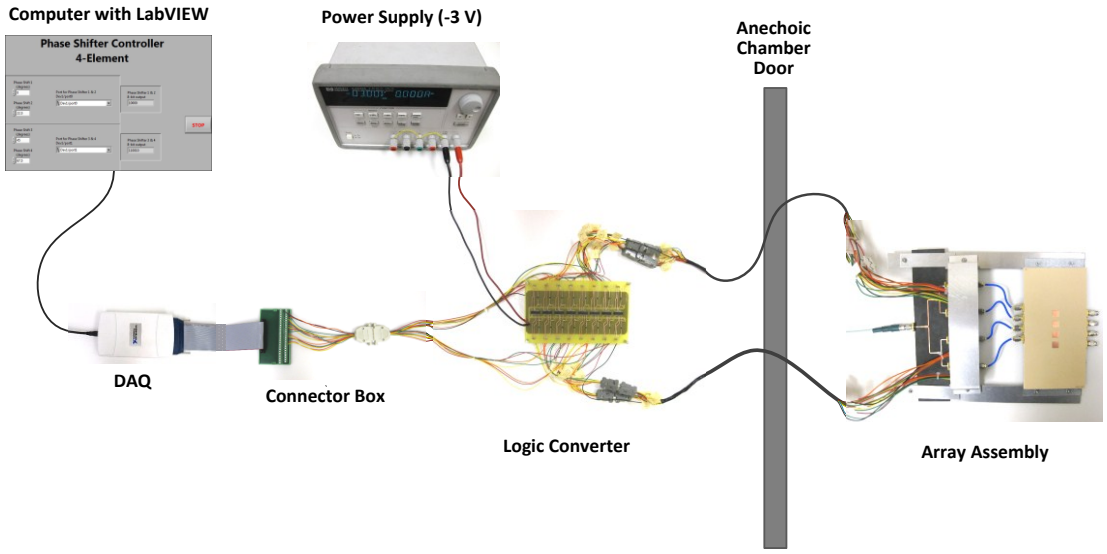

Figure 4.18. Diagram of the phased array system setup.

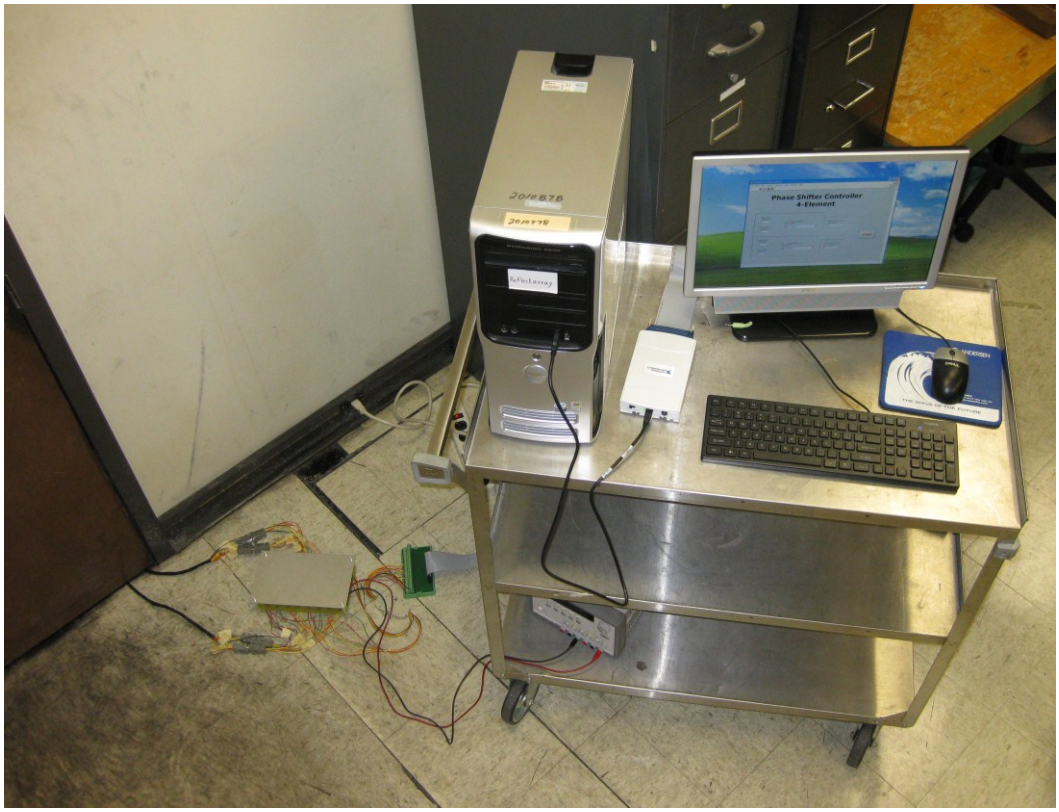

Figure 4.19. Photograph of the phased array system setup.

G. Phased Array Calibration

Before the phased array can be used for the first time, it must be calibrated. Unequal line lengths, phase-shifter errors, and mutual coupling [30] prevent simply offsetting each phase-shifter by identical phases to create the desired scan angle.

Unequal line lengths have the most dramatic effect on calibration. A simple method to calibrate the array is to merely measure the amount of phase shift that the input signal undergoes while traveling through the power divider, phase-shifter, and coaxial line on its way to each feed. The difference in measured phase shift for each

feed can then be subtracted from the desired shift of that feed. The measured phase shifts for lines 1 – 4 are -100°, 65°, 55°, and 60° respectively. There is a difference in phase shift between lines 1 and 4 of 165° which is quite large. However, using this calibration method, the effect of these unequal line lengths can be tuned out. One drawback of this technique is that it does not take into account the phase-shifter errors of each state (as seen in Fig. 4.10b) or mutual coupling [30].

All effects can be accounted for if a far-field phase-alignment calibration approach is used. For this calibration technique, the phased array system is assembled in an anechoic chamber (as seen in Fig. 4.18), and the antenna is oriented at broadside for the duration of the calibration. Each antenna element must be isolated by terminating the other elements' feeds. A far-field gain measurement is then made for all phase states of that element. This is repeated by then isolating the other elements, one at a time, and repeating the measurements for each element. Once a table containing the phase shift of each element for all phase states has been made, the phase settings to be used can be obtained from the calibration table. For example, if a scan angle of 0° is required, phase settings for each shifter should be chosen such that their values in the calibration table are equal. If the array is to be scanned to an angle θ_0, then the phase β between array elements should be

$$\beta = -kd \sin \theta_0 \tag{4.6}$$

where d is the separation between elements and k is the wave number. Then phase settings for each shifter should be chosen such that their values in the calibration table are x, x+β, x+2β, x+3β where x is any number. A plot of the data from one of the calibrations can be seen in Fig. 4.20.

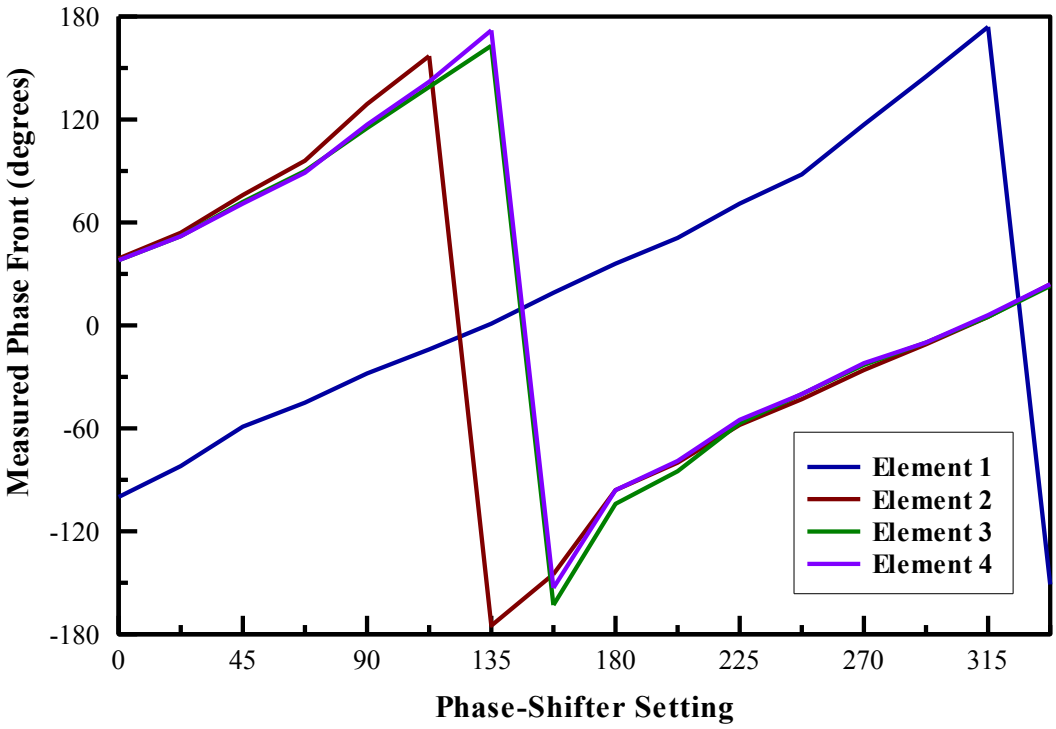

Figure 4.20. Plot of a typical calibration table for the four elements.

There is one small problem with using the far-field phase-alignment method for this phased array. The elements not under test must be terminated, and since variable amplifiers are not used, the only way to do this without disturbing the antenna position is to remove the phase-shifter control lines. This effectively isolates the unwanted elements, but it does this by reflecting power from the phase-shifter rather than

terminating the power. The reflected power from the unwanted elements will combine and interfere with the transmission to the element-under-test. The goal is to isolate the element-under-test and measure it under the same conditions that will be encountered in normal operation, but these reflections disturb that normal operating condition. However, the phase difference from terminating the unwanted elements with a 50 Ω load and unplugging their phase-shifters was measured to be less than 9°, and the variation of this change between elements was measured to be less than 4°. Therefore, the error introduced by unplugging the unwanted elements, rather than terminating them, is minimal.

A comparison of the far-field phase-alignment calibration method and the line length adjustment calibration method is illustrated for a 0° scan angle in Fig. 4.21. Both calibration methods work, but the far-field phase-alignment method gives a higher gain and a nicer beam shape. Consequently, the far-field phase-alignment method will be used.

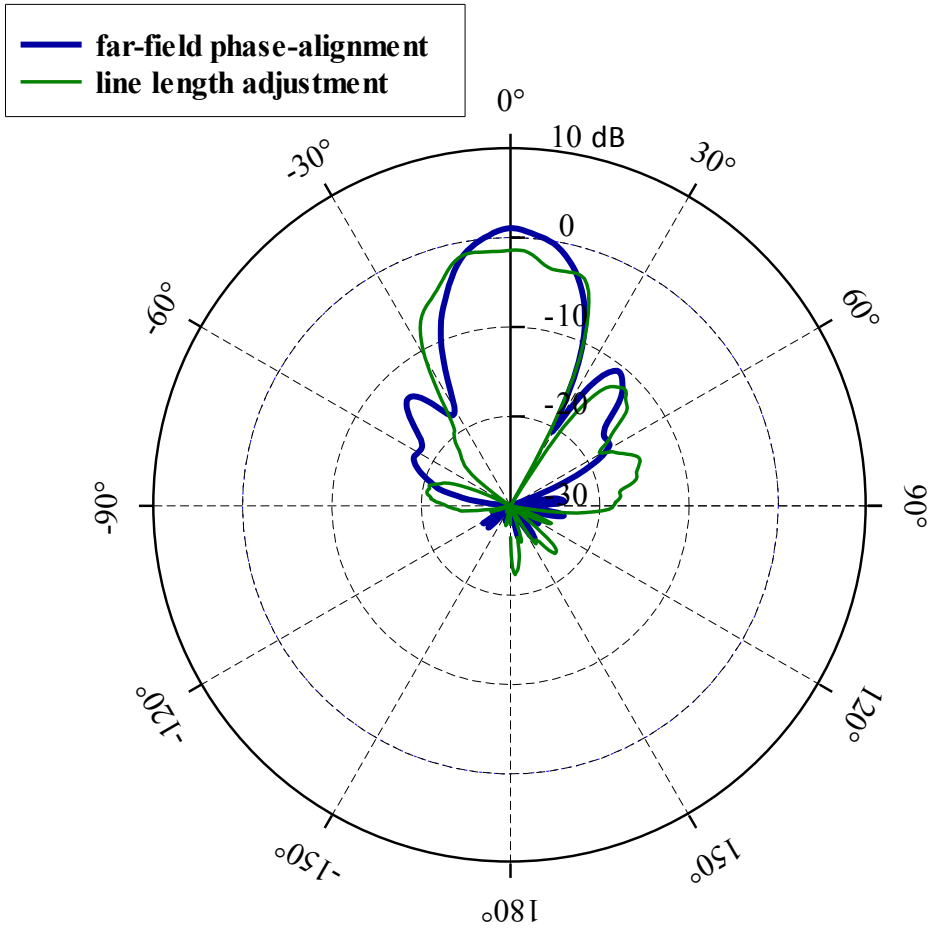

Figure 4.21. Comparison of two phased array calibration methods (the far-field phase-alignment method and the line length adjustment method). Measurement is for a 0° scan angle.

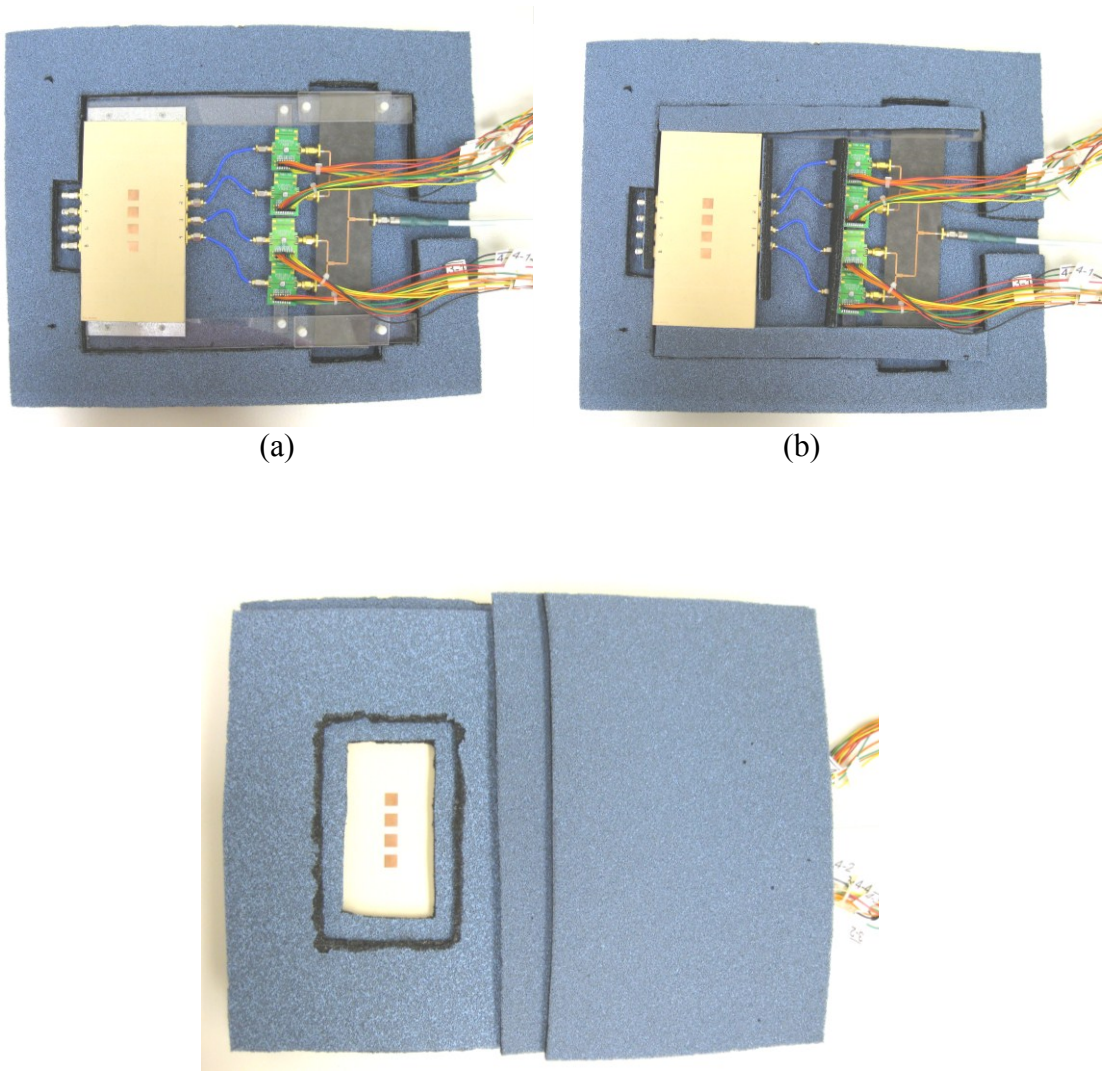
H. Pattern Measurements

The phased array system (Fig. 4.18) is calibrated at 10 GHz, and the pattern is measured from 8.5 to 12 GHz in increments of 0.5 GHz and for scan angles from 0 to 90° in increments of 10°. The array scans as intended and works fairly well, but there are a few abnormalities with the pattern and scan loss. The gain oscillates some with observation angle, and peak gain can sometimes increase with increasing scan angle. This could be caused by a number of factors such as: resonant modes caused by reflection and interaction with array assembly metal, phase quantization errors, calibration errors, and phase-shifter insertion loss variation with phase setting.

The effect from resonant modes caused by reflection and interaction with array assembly metal can be reduced by replacing the array assembly mounting structure with lexan and nylon screws as illustrated in Fig. 4.22a. Also, adding more absorber around the SMA connectors (Fig. 4.22b) and another layer of absorber on top (Fig. 4.22c) can help to prevent and attenuate any reflected waves.



(a) (b)

(c)

Figure 4.22. Photograph of the array assembly with lexan and nylon screws. (a) Placed in a hollowed out chunk of absorber, (b) protected by pieces of absorber, and (c) covered with layers of absorber.

The phase quantization error can be reduced by strategically choosing the reference element which will result in minimum phase quantization error rather than choosing this reference element at random. Since the phase-shifter states are not separated by exactly 22.5°, reference element choice can make a significant difference in phase quantization error. The optimum phase settings for a given phase β can be found using a Matlab [31] program which can be seen in the appendix. If a reference element is chosen at random, the phase error from each element is usually less than 5-12°. However, if the Matlab program is used, the phase error from each element is usually less than 1-3°. This will increase the calibration accuracy and should more correctly align the phase fronts of the elements.

The revamped phased array assembly seen in Fig. 4.22 is calibrated at 10 GHz, and phase-shifter settings are chosen using the Matlab program. The array pattern is then measured as before. The results are similar, but the gain oscillation is reduced, and the scan loss is closer to expectation. Some of the measurements can be seen in Figs. 4.23-4.28.

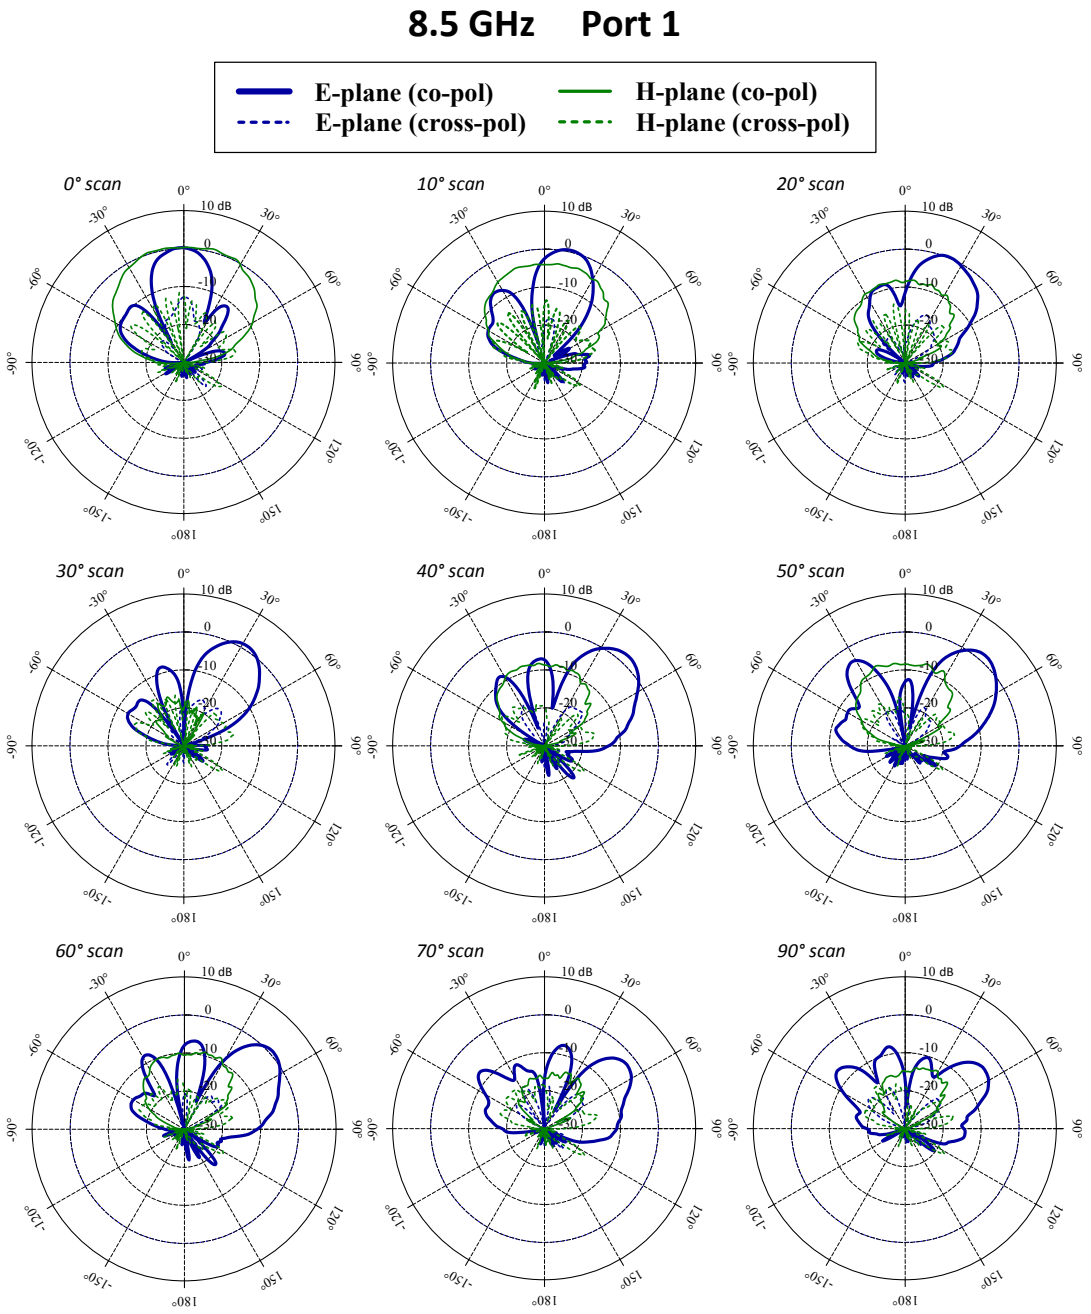


Figure 4.23. Measured radiation pattern of the 4-element phased array. Port 1 at 8.5 GHz.

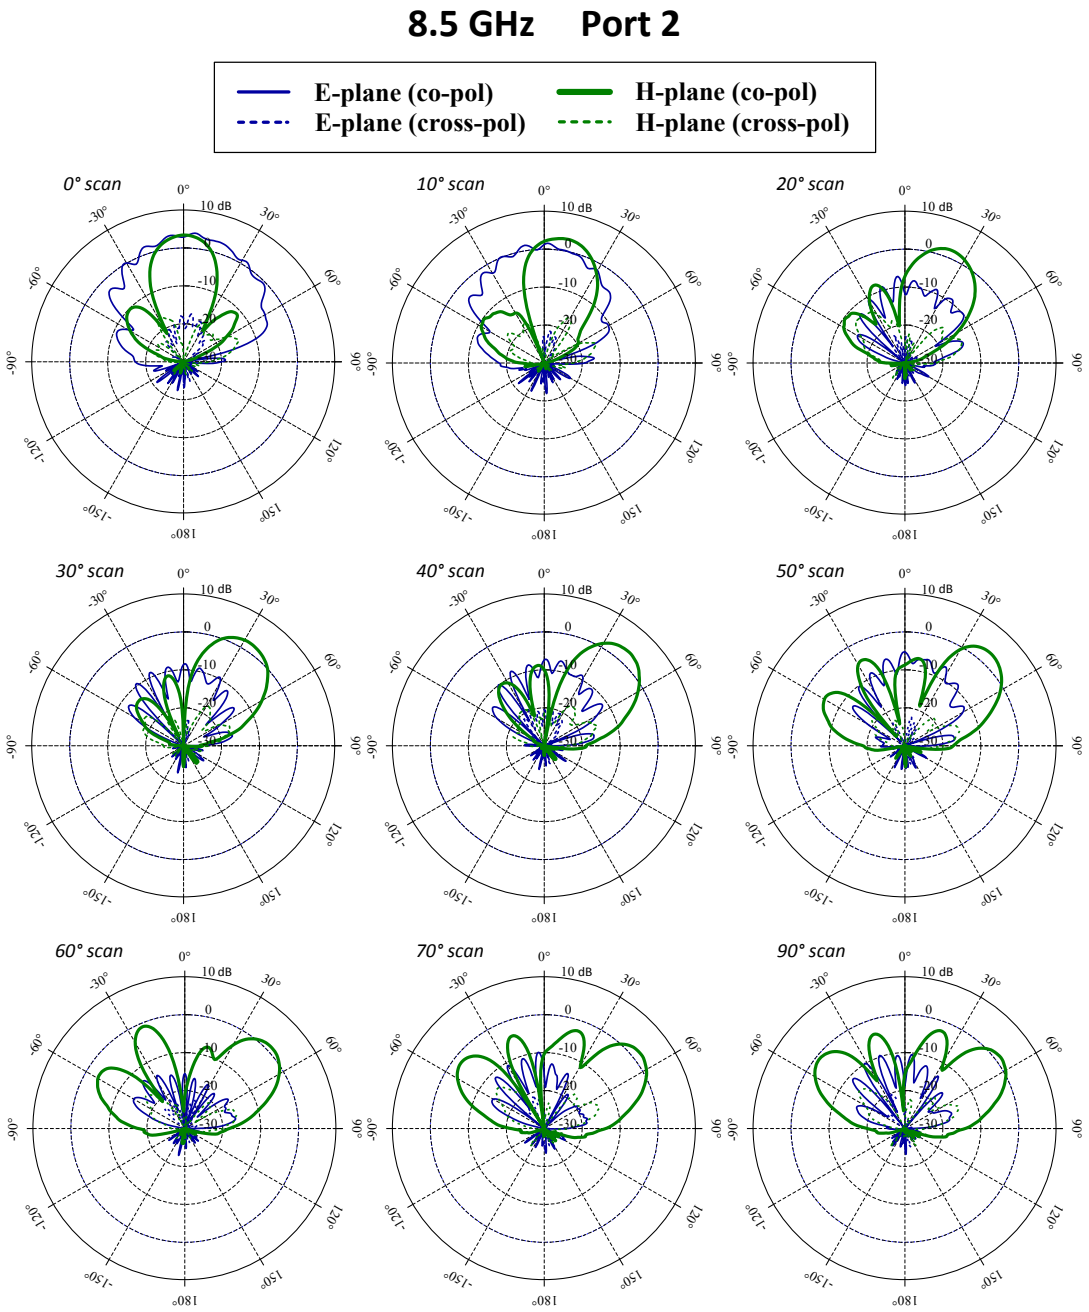

Figure 4.24. Measured radiation pattern of the 4-element phased array. Port 2 at 8.5 GHz.

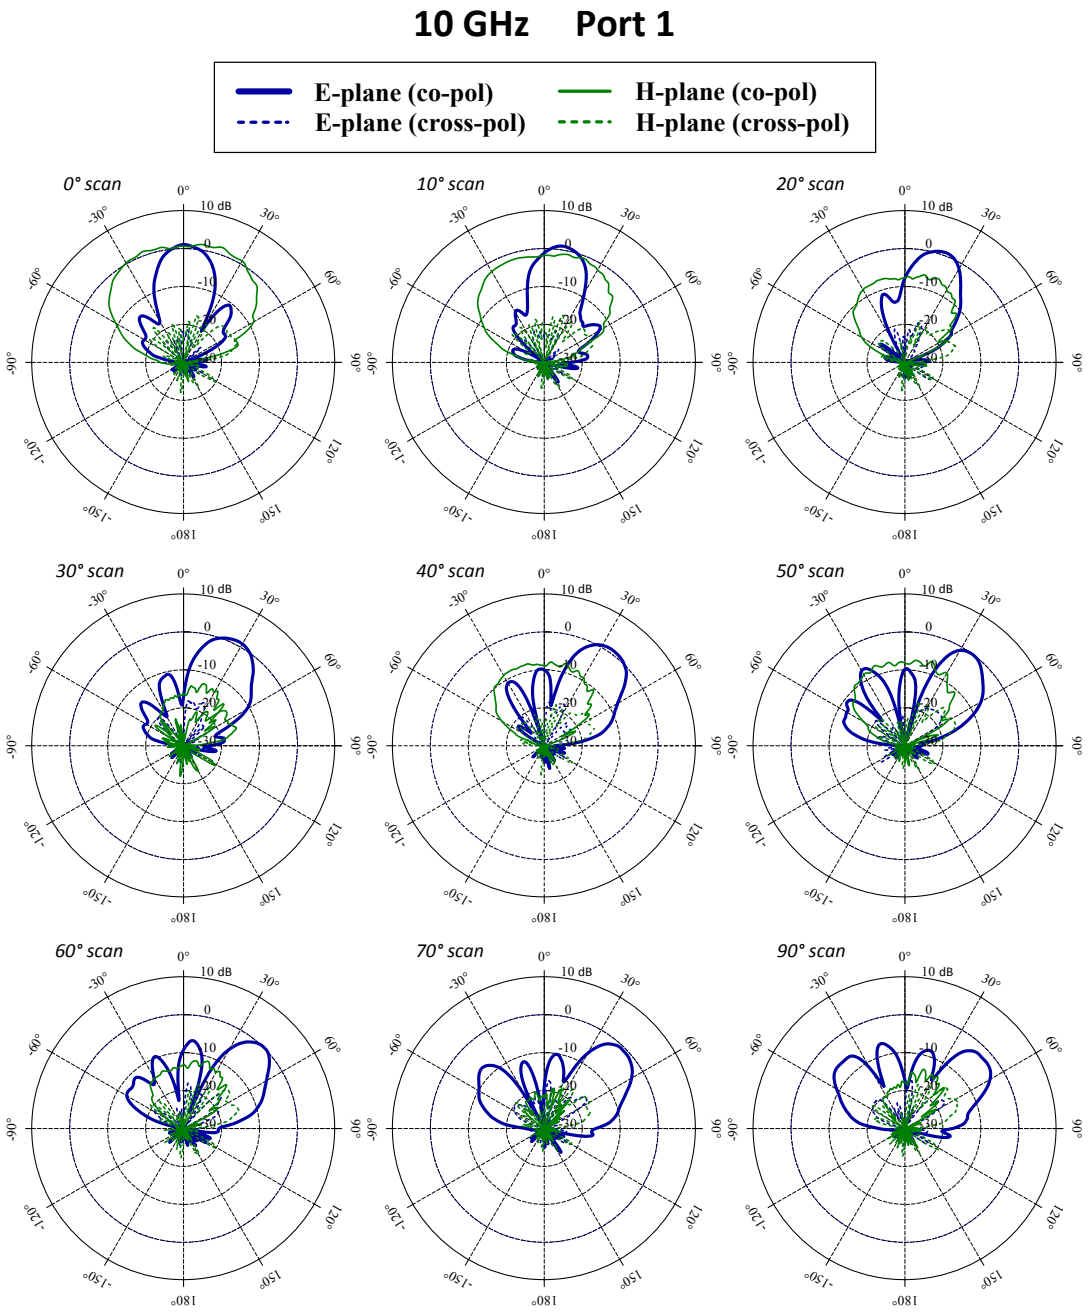

Figure 4.25. Measured radiation pattern of the 4-element phased array. Port 1 at 10 GHz.

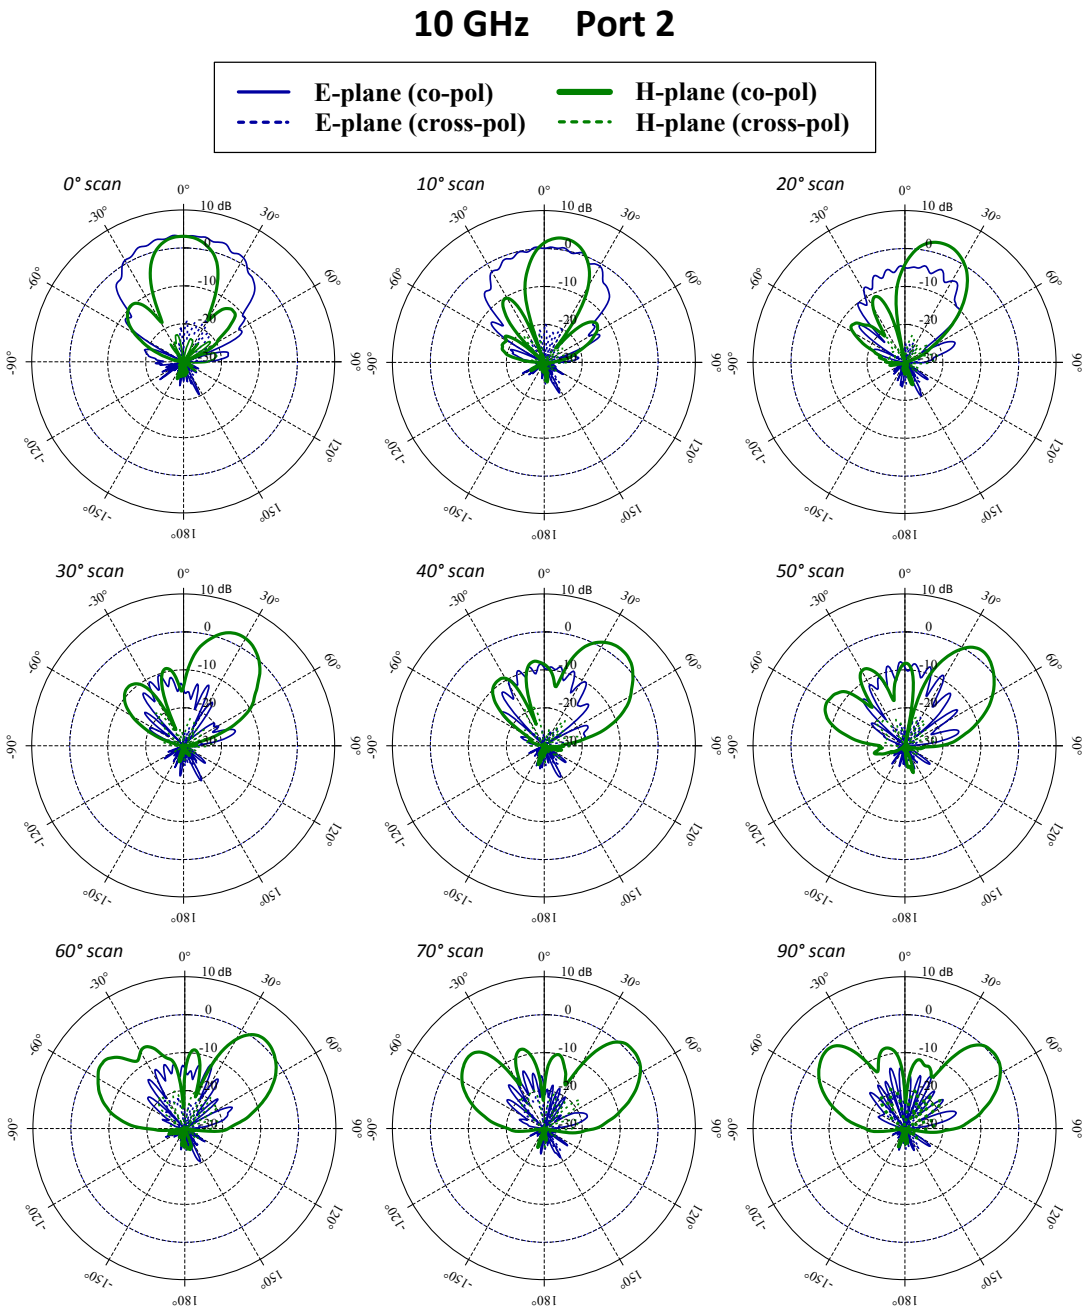

Figure 4.26. Measured radiation pattern of the 4-element phased array. Port 2 at 10 GHz.

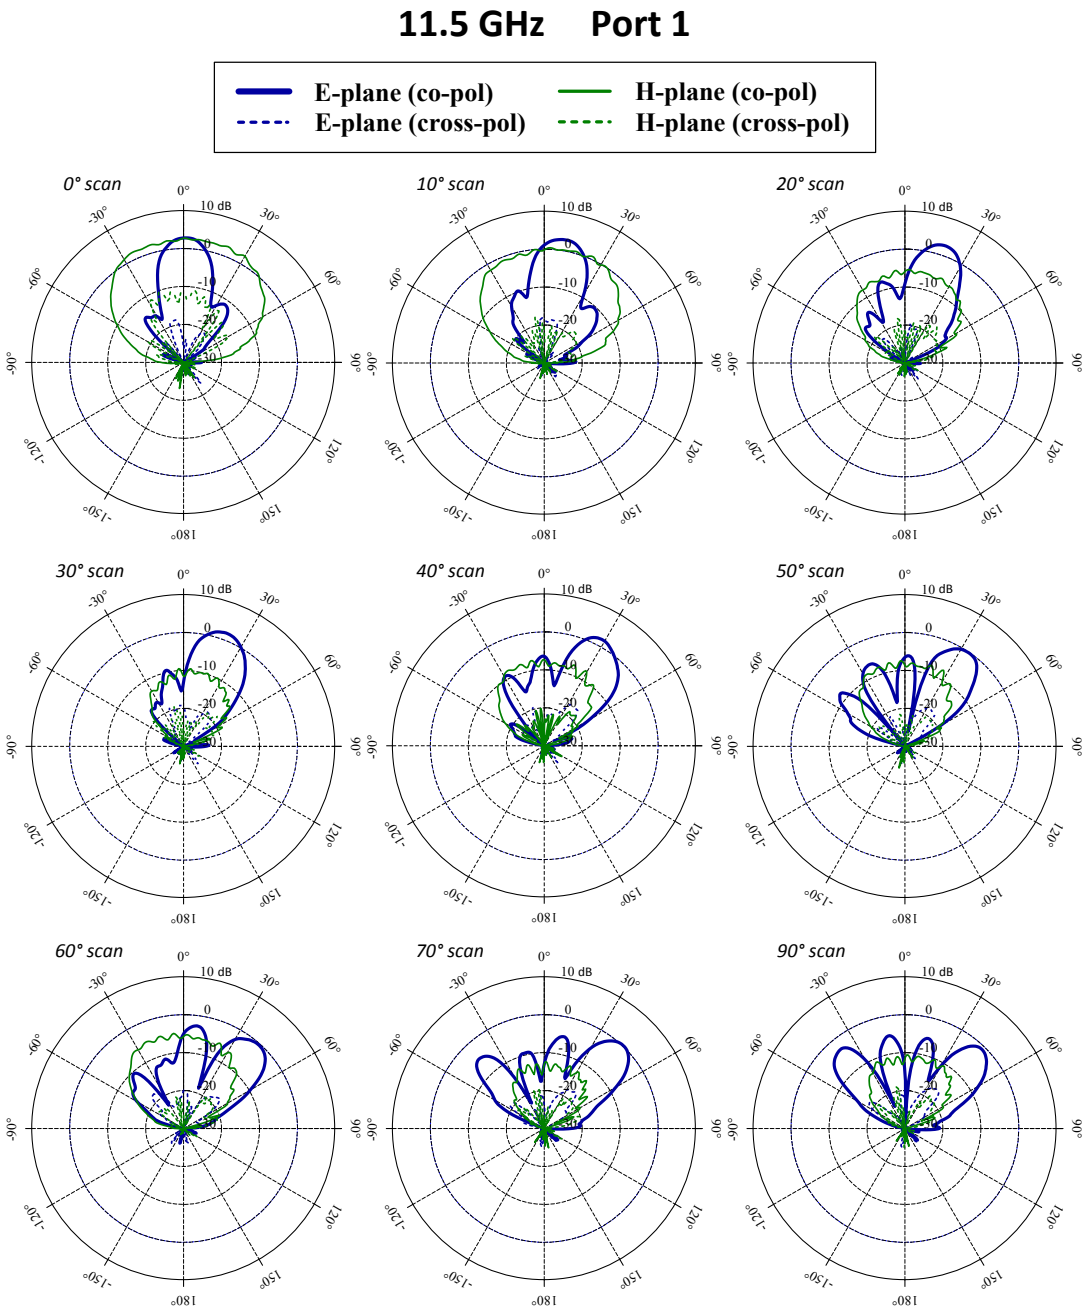

Figure 4.27. Measured radiation pattern of the 4-element phased array. Port 1 at 11.5 GHz.

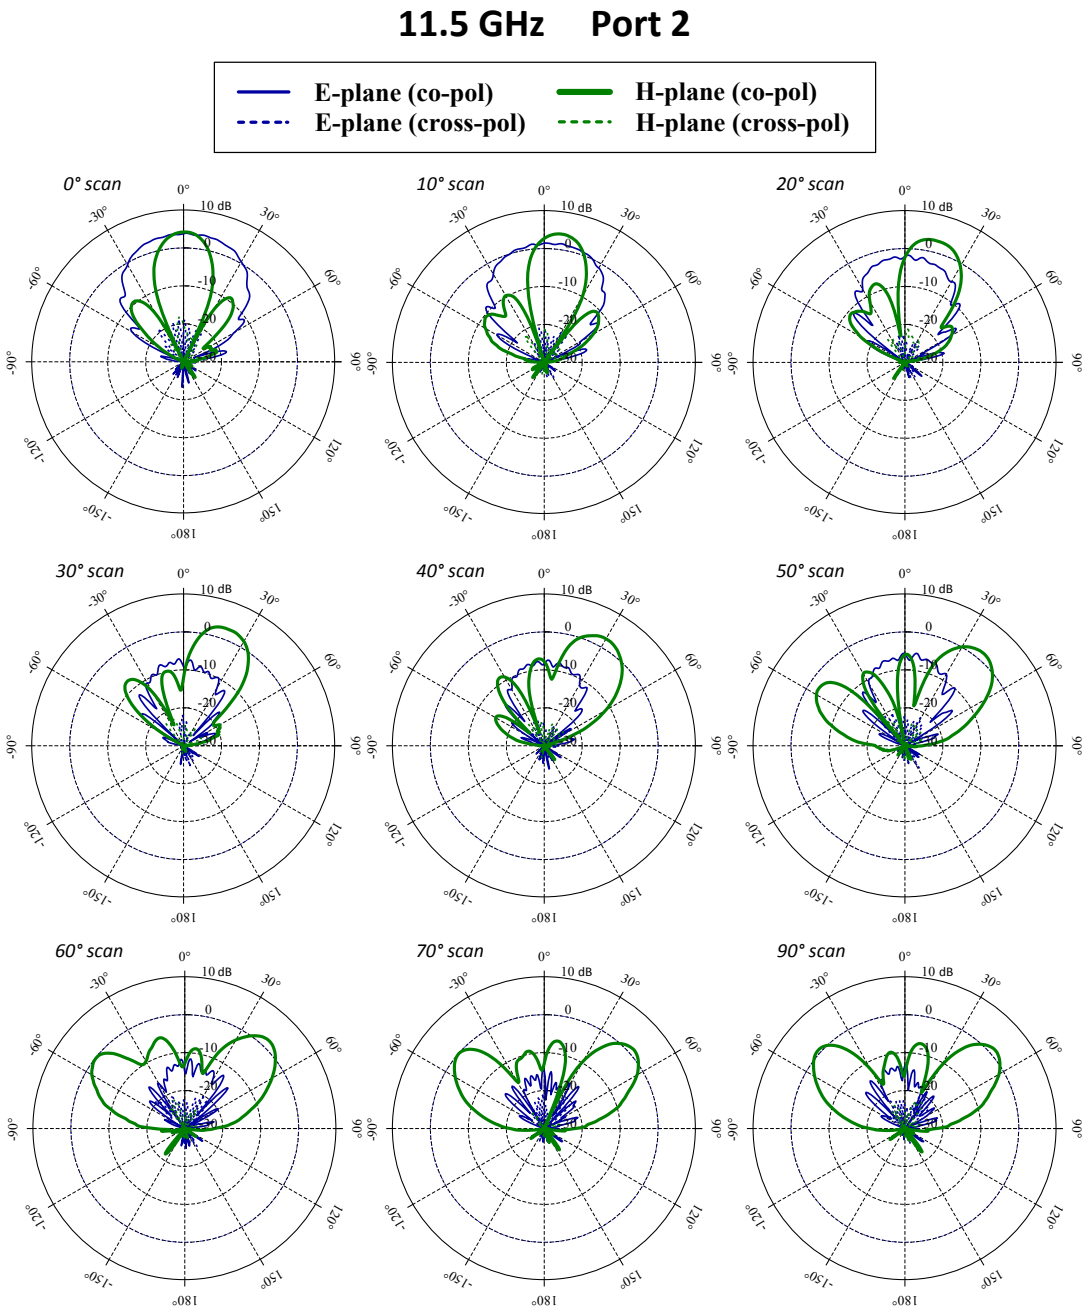

Figure 4.28. Measured radiation pattern of the 4-element phased array. Port 2 at 11.5 GHz.

Since this is a dual-polarized array, the E-plane is the scanning plane for port 1, and the H-plane is the scanning plane for port 2. At the center frequency (10 GHz), the array scans from a setting of 0° to 40° with virtually no change in peak gain (i.e., no scan loss). At the 50° setting, peak gain starts to decrease and continues through the 90° setting. This is caused by the directionality of the single-element antenna which is used. Also, the array steers to an angle slightly less than the setting would indicate. Again, this is due to the directionality of the single-element. The array factor points to the angle specified by the setting, but when it is multiplied by the single-element pattern, the 4-element array does not have an array factor with a narrow enough beamwidth to overcome the decrease in single-element gain.

The maximum scan angle of this array is approximately 45°. There are two sidelobes; the third lobe to appear is a grating lobe which becomes noticeable at a 50° scan, and at a 70° scan it dwarfs the sidelobes and approaches the magnitude of the main lobe. The sidelobes are around 10 dB below the main beam, and the cross-polarization levels are 15 - 20 dB below the main beam.

Port 1 has a measured HPBW (half-power beamwidth) of 21°-29° for the E-plane and 80°-89° for the H-plane. Port 2 has a measured HPBW of 23°-29° for the H-plane and 58°-67° for the E-plane. Note that the E-plane is the scanning plane for port 1, and the H-plane is the scanning plane for port 2. Since the single-element E-plane has a narrower beamwidth than its H-plane, it can be expected that for the array, the scanning plane of port 1 will have a narrower beamwidth than port 2, and the non-scanning plane

of port 2 will have a narrower beamwidth than port 1. This is seen in the measured HPBW.

At frequencies lower than 10 GHz, the element spacing d is less than 0.5λ. It can be seen from (4.6) that if β is constant and d decreases, then θ_0 must increase. Therefore, when β is set for a 10 GHz setting, frequencies lower than this will steer to a larger angle. The opposite is also true; higher frequencies will steer to a smaller angle. This effect is illustrated in Figs. 4.23-4.28.

At some frequencies, the main beam can actually increase in magnitude when the scan angle increases. According to theory, this should not happen, and it is probably due to two of the effects discussed earlier: the phase-shifter's phase instability with frequency and phase-shifter insertion loss variation with phase setting and frequency. The phased array is calibrated at 10 GHz. When other frequencies are used with this calibration, the phase shift can vary as seen in Fig. 4.10. This will effectively cause the calibration to be slightly off for different frequencies. Also, the phase-shifter insertion loss varies with phase setting and frequency, so the shifter setting at larger scan angles could potentially have less insertion loss than at lower scan angles. This would cause an increase in array gain for larger scan angles. This change in insertion loss with frequency and setting is illustrated in Fig. 4.9. These effects cause the slightly unusual results at some frequencies, but the array still behaves well and steers to approximately the desired scan angle at all frequencies using only a single calibration. Of course, non-calibration frequency anomalies can be corrected by a recalibration at any desired frequency.

I. Conclusion

The single-element antenna described in a previous section was used to create a 4x1 element phased array with a 0.5λ element separation at 10 GHz. A 1-to-4 power divider was designed to divide the power evenly between the four elements, and digitally controlled phase-shifters were used to steer the array. LabVIEW and a DAQ control the phase-shifters, and logic conversion circuits are required to convert from the standard 5 V TTL/CMOS logic of the DAQ to the 0/-3V complementary logic that the phase-shifters require. The array was calibrated at 10 GHz using a far-field phase-alignment method, and measurements were taken of the array's performance. The array successfully operates over a 3 GHz bandwidth with a maximum scan angle of approximately 45°.

The phased array can be improved with the addition of more elements. This will decrease the beamwidth of the array factor which will allow larger scan angles and form a more directed beam. Using a phase-shifter with a more consistent insertion loss and phase shift would also improve the array's performance. The addition of controllable amplifiers for each element could correct the phase-shifter's variable insertion loss problem and also allow for a non-uniform amplitude distribution which could narrow the array's beamwidth.

5. RECTENNA HISTORY

In wireless power transmission (WPT) systems, microwave power is transmitted wirelessly from one location to another where it is then converted into a useable form. The rectenna (rectifying antenna) is a crucial component in this system. It consists of a receiving antenna which collects microwave power and a rectifier which converts this microwave power into useable DC power. It is called a "rectenna" from the combination of "rectifier" and "antenna". The rectenna is used in numerous applications such as space power transmission (SPT) [32], wireless sensors [33], RFID tags [34], recycling ambient microwave energy [35], and powering devices in hazardous or difficult to reach places [36]. Since power transmission by wires is extremely efficient and cost effective, wireless power transmission is only a practical replacement in applications where it would be difficult or inconvenient to route power lines from the power source to the receiver or if power needs to be quickly delivered to an area without a useable power infrastructure such as for disaster relief.

Wireless power transmission was originally demonstrated by Heinrich Hertz in 1888 when he used a half-wavelength dipole spark gap to generate and transmit power at 500 MHz. He was able to detect this transmission at the receiver with the help of parabolic reflectors at both the transmitter and receiver. To generate this power, both sides of the dipole were charged with high-voltage which arced across the dipole gap and set up an oscillation along the length of the dipole which radiated from the antenna [37]-[38].

Nikola Tesla further demonstrated wireless power transmission in 1898 when he used Tesla coils to generate power at 150 kHz to light 200 light bulbs positioned 26 miles away [37] [39]. Tesla's high power wireless power transmission endeavors continued from 1899-1910 with limited success, but his activities did bring much attention to the idea [40].

During the 1920's and 1930's, researchers from the United States [41] and Japan [42] conducted feasibility studies into wireless power transmission and concluded that current technology was not sufficiently developed to make WPT feasible [37]. The major shortcoming was that devices did not exist which could transmit large amounts of electromagnetic power in a narrow beam. This shortcoming was addressed in the late 1930's when two microwave generating devices were invented. These were the velocity-modulated beam tube (now modified and known as the klystron tube) and the microwave cavity magnetron [38] [43]. Then in 1960, the US Department of Defense contracted Raytheon to build a very high-power, high-efficiency microwave tube (Amplitron) which had an output of 400 kW of CW power at 3 GHz and an efficiency of 80 percent [44]. This filled in the high-power microwave tube technology gap [38].

Another technology not sufficiently developed and preventing complete wireless power transmission systems was the conversion of microwave power to DC power [38]. The US Air Force contracted a number of companies to study the rectification of microwave power [45]. The most important study for WPT was one at Purdue University investigating the use of semiconductor diodes as an efficient rectifier [46].

Also during this time, Raytheon supported William Brown in developing a close-spaced thermionic diode rectifier to be used for a WPT demonstration [47].

In May of 1963 William Brown and others demonstrated a complete WPT system at Raytheon's Spencer Laboratory to a large group of US DOD officials who had sponsored the development of an Amplitron. For the demonstration, a magnetron was used to generate 400 W of microwave power which was transmitted to a receiver and used to drive a DC motor attached to a fan at 100 W [38].

Motivated by Raytheon's previous successes, the US Air Force expressed interest in powering aircraft with WPT. In October of 1964, William Brown and others demonstrated the sustained flight of a tethered helicopter powered by WPT [48]. This demonstration garnered much news coverage both on TV and the newspaper, including a spot on Walter Cronkite's CBS news program. This event validated the possibility of powering larger surveillance and communication aircrafts with WPT, and it was the first time that most people had heard of wireless power transmission or rectennas [37].

The Marshall Space Flight Center (MSFC) became interested in WPT as a means to power satellites from a central space station in low-Earth orbit [40] following a demonstration given by Brown in a board room where he powered a rectenna driven propeller from a 100 W microwave beam on the other side of the room [38]. This resulted in a contract in 1970 with Raytheon to build a high efficiency WPT system demonstration. An initial system was demonstrated at the MSFC in September 1970 with an overall DC-to-DC efficiency of 26%. The next few years of the contracts included work on improving rectenna design, microwave beam launching methods, and

measurement tools which culminated in a system with an overall DC-to-DC efficiency of 48%. Important improvements included using a large transmitting antenna with a Gaussian beam and minimal sidelobes. The use of a Gaussian beam meant that the power density at the center of the rectenna array may be 50 times higher than at the edge of the rectenna array. The spacing of the rectenna elements and the DC load of each element were adjusted to maximize absorbed power and efficiency [38].

In 1968, Dr. Peter Glaser introduced a concept which would change the future development of wireless power transmission [38]; this was the concept of the solar-power satellite (SPS) or space solar power (SSP) [49]. This describes a system whereby a geosynchronous satellite comprised of solar cells collects the sun's energy and transmits this energy via microwaves to a giant array of rectennas on earth's surface. The rectennas would then convert this microwave power to DC which would supply the power grid. This was proposed to be a new form of renewable energy which could potentially replace limited and polluting fossil fuels.

The proposed solar-power satellite concept led to a technical session on SPS in 1970 at the International Microwave Power Institute at Hague, and its papers were published in a special issue of the Journal of Microwave Power [50]. NASA also funded a study in 1973 on the feasibility of a satellite solar power station led by a four company team of Arthur D. Little, Raytheon, Grumman Aerospace, and Textron [51]. This led NASA to further support microwave power transmission with oversight from both the Jet Propulsion Laboratory (JPL) and Lewis Research Center (LeRC) [52]-[53]. One of the studies led to a demonstration in the Mojave Desert at JPL's Goldstone Facility in

1975 where power was transmitted one mile with a DC output of 30 kW [53]. This was an increase in transmitted power of 50 times and an increase in distance of 100 times over what had previously been demonstrated [40]. Another study led by LeRC from 1976-1977 led to a transition from a three-plane rectenna system to a two-plane system which eventually allowed the much lighter, cheaper, and simpler thin-film etched circuits to replace the old bulky standard [38]. Following this development, almost all rectennas have been etched on thin-film using photolithography.

Rectenna conversion efficiency continued to improve, and in 1977 Brown measured the highest microwave conversion efficiency ever recorded. He used a GaAs-Pt Schottky barrier diode and an aluminum bar dipole to achieve a 90.6% conversion efficiency [54].

In 1980, Canada created the Stationary High-Altitude Relay Program (SHARP) to develop a long endurance high-altitude aircraft powered by WPT [55]. In September of 1987, a 1/8 scale SHARP prototype flew for 20 minutes at an altitude of 150 meters under the power of WPT. The aircraft had a wingspan of 4.5 meters and was powered by a 10 kW source transmitted at 2.45 GHz by a parabolic dish antenna on the ground [37].

The 1980's saw the shift of WPT leadership from the United States to Japan. This was spurred by Japan's desire to meet their increasing energy demands with limited natural resources [37]. In 1983, Japan carried out their Microwave Ionosphere Nonlinear Interaction Experiment (MINIX) [56] where 830 W was transmitted from one

rocket to another in the ionosphere. This marked the first WPT experiments in the ionosphere [37].

Wireless power transmission systems tended to operate at 2.45 GHz because of its minimal attenuation through the atmosphere, abundant technology base, and its location in the center of the industrial, scientific, and medical (ISM) band. This was until ARCO Power Technologies designed a rectenna in 1991 at 35 GHz with a 72% conversion efficiency [57]. This frequency change reduced component size and aperture area; however the components at this frequency are both expensive and inefficient. Therefore, 5.8 GHz (also in the ISM research band) is used as a compromise between these frequencies because it decreases component size and aperture area without the expense and inefficiency incurred at 35 GHz. This rise in frequency, however, does result in higher attenuation through the atmosphere in thunderstorms [58].

In the 1990's, Japan conducted the Microwave Lifted Airplane Experiment (MILAX) which involved collaboration with a number of Japanese Universities and corporations [59]. A balsa wood airplane with a 2.5 meter wingspan was flown for 400 meters at an altitude of 15 meters which lasted 40 seconds. It was powered by a phased array transmitter operating at 2.411 GHz and mounted to a van. The van followed the airplane and transmitted power to rectennas mounted on the airplane [37].

In 1993, Japan conducted the International Space Year – Microwave Power Transmission in Space (ISY-METS) experiment to demonstrate WPT in space between two rockets [60]. One rocket transmitted 800 W of power to the other rocket at 2.45

GHz. The dual-polarized rectenna was developed by McSpadden and Chang at Texas A&M University [61].

In the late 1990's, dual and circular polarization became the preferred polarization for wireless power transmission, especially SSP. Microwaves passing through the earth's atmosphere undergo Faraday rotation which can cause alignment problems with linear polarization systems and severely degrade performance. Dual and circular polarization systems do not suffer this same performance degradation since broadside alignment of transmitting and receiving antennas is arbitrary. This allows both antennas of dual and circularly polarized systems to be rotated without any change in performance [37].

NASA reassessed the SSP concept with its "Fresh Look Study" from 1995-1997 and concluded that with recent technological advances, SSP could be feasible but still remained challenging [62]. This led to an SSP Exploratory Research and Technology (SERT) study in 1999 which involved researchers from around the United States. One result from the SERT study was Strassner and Chang's 2002 design of a circularly polarized rectenna array which utilized a folded dipole antenna called a dual rhombic loop antenna (DRLA). The DRLA is circularly polarized and has a large gain of 10.7 dBi. The array has a 78% RF-to-DC conversion efficiency and operates at 5.61 GHz [63]. Also in 2002, McSpadden and Mankins estimated that SPS systems have the potential to achieve 45% DC-to-DC efficiencies [64].

A serious problem which arises in WPT systems is that of beam alignment. If the microwave beam is narrow, as would be required for a long-range, high-efficiency

system, it is difficult to keep the transmitter and receiver properly aligned. This is especially problematic with SPS systems and aircraft applications since the transmission distance is large and the atmosphere can unpredictably alter the microwave beam's path. A proposed method to solve this problem is through the use of a retrodirective array [65]-[68]. This system uses a pilot beam to align the antennas and alter the direction that the transmitting antenna array is focused. The phase of the pilot beam is acquired by receivers located on each element of the transmitting array. This phase is then compared to a reference, phase conjugated and fed back to the phase controller for that element of the transmitting array.

There are some environmental concerns about the use of an SPS system. Electromagnetic exposure is the largest concern from the public, but it has been shown that potential exposure of the general public from a 5-GW reference SPS system would be 0.1 $\mu W/cm^2$ in most places and 10 $\mu W/cm^2$ in some small grating lobe areas. This is well below accepted environmental safety levels around the world which range from 100-10,000 $\mu W/cm^2$. Radio frequency interference should be a larger environmental concern. Many wireless systems operate at 2.45 GHz, and an SPS has the potential to disrupt these communications; unblocked harmonics are also a potential interference. Frequency allocation will be very important for a successful SPS system [69]. High powered microwave transmission from space will also cause some localized heating of the ionosphere. There is some concern that this could interfere with telecommunication systems [70], perturb the earth's magnetic field, or have some other environmental impact [71].

The application of wireless power transmission currently drawing the most attention is space solar power. This has become even more true with Japan's announcement that it plans to have a MW class SSP system in place in the 2020's and a commercial 1 GW class SSP system in place in the 2030's [72]. This stems from Japan's desire for unlimited clean energy to replace its limited energy resources and reliance on foreign oil. With this SSP commitment and the numerous other WPT applications, rectennas have a bright and promising future.

6. RECTENNA OPERATION THEORY *

A. Wireless Power Transmission System

Wireless power transmission (WPT) systems and wireless communication systems are based on the same technology with the Maxwell equations governing both. The fundamental difference between the two is efficiency.

In wireless communication systems, the microwave is simply a carrier of information, so bandwidth is required to encode this information, and noise is a major concern. Efficiency is not the top priority and only becomes problematic if the received power is below the noise level. However, WPT systems do not carry any information, so a very narrow band can be used, and noise is not a problem. Efficiency, however, is of paramount importance for a practical WPT system. It is dependent on component efficiencies as well as the ability to focus the microwave beam on the rectenna.

The wireless power transmission system consists of three core system blocks as seen in Fig. 6.1. The first block is the DC-to-RF transmission block which converts the DC (or AC) source power to RF power and also radiates this power. The source of the power is dependent on the application and could be photovoltaic solar cells for use in space solar power (SSP), or it could be a power plant for terrestrial applications. The power can be converted to RF by either a solid-state semiconductor circuit (below 10 GHz) or a microwave tube such as a magnetron or a klystron [38]. The efficiency of the

first block η_t is the product of the DC-to-RF conversion efficiency and the transmission efficiency.

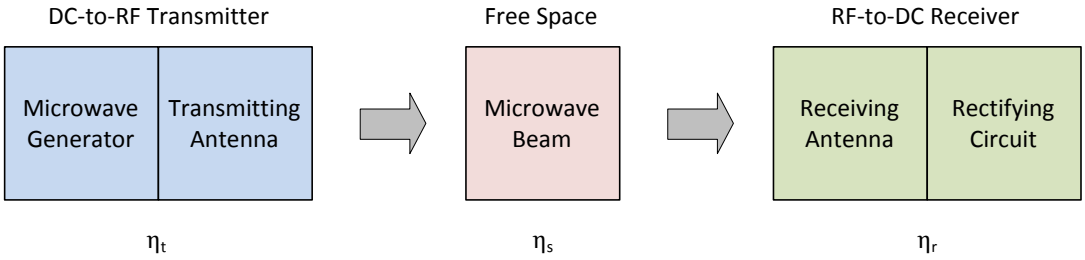

Figure 6.1. Block diagram of a wireless power transmission (WPT) system.

The second block is the free space transmission channel which accounts for propagation losses through the space separating the transmitter and receiver. Its efficiency η_s is the ratio of received power to transmitted power. For high-efficiency transmission, the microwave power must be transmitted with optimal power density. Goubau and Schwering showed that microwave power can be transmitted with efficiencies approaching 100% if the correct transmitting aperture is properly illuminated [73]-[74]. The efficiency is a function of the parameter τ [75] which is given by

$$\tau = \frac{\sqrt{A_r A_t}}{\lambda D} \tag{6.1}$$

where A_r and A_t are the aperture areas of the receiver and transmitter respectively, λ is the wavelength of the transmitted wave, and D is the distance between the transmitter and receiver. A graph of efficiency vs the parameter τ can be seen in [75]. This

presumes an aperture power density as seen in [75]. As the efficiency approaches 100%, the aperture power density approaches the shape of an edge truncated Gaussian curve. The efficiency can be approximated as

$$\eta = \left(1 - e^{-\tau^2}\right) \times 100\% \quad . \tag{6.2}$$

Larger values of τ result in higher efficiency, and the receiving and transmitting aperture areas are directly related to τ, so larger apertures result in higher transmission efficiency. Therefore, a compromise must be found between size and efficiency.

The final block is the RF-to-DC receiving block which receives the microwave power with the receiving antenna and converts this power into DC power with a rectifying circuit; this power conversion efficiency η_r determines the performance of the rectenna. This final block is called a rectenna from the combination of "rectifying" and "antenna". A block diagram of the basic components of a rectenna can be seen in Fig. 6.2 and includes an antenna, a harmonic rejection filter, a diode, a DC-pass filter (capacitor), and a load. The harmonic rejection filter allows microwaves to enter the rectifying circuit but rejects any harmonics created by the diode due to its non-linear behavior. This prevents diode harmonics from radiating back out through the antenna. The diode converts the microwave power into DC power, and the DC-pass filter reflects any unconverted microwave power back to the diode which prevents microwave power from reaching the load. By utilizing filters to block microwave power on both sides of the diode, any unconverted microwave power should be reflected back to the diode and eventually rectified to DC power, thereby improving conversion efficiency. The only

way that energy can escape from the system is in the form of DC at the output or as a reflected fundamental at the input. The DC output voltage is measured across the load. A method to further reduce harmonic radiation from the rectenna is through the use of frequency selective surfaces. In this scheme, a frequency selective surface which passes the fundamental frequency and blocks the second and third harmonics is placed in front of the rectenna. This will attenuate harmonics which attempt to radiate from the rectenna [76]-[77].

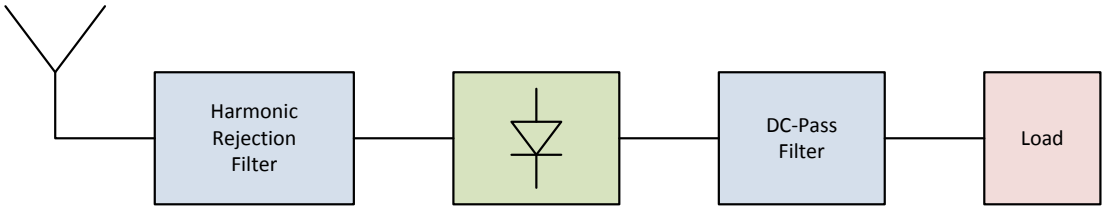

Figure 6.2. Block diagram of a rectenna.

Optimization of the rectifying circuit is important to maximize efficiency. The diode must be matched to the input power level, the input impedance, and the load. The distance between the diode and capacitor is crucial because in addition to reflecting microwave power, the capacitor is used to tune out the diode's reactance and improve conversion efficiency. This distance is typically a quarter-wavelength at the fundamental frequency, and since the capacitor can be considered a short at RF, this will have the diode seeing an open circuit at ω, 3ω, 5ω, . . . and a short circuit at 2ω, 4ω, 6ω, . . . This results in the blockage of microwave power (fundamental frequency and all

harmonics) and the passing of DC power. If the rectenna is properly designed then the efficiency becomes a property of diode parameters.

The conversion efficiency of the rectenna is calculated as

$$\eta = \frac{P_{DC}}{P_{received}} \times 100\% \tag{6.3}$$

where P_{DC} is the measured output power across the load at DC and $P_{received}$ is the RF power received by the rectenna's antenna. $P_{received}$ can be calculated using the Friis transmission equation [74] by

$$P_{received} = P_t G_t G_r \left(\lambda_0 \big/ 4\pi r \right)^2 = A_{er} \frac{P_t G_t}{4\pi r^2} \tag{6.4}$$

where the effective area of the receiving antenna is

$$A_{er} = \frac{G_r \lambda_0^2}{4\pi} \quad . \tag{6.5}$$

P_t is the transmitted power, G_t and G_r are the transmitting and receiving antenna gains respectively, λ_0 is the free space wavelength, and r is the distance between the transmitter and the rectenna. Rectenna efficiencies are oftentimes given as a function of received power density S_D which can be calculated from

$$S_D = \frac{P_{received}}{A_{er}} = \frac{P_t G_t}{4\pi r^2} \quad . \tag{6.6}$$

The overall efficiency η_{all} of the wireless power transmission system is the ratio of DC output power at the rectenna to DC (or AC) input power and is given by

$$\eta_{all} = \eta_t \times \eta_s \times \eta_r \quad . \tag{6.7}$$

B. Rectenna Operation Theory

The basic rectenna rectifying circuit is based on a half-wave rectifier with a capacitor added in shunt. It is therefore important to understand the operation of a half-wave rectifier so that the rectenna's operation can be understood. An explanation of a half-wave rectifier can be found in [78] and rectenna operation theory is discussed in [58],[79]-[81]. Some of this information will be summarized here.

A half-wave rectifier and its voltage waveforms are illustrated in Fig. 6.3. Assuming an ideal diode and a perfect input sinusoid v_s, during the positive half-cycle ($v_s \geq 0$) the diode will not conduct which will cause all of the current to flow through the load R_L. During the negative half-cycle ($v_s \leq 0$), the current will flow through the diode,

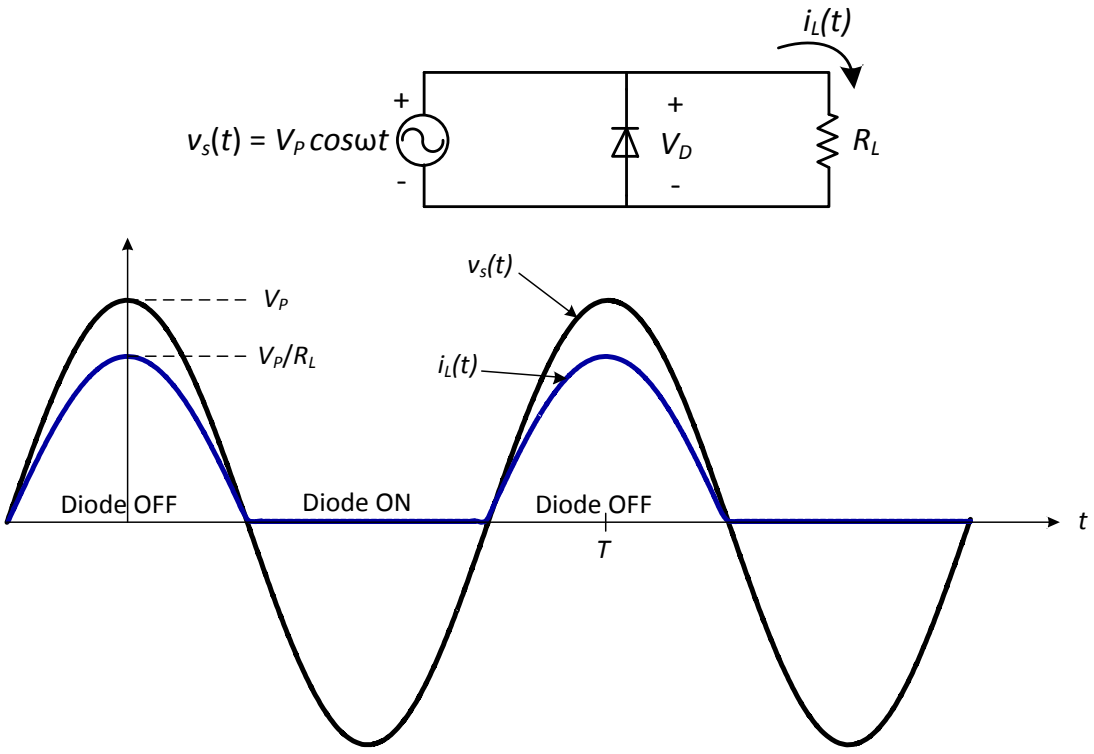

Figure 6.3. Half-wave rectifier circuit and waveforms.

bypassing the load. This will cause the current through R_L to be unidirectional and have a finite average value or a DC component. This is a rectification of the source current which can be used to generate DC from AC. The average rectified DC current $I_{L,DC}$ can be found from

$$I_{L,DC} = \frac{1}{T}\int_{T} i_L(t)\,dt = \frac{1}{T}\left(\int_{-T/4}^{T/4} \frac{V_P}{R_L}\cos\omega t\,dt\right) \tag{6.8}$$

where T is the period of the incident sinusoid and $\omega = 2\pi/T$. Solving this integral gives an average DC current of

$$I_{L,DC} = \frac{V_P}{\pi R_L}\ . \tag{6.9}$$

Applying Ohm's law gives an average rms DC voltage across the load of V_p/π.

If a capacitor (DC-pass filter) is added in shunt to this half-wave rectifier circuit, it will result in the waveform seen in Fig. 6.4. The voltage across the load is

$$v_L(t) = V_P\, e^{-t/R_L C} \tag{6.10}$$

where R_LC is the time constant and t is the time measured from the peak of the waveform where $v_L(t) = V_p$. The exponential decrease in the load voltage can be approximated by a straight line since the period is very short compared to the time constant at microwave frequencies. Equation (6.10) can be expanded using a power series [82] as

$$v_L(t) = V_P\, e^{-t/R_L C} = V_P\left[1 + \frac{-t/R_L C}{1!} + \frac{\left(-t/R_L C\right)^2}{2!} + \frac{\left(-t/R_L C\right)^3}{3!} + \ldots\right]. \qquad (6.11)$$

Because of the straight line approximation for the exponential decay, the linear terms of (6.11) are kept while the rest are discarded. The minimum value of v_L is at $t = T$ and is then

$$V_{\min} = v_L(t = T) \approx V_P\left(1 - \frac{T}{R_L C}\right) = V_P\left(1 - \frac{1}{f R_L C}\right) \ . \qquad (6.12)$$

Once the voltage $v_L(t)$ deceases to V_{min}, the diode will be non-conducting and the source voltage will be rising above V_{min} which will again raise the load voltage v_L to its peak value of V_P. The peak-to-peak ripple voltage of V_L is

$$V_r = V_{\max} - V_{\min} = \frac{V_P}{f R_L C} \ , \qquad (6.13)$$

and the average rms DC voltage across the load is

$$V_{L,DC} = \frac{V_{\max} + V_{\min}}{2} = V_P\left(1 - \frac{1}{2 f R_L C}\right) \approx V_P \ . \qquad (6.14)$$

At microwave frequencies, the time constant $R_L C$ is much larger than the period T which gives rise to a small ripple voltage V_r, resulting in an average DC load voltage of approximately V_P. Consequently, it has been shown that by adding the shunt capacitor, the average DC load voltage is raised from V_P/π to approximately V_P.

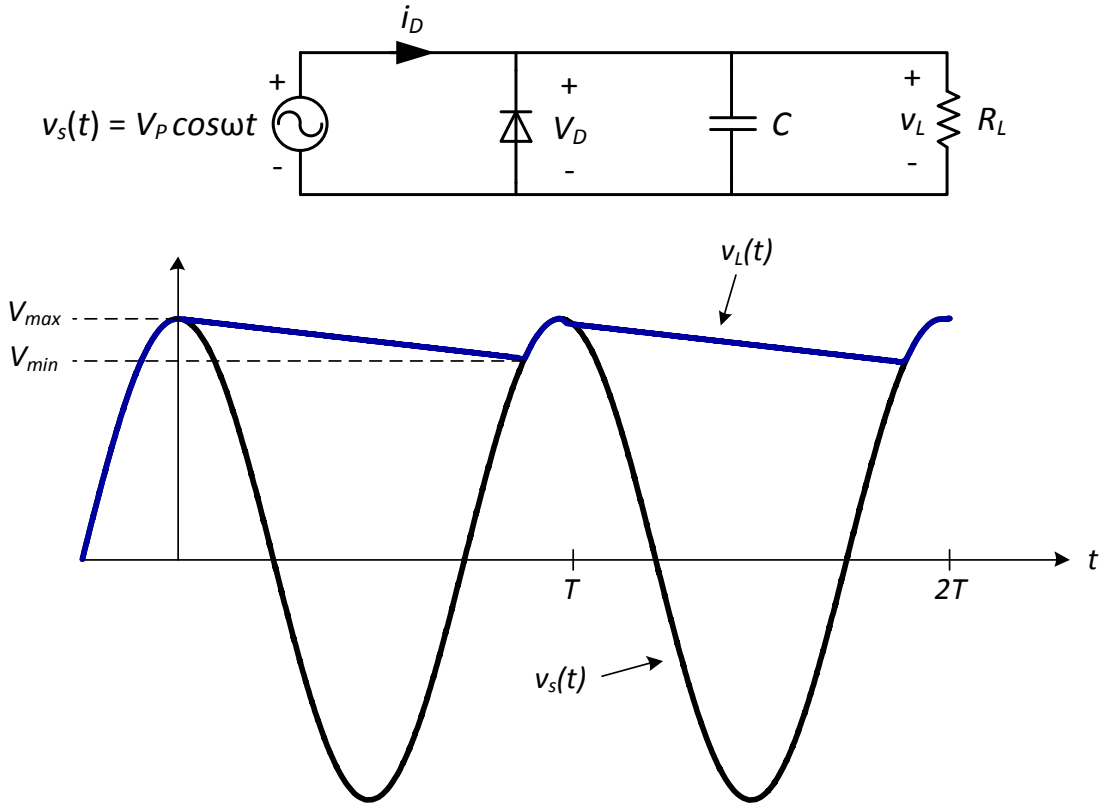

Figure 6.4. Half-wave rectifier with capacitor circuit and waveforms.

C. Analytical Model of Rectenna Efficiency

A simplified mathematical model described by Yoo [79]-[80] can be used to predict the conversion efficiency of the rectenna. This model makes a number of simplifications which prevent it from being accurate enough to be useful for precise rectenna design, but it does demonstrate rectenna behavior and reveal the effect of parameter variation on performance. It is only dependent on the simplified diode parameters and microwave circuit losses at the fundamental frequency. This model does not include harmonics created by the diode, and diode parasitics are excluded. It also assumes ideal diode characteristics (Fig. 6.5) such as: $R_j = 0$ for forward bias, $R_j = \infty$ for reverse bias, and no current through C_j during forward bias. Due to ideal condition assumptions, the results from this model can be considered as the maximum conversion efficiencies that would result from a diode with the same parameters.

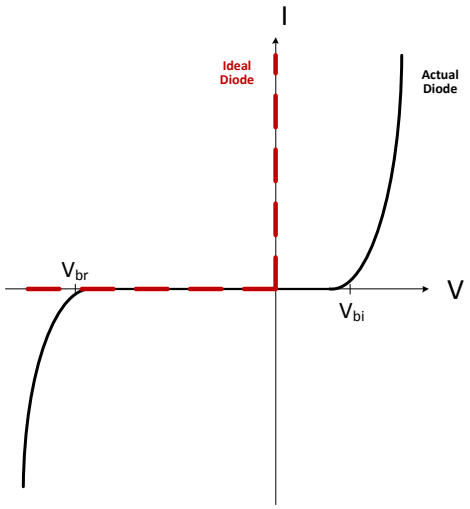

Figure 6.5. Voltage-Current curves of an ideal diode and an actual diode. The built-in turn-on voltage V_{bi} is the voltage at which forward current starts to flow through the diode. The reverse breakdown voltage V_{br} is the minimum reverse voltage which will cause reverse current flow through the diode.

The equivalent circuit of the diode rectifier which is used to derive the mathematical model is shown in Fig. 6.6. The nonlinear components R_j and C_j represent the diode junction with ideal diode conditions applied: junction resistance $R_j = 0$ for forward bias and $R_j = \infty$ for reverse bias. The voltage V_D is the voltage across the diode and the voltage V_j represents the voltage across the diode's junction. The diode's voltage waveforms are displayed in Fig. 6.7. The angle θ_{on} is the forward bias turn-on angle and ϕ is the phase lag of the junction voltage behind the incident diode voltage.

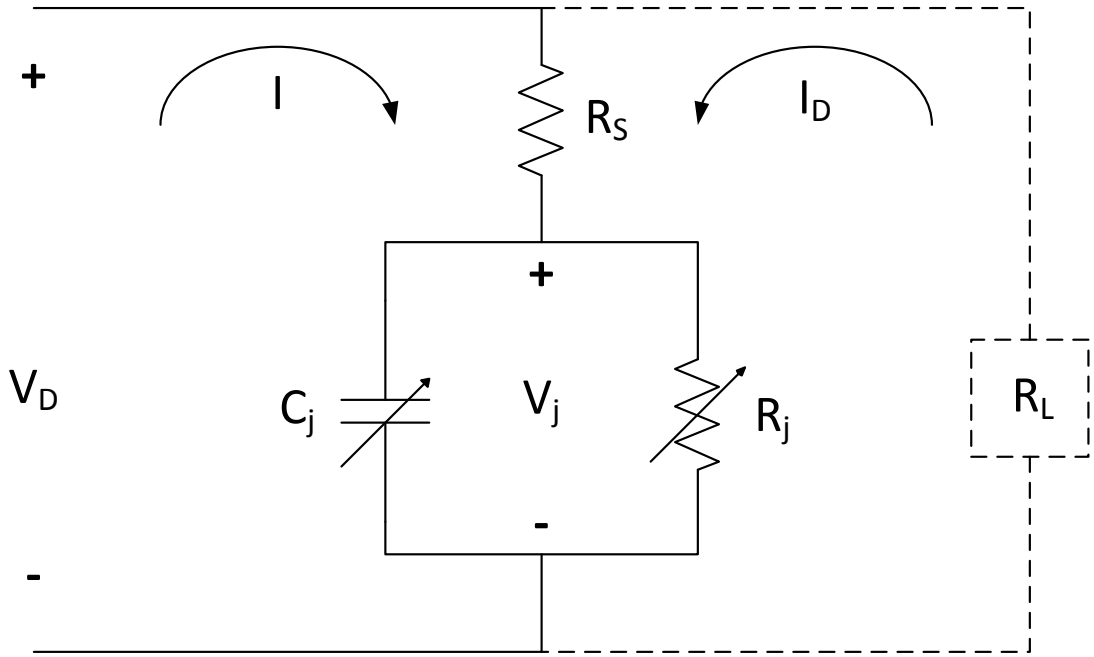

Figure 6.6. Equivalent circuit of the diode rectifier.

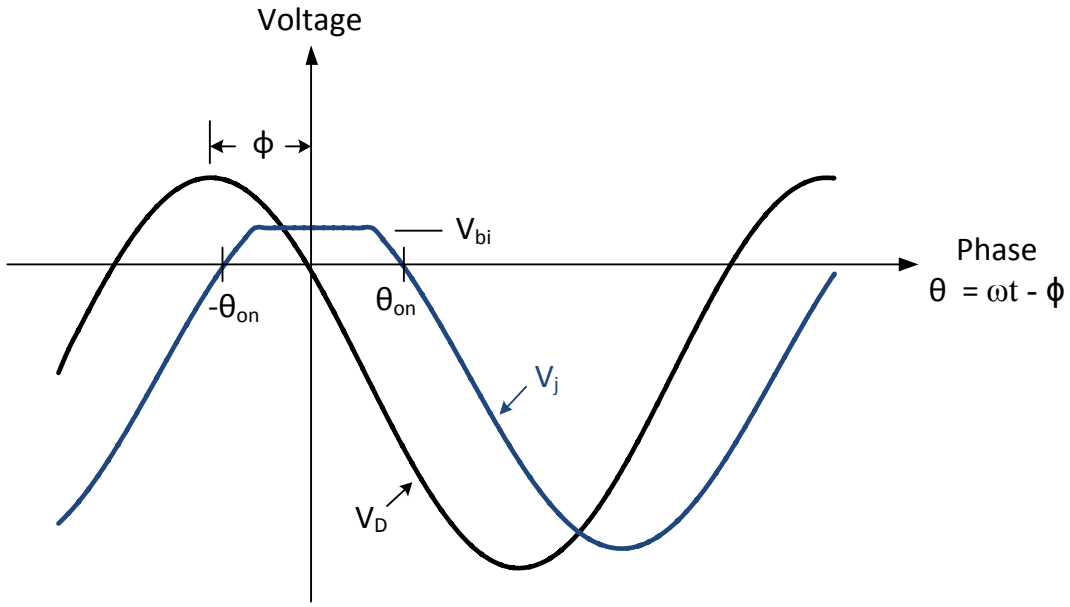

Figure 6.7. Voltage waveforms of the diode rectifier. V_D is the voltage across the physical diode, and V_j is the voltage across the diode junction.

The incident diode voltage V_D is composed of a fundamental frequency and a DC component. It can be expressed as

$$V_D = -V_0 + V_1 \cos(\omega t) \tag{6.15}$$

where V_0 is the self-biasing DC output voltage across the load R_L and V_1 is the peak voltage of the incident microwave signal. The incident microwave signal produces a DC output voltage which biases the diode. This biasing level increases through a few cycles and also as the input power level increases. The diode junction voltage is

$$V_j = \begin{cases} -V_{j0} + V_{j1}\cos(\omega t - \phi) & \text{, when diode is off} \\ V_{bi} & \text{, when diode is on} \end{cases} \tag{6.16}$$

where V_{j0} is the DC component of the diode junction voltage and V_{j1} is the peak voltage of the first harmonic of the diode junction voltage when the diode is off ($V_j < V_{bi}$). When the diode is on, the junction voltage V_j is equal to the built-in turn-on voltage of the diode V_{bi} which is set to zero in this derivation (ideal diode). The phase ϕ is the angle that the diode's junction voltage lags the incident microwave's voltage.

The DC output voltage V_0 can be determined from the junction voltage V_j. The average value of V_j in each cycle can be calculated as

$$V_{j,dc} = \frac{1}{2\pi}\int_{0}^{2\pi} V_j \, d\theta = \frac{1}{2\pi}\int_{-\theta_{on}}^{\theta_{on}} V_{bi} \, d\theta + \frac{1}{2\pi}\int_{\theta_{on}}^{2\pi-\theta_{on}} (-V_{j0} + V_{j1}\cos\theta)\, d\theta \,. \qquad (6.17)$$

The first term in (6.17) corresponds to the forward-biased region, and the second term corresponds to the reverse-biased region. Note that the phase lag ϕ is assumed to be zero for this derivation. Integrating (6.17) gives

$$V_{j,dc} = V_{bi}\frac{\theta_{on}}{\pi} - V_{j0}\left(1 - \frac{\theta_{on}}{\pi}\right) - \frac{V_{j1}}{\pi}\sin\theta_{on} \quad . \qquad (6.18)$$

Applying Kirchhoff's voltage law along the DC path as illustrated in Fig. 6.6 by the dotted line gives

$$V_0 = V_{j,dc}\frac{R_L}{R_S + R_L} \,. \qquad (6.19)$$

The diode switching occurs when the junction voltage V_j is equal to the turn-on voltage V_{bi} and $\omega t = \theta_{on}$, so from (6.16),

$$V_{bi} = V_j = -V_{jo} + V_{j1}\cos\theta_{on} \qquad (6.20)$$

which can be rearranged to give an expression for the turn-on angle

$$\cos\theta_{on} = \frac{V_{bi} + V_{j0}}{V_{j1}} \quad . \tag{6.21}$$

When the diode is off, R_j is infinite and Kirchhoff's voltage law can be applied to the RF loop in Fig. 6.6 to give

$$-V_D + IR_S + V_j = 0\,, \tag{6.22}$$

and since all current is flowing through C_j when the diode is off,

$$I = \frac{d(C_j V_j)}{dt}\,. \tag{6.23}$$

Equations (6.22) and (6.23) can be combined to give

$$I = \frac{d(C_j V_j)}{dt} = \frac{V_D - V_j}{R_S} \tag{6.24}$$

where C_j can be expressed as a harmonic function of V_D:

$$C_j = C_0 + C_1\cos(\omega t - \phi) + C_2\cos(2\omega t - 2\phi) + ... \tag{6.25}$$

Substituting (6.15), (6.16), and (6.25) into (6.24) and neglecting terms higher than the second harmonic gives

$$\omega R_S\left(C_1 V_{j0} - C_0 V_{j1}\right)\sin\theta = V_{j0} - V_0 + \left(V_1\cos\phi - V_{j1}\right)\cos\theta - V_1\sin\phi\sin\theta \tag{6.26}$$

where $\theta = \omega t - \phi$ for simplicity. Since this equation is valid whenever the diode is off, each sinusoidal term should separately be satisfied during the diode's off period as follows:

$$V_{j0} = V_0 \tag{6.27}$$

$$V_{j1} = V_1\cos\phi \tag{6.28}$$

$$V_1 \sin\phi = \omega R_S \left(C_0 V_{j1} - C_1 V_{j0} \right) \ . \tag{6.29}$$

An expression for the turn-on angle can be derived by combining (6.18), (6.19), (6.21), and (6.27) into

$$\tan\theta_{on} - \theta_{on} = \frac{\pi R_S}{R_L \left(1 + \frac{V_{bi}}{V_0} \right)} \ . \tag{6.30}$$

It can be seen that the ratio of R_s to R_L and the ratio of V_{bi} to V_0 are the only variables that determine θ_{on}. Note that the input power will affect V_0, but the expression for θ_{on} is not directly dependent on input power.

The diode efficiency η is defined as

$$\eta = \frac{P_{DC}}{P_{Loss} + P_{DC}} \tag{6.31}$$

where P_{DC} is the DC output power and P_{Loss} is the power dissipated by the diode. P_{DC} and P_{Loss} are defined as

$$P_{DC} = \frac{V_0^2}{R_L} \tag{6.32}$$

$$P_{Loss} = Loss_{on,R_S} + Loss_{off,R_S} + Loss_{on,diode} \tag{6.33}$$

where $Loss_{on,Rs}$ and $Loss_{off,Rs}$ are the losses from R_S when the diode is on and off, respectively. $Loss_{on,diode}$ is the loss from the diode when the diode is on. The loss terms of (6.33) can be expressed as

$$Loss_{on,R_S} = \frac{1}{2\pi} \int_{-\theta_{on}}^{\theta_{on}} \frac{\left(V_D - V_{bi} \right)^2}{R_S} d\theta \tag{6.34}$$

$$Loss_{off,R_S} = \frac{1}{2\pi}\int_{\theta_{on}}^{2\pi-\theta_{on}} \frac{\left(V_D - V_j\right)^2}{R_S} d\theta \tag{6.35}$$

$$Loss_{on,diode} = \frac{1}{2\pi}\int_{-\theta_{on}}^{\theta_{on}} \frac{\left(V_D - V_{bi}\right)V_{bi}}{R_S} d\theta \quad . \tag{6.36}$$

Since the junction resistance is assumed to be infinite during the off cycle of the diode, the loss through the diode during the off cycle is neglected. These power loss terms are the time-average products of the voltage across each element and the current through this element. The total power lost from the series resistance R_s can be found from using (6.15), (6.16), (6.24), and (6.28) in (6.34) and (6.35) and setting $\phi = 0$ as

$$L_{R_S} = \frac{1}{2\pi R_S}\left[\int_{-\theta_{on}}^{\theta_{on}} \left(-V_0 - V_{bi} + V_1\cos\theta\right)^2 d\theta + \left(\omega R_S C_j V_1\right)^2 \int_{\theta_{on}}^{2\pi-\theta_{on}} \sin^2\theta\, d\theta\right], \tag{6.37}$$

and the power lost from the diode junction can be found from substituting (6.15) into (6.36) and setting $\phi = 0$ as

$$L_{diode} = \frac{1}{2\pi R_S}\int_{-\theta_{on}}^{\theta_{on}} V_{bi}(-V_0 - V_{bi} + V_1\cos\theta)d\theta \quad . \tag{6.38}$$

During the diode off cycle, the voltage drop across R_s is so small that the phase difference ϕ can be set to zero in (6.28) to obtain

$$V_{j1} = V_1 \quad . \tag{6.39}$$

V_1 in (6.38) can be determined when the diode is off by substituting (6.16), (6.27), and (6.39) into (6.20) as

$$V_1 = \frac{V_0 + V_{bi}}{\cos\theta_{on}} \quad . \tag{6.40}$$

Finally, an expression for the diode efficiency η can be found by using (6.32), (6.33), (6.37), and (6.38) in (6.31). This gives

$$\eta_D = \frac{1}{1 + A + B + C} \tag{6.41}$$

where

$$A = \frac{R_L}{\pi R_S}\left(1 + \frac{V_{bi}}{V_0}\right)^2 \left[\theta_{on}\left(1 + \frac{1}{2\cos^2\theta_{on}}\right) - \frac{3}{2}\tan\theta_{on}\right] \tag{6.42}$$

$$B = \frac{R_S R_L C_j^2 \omega^2}{2\pi}\left(1 + \frac{V_{bi}}{V_0}\right)\left(\frac{\pi - \theta_{on}}{\cos^2\theta_{on}} + \tan\theta_{on}\right) \tag{6.43}$$

$$C = \frac{R_L}{\pi R_S}\left(1 + \frac{V_{bi}}{V_0}\right)\frac{V_{bi}}{V_0}\left(\tan\theta_{on} - \theta_{on}\right). \tag{6.44}$$

The input impedance of the diode can be found from the current I which flows through R_S during one cycle by utilizing a Fourier series as

$$I = I_0 + I_{1r}\cos(\omega t) + I_{1i}\sin(\omega t) \tag{6.45}$$

where I_0 is the DC component and I_{1r} and I_{1i} are the real and imaginary parts of the fundamental frequency component, respectively. Using (6.24) and $\theta = \omega t - \phi$, these current components are given by

$$I_0 = \frac{1}{2\pi R_S}\left[\int_{-\theta_{on}}^{\theta_{on}} \left(V_D - V_{bi}\right) d\theta + \int_{\theta_{on}}^{2\pi - \theta_{on}} \left(V_D - V_j\right) d\theta\right] \tag{6.46}$$

$$I_{1r} = \frac{1}{\pi R_S}\left[\int_{-\theta_{on}}^{\theta_{on}} \left(V_D - V_{bi}\right)\cos(\theta + \phi) d\theta + \int_{\theta_{on}}^{2\pi - \theta_{on}} \left(V_D - V_j\right)\cos(\theta + \phi) d\theta\right] \tag{6.47}$$

$$I_{1i} = \frac{1}{\pi R_S}\left[\int_{-\theta_{on}}^{\theta_{on}} \left(V_D - V_{bi}\right)\sin(\theta+\phi)d\theta + \int_{\theta_{on}}^{2\pi-\theta_{on}} \left(V_D - V_j\right)\sin(\theta+\phi)d\theta\right], \quad (6.48)$$

and the input impedance of the diode at the fundamental frequency expressed as a phasor is

$$Z_D = \frac{V_1}{I_{1r} - jI_{1i}} \quad . \quad (6.49)$$

Assuming that no current flows through C_j when the diode is on and that all of the current flows through C_j when the diode is off, the diode current in one cycle can be found from

$$I_{1r} - jI_{1i} = \frac{1}{\pi R_S}\int_{-\theta_{on}}^{\theta_{on}} \left(-V_0 - V_{bi} + V_1\cos\theta\right)\cos\theta\, d\theta + j\frac{\omega C_j V_1}{\pi}\int_{\theta_{on}}^{2\pi-\theta_{on}} \sin^2\theta\, d\theta \,. \quad (6.50)$$

The input impedance of the diode can then be written as

$$Z_D = \frac{\pi R_S}{\cos\theta_{on}\left(\frac{\theta_{on}}{\cos\theta_{on}} - \sin\theta_{on}\right) + j\omega R_S C_j\left(\frac{\pi-\theta_{on}}{\cos\theta_{on}} + \sin\theta_{on}\right)} \quad . \quad (6.51)$$

If impedance matching is utilized to tune out the reactance of the diode impedance, the diode input impedance can be simplified to

$$R_D = \frac{1}{\text{Real}(Y_D)} = \frac{\pi R_S}{\cos\theta_{on}\left(\frac{\theta_{on}}{\cos\theta_{on}} - \sin\theta_{on}\right)} \quad . \quad (6.52)$$

Equation (6.30) can be used to find the turn-on angle θ_{on}, and once this is known, (6.41)-(6.44) and (6.52) can be used to calculate the theoretical maximum conversion efficiency and input resistance of a diode as a function of fundamental diode parameters. As an

example, a plot of conversion efficiency versus a normalized parameter $\omega R_S C_j$ for different R_S/R_L ratios is displayed in Fig. 6.8. Also, plots of conversion efficiency and input resistance versus load resistance for a diode with parameters $C_j = 2$ pF and $R_S = 0.5$ Ω operating at 5.8 GHz are shown in Figs. 6.9-6.10.

The junction capacitance C_j can be calculated from

$$C_j = C_{j0}\sqrt{\frac{V_{bi}}{V_{bi} + |V_0|}} \tag{6.53}$$

where C_{j0} is the zero bias junction capacitance.

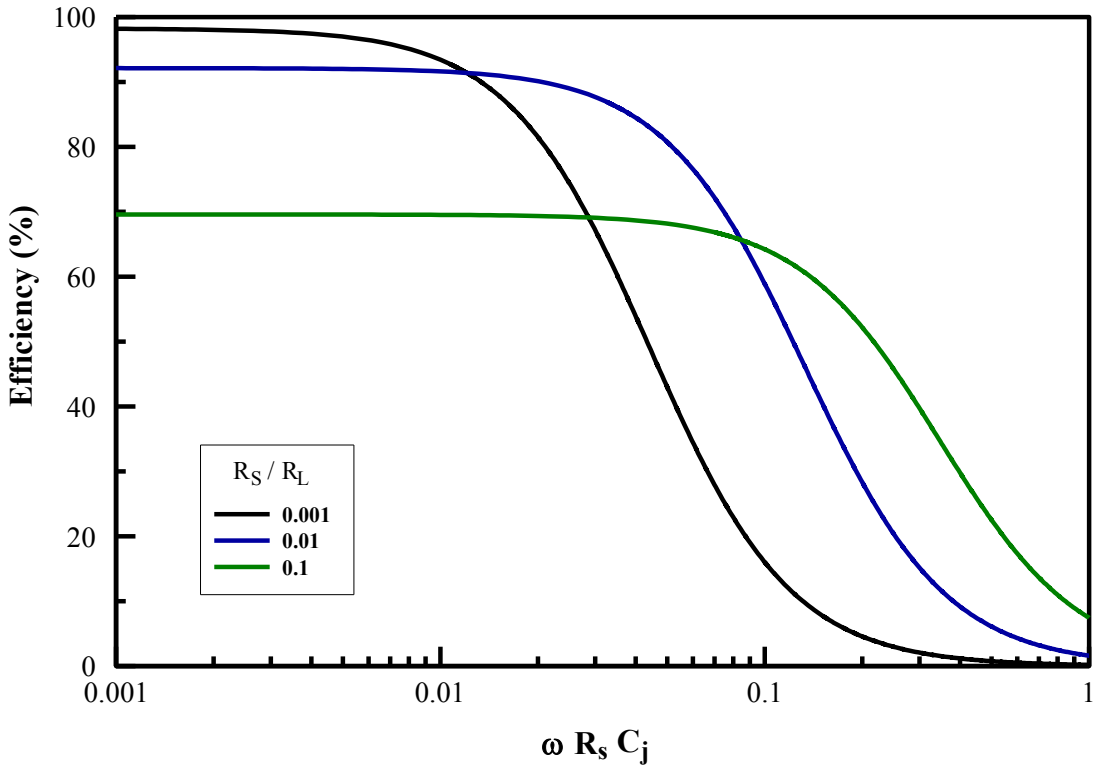

Figure 6.8. Conversion efficiency of an ideal diode versus the normalized parameter $\omega R_S C_j$ for different R_S/R_L ratios.

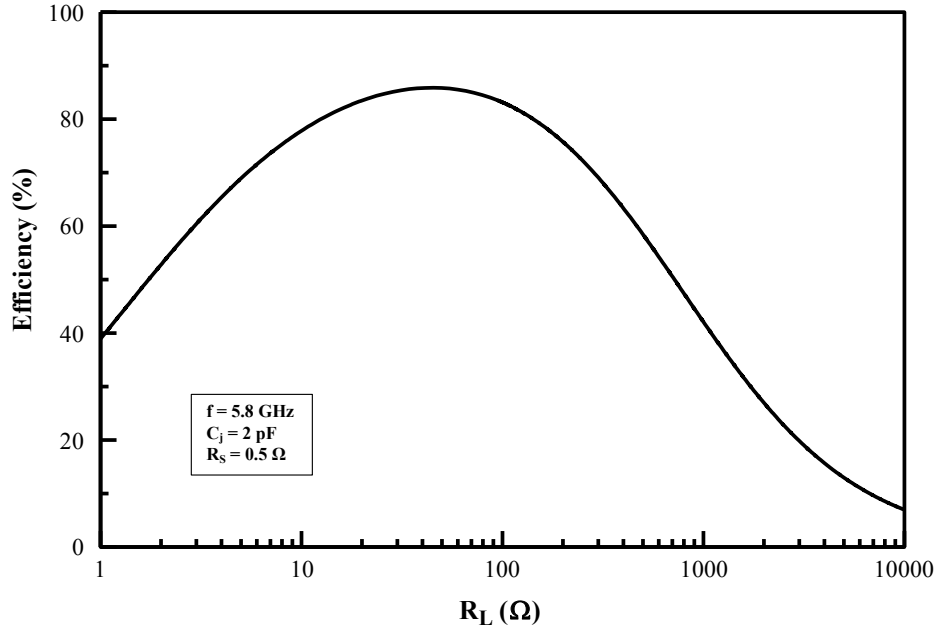

Figure 6.9. Conversion efficiency of an ideal diode versus load resistance (for a 5.8 GHz ideal diode with set parameters).

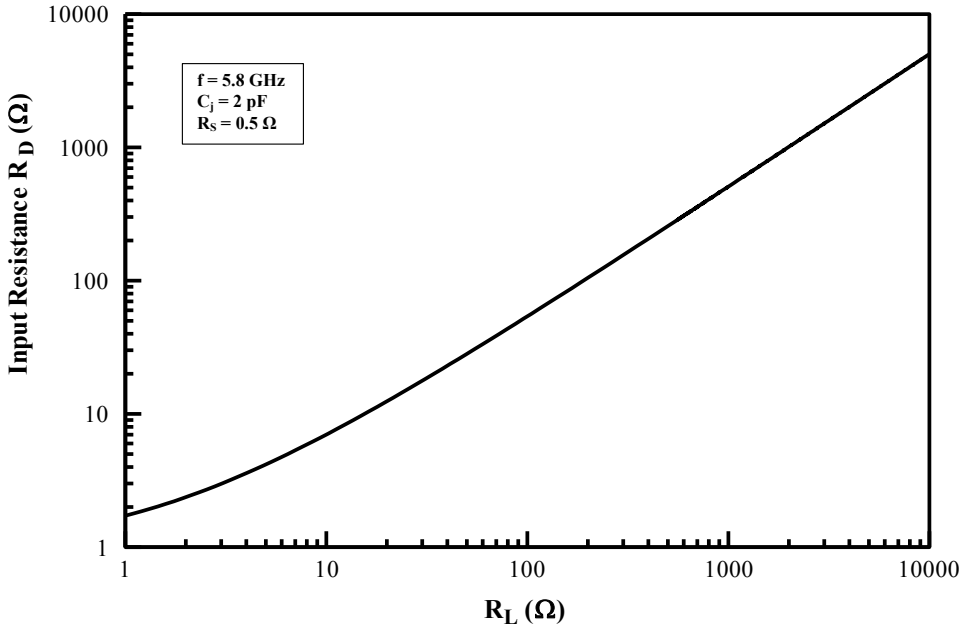

Figure 6.10. Input resistance of an ideal diode versus load resistance (for a 5.8 GHz ideal diode with set parameters).

D. Effect of Input Power on Rectenna Efficiency

The magnitude of the input power to the rectenna has a dramatic effect on its power conversion efficiency. With increasing input power, the diode conversion efficiency will rise to a point and then start to decrease [79].

At low input power levels, the conversion efficiency is low because the diode voltage is below or comparable to the turn-on voltage V_{bi} which means that the diode is not fully turned on. As the diode voltage exceeds the turn-on voltage, this effect disappears and the conversion efficiency levels off. Also, as power increases, the higher order harmonics will come into play and decrease efficiency. Finally, efficiency abruptly decreases when the power level increases to a point where the diode voltage swing exceeds the diode's breakdown voltage V_{br}. The critical point where the breakdown voltage effect takes over is when the power level is equal to $V^2_{br}/4R_L$. These effects combine to give a net conversion efficiency curve [79].

E. Diode Selection

The diode is the most crucial component in rectenna design because in a well-designed rectenna, it has the largest effect on efficiency. GaAs and Si diodes can both be used in a rectenna. GaAs is usually preferable for high efficiency because it has more than six times the electron mobility of Si, but Si has higher thermal conductivity which is better for long-term reliability.

Diode selection is dependent on system design parameters such as frequency and input power. In general, a small series resistance R_S and low turn-on voltage V_{bi} are

preferred because this will reduce rectenna losses. The diode's reverse breakdown voltage V_{br} limits the diode's power handling capacity and should be large enough to handle the expected power level. V_{br} and the DC output voltage V_0 should be chosen such that $V_0 < V_{br}/2$. Since all parameters are related to each other, diode parameter tradeoffs must be made.

7. DIODE MODEL *

A. Background and Introduction

Computer simulation has become an increasingly popular design tool for microwave circuits and systems, and the design of a rectenna is no exception. The capability of simulating a rectenna design will allow for the analysis of new ideas and tuning of parameters without the added expense and time of fabricating and measuring each new design to test its validity.

All parts of the rectenna, with the exception of the diode, can be easily modeled using standard microwave simulation software. The antenna and transmission lines can be modeled using EM modeling software such as IE3D [12] or HFSS [13], and the capacitor and load (resistor) are standard components which can be modeled in any software capable of circuit-level simulation, such as Agilent ADS [83]. However, diodes present a problem with off-the-shelf modeling because the parameters of different diodes vary from each other, so there is not a uniform standard model which works for all diodes. Models of a few popular diodes are usually included in circuit level simulator software or may be provided by the manufacturer, but if a diode, which is not provided with a model, is to be used in a rectenna then a model for this particular diode should be created. After this diode model is created, it will be possible to simulate the entire rectenna design and avoid unnecessary fabrication and testing.

Device models are usually not generic, and the limitations of the model must be appreciated. The model must be designed to work in the target application. For use in rectenna modeling, a nonlinear harmonic balance simulator is utilized, so the model must be compatible with this type of simulation.

A harmonic balance analysis [84]-[85] can be used to solve the steady-state of a nonlinear circuit which is excited by a single-tone. It works in the frequency domain by balancing currents and voltages until Kirchhoff's Current Law is satisfied at the fundamental frequency and a specified number of harmonics. An initial guess is made at node voltages which are used to calculate currents. These currents are then checked for adherence to Kirchhoff's Current Law. An iterative process is used to update the node voltages, and the procedure is repeated until Kirchhoff's Current Law is satisfied.

The model should imitate the operation of the device within the required simulation environment by generating similar characteristics to the physical diode by utilizing an analogous system. Device models can be either physical device models or equivalent circuit models.

Equivalent circuit models [86] are common for circuit design applications because they are relatively easy to implement, and they can seamlessly mimic the electrical performance of the device being modeled. However, it can be difficult to relate the model parameters to the physical device parameters because of the non-linear behavior, frequency dependence, and biasing of most devices. This can restrict the use of equivalent circuit models because they are generally not suitable for predicting the performance of new devices or modeling large-signal operation [87].

Physical device models are based on the physical operation of carrier transport and therefore provide greater insight into how the device operates. They are usually not restricted to certain applications like an equivalent circuit model, and they can be used to predict the performance of new devices. However, these advantages come at the price of requiring considerably more computer simulation time and memory [87].

B. Diode Equivalent Circuit

The diode might be the simplest modern solid-state device in existence and is probably the easiest to accurately characterize and model; the model can be both simple and accurate [88]. The equivalent circuit model of a diode takes much less computing power to evaluate than a physical device model, and it is simple and accurate under a wide range of conditions. It is for these reasons that a standard diode equivalent circuit will be the basis of the rectenna's diode model. The standard diode model which will be used is illustrated in Fig 7.1 [89].

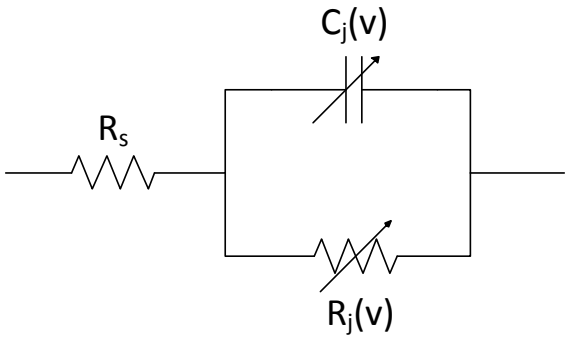

Figure 7.1. Equivalent circuit of the diode.

Mathematical expressions for the voltage-dependent parameters can be obtained from analytical expressions based on the internal physics of the diode [90]. The parasitic series resistance R_s represents the spreading resistance which is associated with the bonding wire, the semiconductor substrate, and the ohmic contact. The series resistance is also nonlinear but only varies slightly under forward bias, so it can be treated as linear [88].

The voltage-dependent resistor R_j is interchangeable with a voltage-dependent current source I_j. This nonlinear current can be expressed by a simple expression which is derived assuming that conduction occurs primarily by means of the thermionic emission of electrons over a barrier. Conduction by other means such as tunneling does occur with a limited scope, but this thermionic emission assumption is valid for Schottky diodes operating close to room temperature with moderate doping densities [88]. The nonlinear current source follows the Shockley equation:

$$I_j = I_0\left(e^{V_j/nV_t} - 1\right) \tag{7.1}$$

where V_t is the thermal voltage which is equal to kT/q and has a value of 25.69 mV at 25°C, k is Boltzmann's constant, T is absolute temperature, q is the electron charge, and V_j is the voltage across the junction. The model parameters I_0 and n are used to model the effects of the junction and differ from diode to diode. The current parameter or saturation current I_0 is a proportionality constant, and the ideality factor n accounts for imperfections in the junction [88].

The voltage-dependent capacitor C_j is the junction capacitance. In a Schottky diode, a reverse-biased junction creates a wider depletion region, and more electrons move to the anode which leaves behind more positive charge. A forward-biased junction creates a narrower depletion region, and fewer electrons move to the anode which results in less stored charge. This creates a situation where a negative voltage increases the amount of negative charge stored on the anode and a positive voltage reduces the amount of negative charge stored [88]. This results in the junction behaving as a nonlinear capacitor [89] which can be expressed as

$$C_j = \frac{C_0}{\left(1 - V_j / V_0\right)^{\gamma}} \tag{7.2}$$

where V_0 is the diffusion potential, C_0 is the zero-voltage junction capacitance, γ is the grading coefficient, and V_j is the voltage across the junction. It can be assumed that the junction is uniformly doped and the transition between regions is abrupt ($\gamma = 0.5$) [88] which simplifies the equation to

$$C_j = C_0 \sqrt{\frac{V_0}{V_0 - V_j}} \ . \tag{7.3}$$

The diode comes in a package, and at microwave frequencies the effect of this packaging must be taken into account. The packaging creates parasitics which limit the performance of the diode. A package parasitic inductance L_p is added to account for the inductance of wires or conductors used to connect the die inside to the exterior terminations. A package parasitic capacitance C_p and a beam-lead parasitic capacitance

C_b are added to account for the capacitance due to the dielectric constant of the solid packaging. The modified equivalent circuit can be seen in Fig 7.2 [89].

The values of the equivalent circuit's parameters can be calculated by measuring the diode's small-signal S-parameters. The voltage dependence can be determined by measuring the small-signal S-parameters at various bias levels and combining these measurements to create a large-signal model [91]. The procedure involves altering the values of the circuit parameters until the S-parameters of the equivalent circuit sufficiently match the measured S-parameters. An optimization procedure is generally required for this multi-variable procedure, and unique solutions usually do not exist [92]. Software packages can be used to fit the S-parameters [93], but if this software is not available, another method must be used.

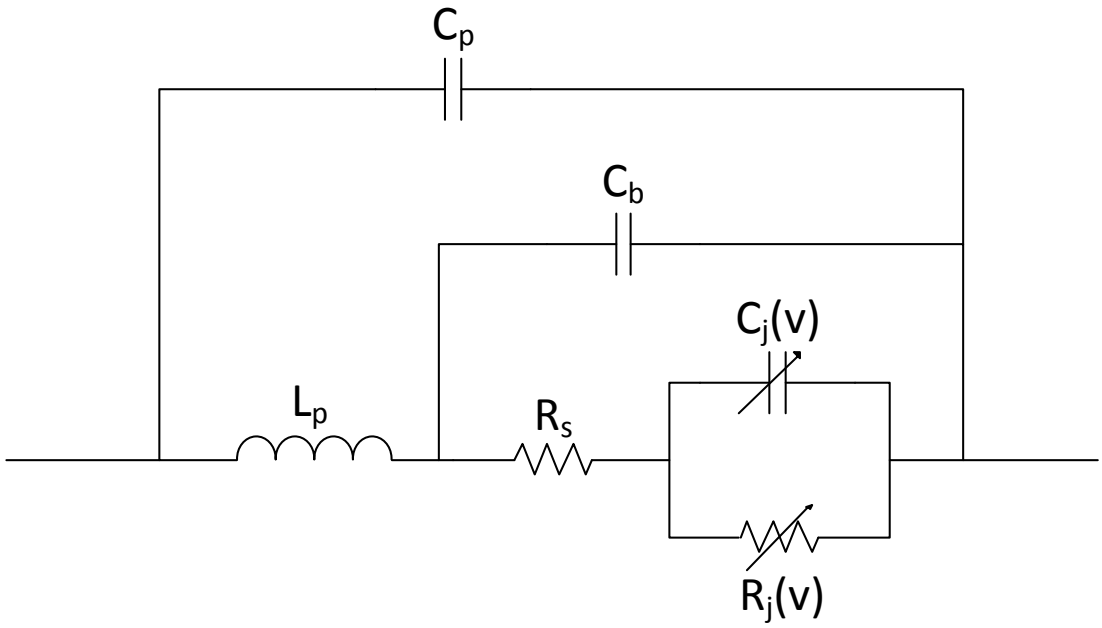

Figure 7.2. Equivalent circuit of the diode (including package parasitics).

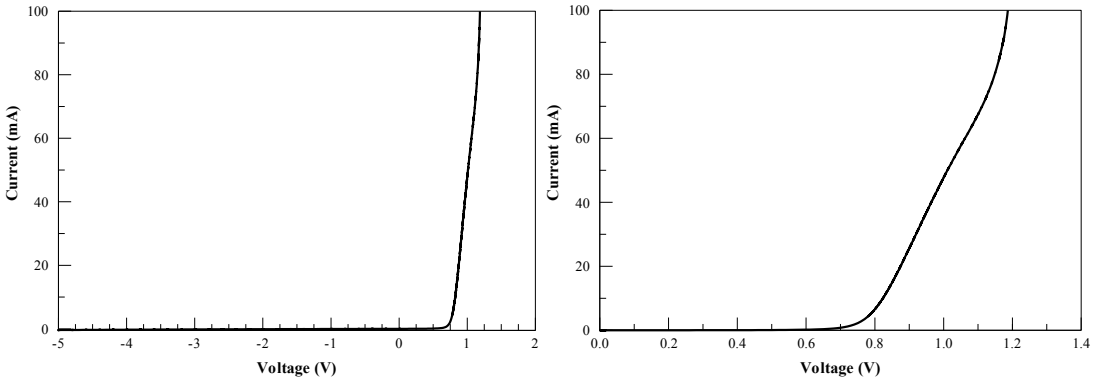
C. Measurements

A popular diode used in rectenna design is the M/A-COM GaAs Schottky barrier diode (MA4E1317). This diode will be modeled for use in a 5.8 GHz rectenna system.

The current-voltage curve at DC should be measured so that the DC components of the model (R_s and R_j) can be calculated [94]. This can be done with a curve tracer, or a high resolution voltmeter and ammeter can be used if a curve tracer is not available. The diode must be mounted on a test board to allow the measurement equipment to contact the diode terminals, so care must be taken not to add any extra resistance with the test board. A silver adhesive (Diemat DM6030Hk/F954) is used to connect the diode to the test board. Also, the diode characteristics will be permanently altered if it is burned out. This can happen if over 100 mW is applied to the diode or if the breakdown region is reached. The diode can reach varying degrees of being burned out. Sometimes once burned out, it will become an open or a short, but other times it will just start to permanently behave differently by allowing more current to flow for the same applied voltage. Extra care must be taken to ensure that the diode is not burned out to any degree before the measurements are complete. Seven diodes were measured to ensure that the measurements of a "typical" diode were used to create the model. One of the measured curves of "typical" values can be seen in Fig 7.3.



(a) (b)

Figure 7.3. (a) Diode DC measurements and (b) zoomed in view.

S-parameter measurements of the diode must be taken at numerous bias levels using the Thru-Reflect-Line (TRL) calibration method [95]. A network analyzer is used to measure the S-parameters as ratios of complex voltage amplitudes. These S-parameters should be measured at the diode reference plane as shown in Fig 7.4. However, the measurement plane is at a point within the network analyzer, and losses and phase delays will be introduced to the measurement caused by cables, connections, and transitions that must be in place for the network analyzer to connect to the diode. These losses and phase delays can be lumped into a two-port error box placed at both ports of the diode between the measurement plane and the device plane (Fig 7.5). The TRL calibration method can be used to characterize these error boxes before the measurements of the diode are made. The effects of the error boxes can then be removed from the measurements, leaving only the error-corrected S-parameters of the diode.

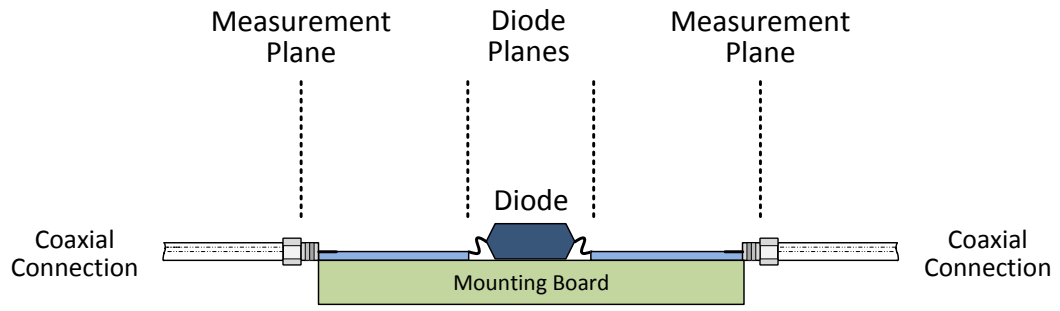


Figure 7.4. Measurement and Device Planes for S-parameter measurements of a diode.

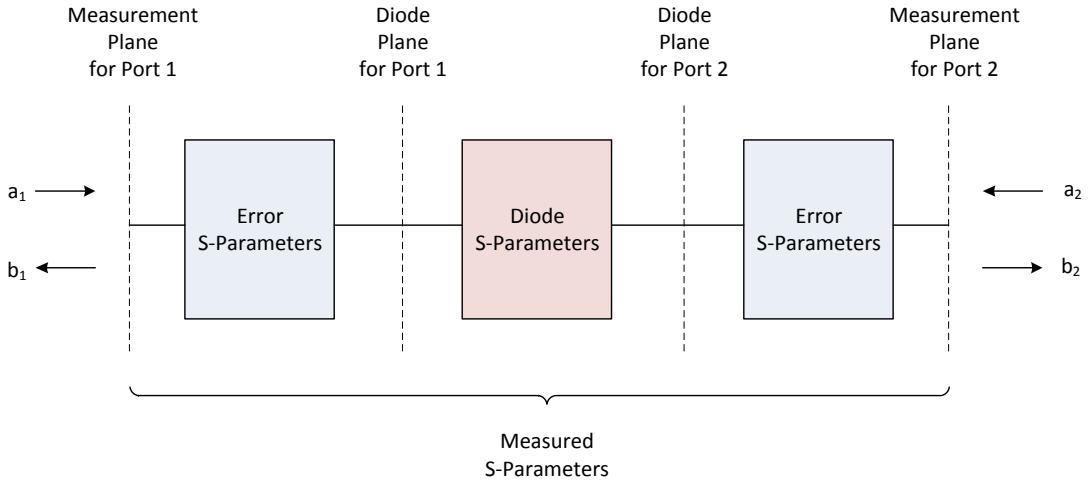

Figure 7.5. Block diagram of a diode's S-parameter measurements.

Three connections are used by the TRL method to determine the error boxes. The Thru connection is made by connecting port 1 directly to port 2 at the device plane. This can be realized by using the same test fixture that will be used for the diode measurement but with the diode removed; the two device planes will be moved infinitesimally close to each other. The Reflect connection is made by terminating each measurement port with a load having a large reflection coefficient. This can be realized by using the same test fixture that will be used for the diode measurement but with the connections to the ports terminated at the device plane. The Line connection is made by connecting port 1 to port 2 through a length of matched transmission line. This can be realized by using the same test fixture as is used for the Thru connection but with an extra length of transmission line added [11]. A diagram of the calibration connections can be seen in Fig 7.6.

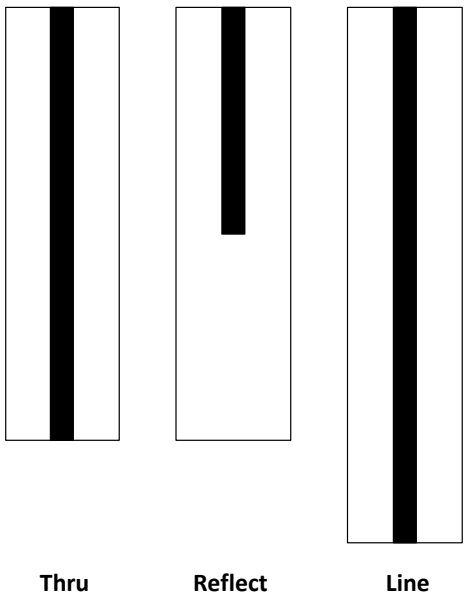

Figure 7.6. Calibration set for TRL measurement.

The S-parameters should be measured over a span of frequencies, but the TRL method places a restriction on the range of frequencies that can accurately be measured. The optimal extra length of the Line (beyond the Thru length) is ¼ wavelength (or 90° of insertion phase) at the center of the frequency range. The insertion phase of the ¼ wavelength Line [96] will vary with frequency as:

$$\text{phase (degrees)} = (360 \times \text{frequency} \times \text{electrical length}) / c \tag{7.4}$$

which can be rearranged to give the electrical length of a ¼ wavelength at the center frequency

$$\text{electrical length (cm)} = 15 / (f_1(\text{GHz}) + f_2(\text{GHz})) \tag{7.5}$$

where f_1 is the start frequency and f_2 is the stop frequency. The insertion phase requirement is that the phase φ over the operating frequency should be $20° \leq \varphi \leq 160°$ [96].

To capture 5.8 GHz and its second harmonic, a frequency range of 4 to 13 GHz is measured which has a center frequency of $f_0 = 8.5$ GHz. The electrical length for this range is calculated from (7.5) as 0.8824 cm. The phase delays from the added ¼ wavelength at the start and stop frequency are calculated from (7.4) as

$$\text{phase (@ 4 GHz)} = 42° \tag{7.6}$$

$$\text{phase (@ 13 GHz)} = 138° \tag{7.7}$$

which meet the insertion phase requirement.

The Thru, Reflect, Line, and numerous diode mounts are etched on 20 mil RT/Duroid 5880 substrate which has a dielectric constant of 2.2. A Thru line length of 110 mm is used, and the physical length of the extra ¼ wavelength on the Line is 6.46

mm. The strip width is 1.52 mm to provide a 50 Ω line at the center frequency. The calibration sets and a diode mount can be seen in Fig 7.7.

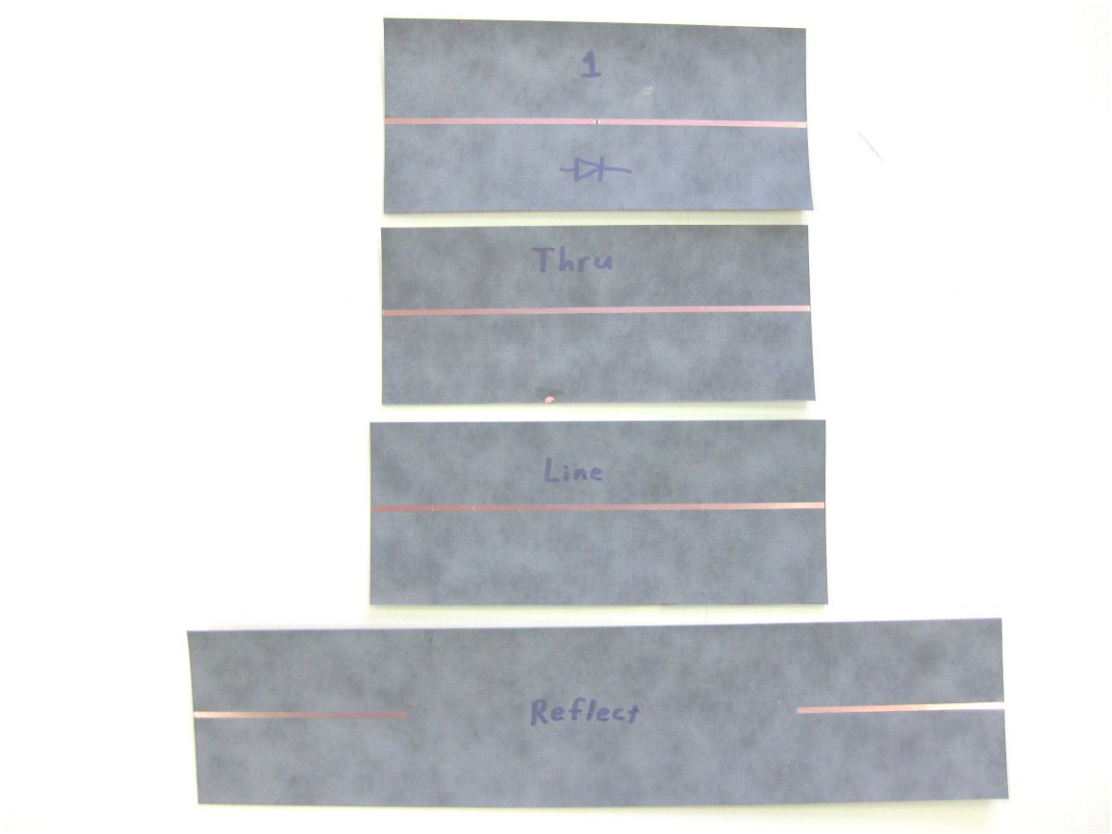

Figure 7.7. Etched calibration set and test fixture for diode TRL measurement.

To calibrate the network analyzer and measure the diode, a measurement setup should be constructed as illustrated in Fig 7.8. Bias-Tees must be used on both sides of the test fixture so that the diode can be biased to various voltages without damaging the network analyzer. The Bias-Tees should be in place (as they will be used for diode measurement) when the calibration sets are used so that the effects of the Bias-Tees are accounted for in the error box calculation. It is important to note that there is some resistance in the Bias-Tees which will result in a voltage drop across the Bias-Tee when a DC current flow is established. Therefore, not all of the voltage provided by the DC-voltage source will appear as a bias across the diode, so a voltmeter should be used to measure the actual bias being applied to the diode.

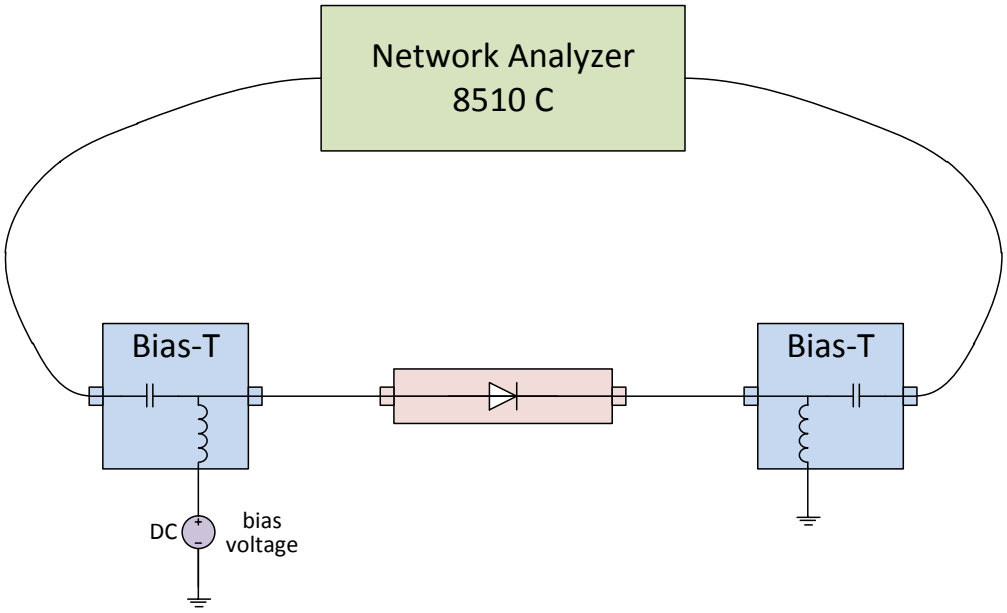

Figure 7.8. Setup for TRL calibrated S-parameter measurement of a diode.

The Agilent 8510C network analyzer can be set to compute the error boxes and directly apply them to the measured S-parameters by entering the correct settings and letting the network analyzer know what kind of calibration set is being used. There is some difficulty in creating consistent connections for all calibration sets and diode mounts. Ten diodes were measured at sixteen bias levels with a Thru length of 110 mm. One of the better measurement sets can be seen in Figs. 7.9-7.10. Some oscillation with frequency can be seen in the figures which is a result of inconsistent connections. Another set of four diodes was measured with a new calibration set which has a Thru length of 37.88 mm in an attempt to reduce some of the transmission line effects on the measurements, but the same oscillation with frequency occurred. The new measurements had fewer oscillations across the frequency range because the shortened length could not support as many wavelengths, but the oscillations had similar amplitude variations. This confirmed that the oscillations were indeed due to connection inconsistencies.

D. Model Parameter Extraction

Once measurements of the diode's DC current-voltage relation and its small signal S-parameters at various bias levels are successfully taken, the equivalent circuit parameters can be fit to the measurements.

The DC parameters R_s and I_j (interchangeable with R_j) can be fit to the DC current-voltage data because at DC these are the only components with any effect. The equivalent circuit will reduce to Fig 7.11. Note the relation $V_j = V_D - R_s I_j$, where V_D is the measured voltage across the diode and I_j is the measured diode current. The current-voltage curve can be broken down into two regions: the exponential region and the linear region (Fig 7.12) [97]. At low current, the junction resistance R_j is very large. When current increases, the junction resistance decreases, so at some point the junction resistance will become negligibly small. The diode's series resistance will then become the dominant resistor, and the curve will become linear. This means that when current increases, the ohmic effect takes over. In the exponential region, R_j dominates, so

$$I_j = I_0\left(e^{V_j/nV_t} - 1\right) \tag{7.8}$$

can be fit to this region where I_j is used in place of R_j. This curve can be transformed into a linear curve so that linear regression techniques can be utilized:

$$I_j = I_0\left(e^{V_j/nV_t} - 1\right) \tag{7.9}$$

$$\log(I_j) = \log(I_0) + \frac{1}{nV_t}\log(e)\,V_j \ . \tag{7.10}$$

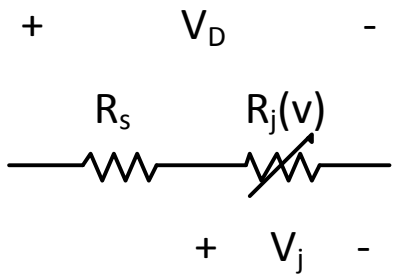

Figure 7.11. Equivalent circuit of the diode at DC.

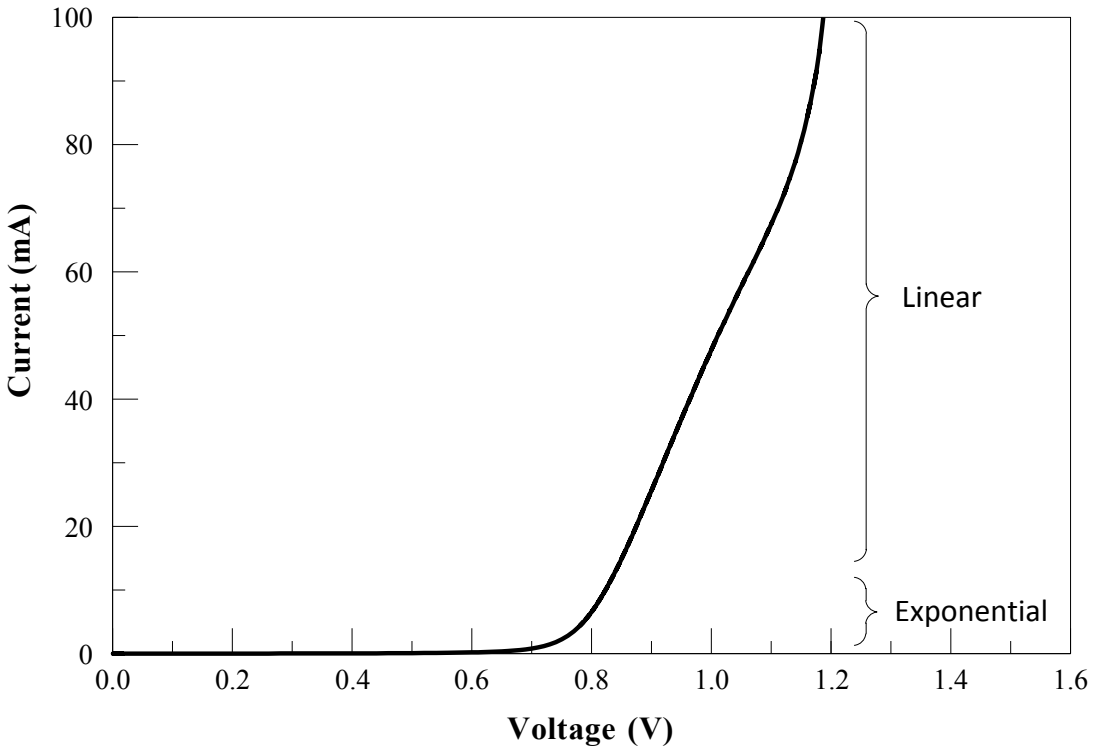

Figure 7.12. Linear and exponential regions of the diode's DC current-voltage curve.

Note that the "-1" in (7.9) is dropped with minimal effect. Equation (7.10) is of the linear form y = m x + b where

$$y = \log(I_j) \tag{7.11}$$

$$b = \log(I_0) \tag{7.12}$$

$$m = \frac{1}{nV_t}\log(e) \tag{7.13}$$

$$x = V_j \tag{7.14}$$

which can be fit to the data in the exponential region using a linear regression. In the linear region, R_s dominates, so

$$R_s = V_D / I_j \tag{7.15}$$

can be fit to this region. R_s is simply the inverse of the curve's slope in the linear region. There is a gradual transition between the exponential region and the linear region, so the slope should be measured at some distance from the exponential region to insure that R_j's effect is minimal. The model parameters are calculated to be:

$$R_s = 4\ \Omega \tag{7.16}$$

$$I_0 = 10^{-14}\ \text{A} \tag{7.17}$$

$$n = 1.06\ . \tag{7.18}$$

The curve is fit with an R^2 value [98] of 0.9901 and is illustrated in Fig 7.13 along with the measured data. Alternatively, a nonlinear regression can be used to fit the curve if capable software is available.

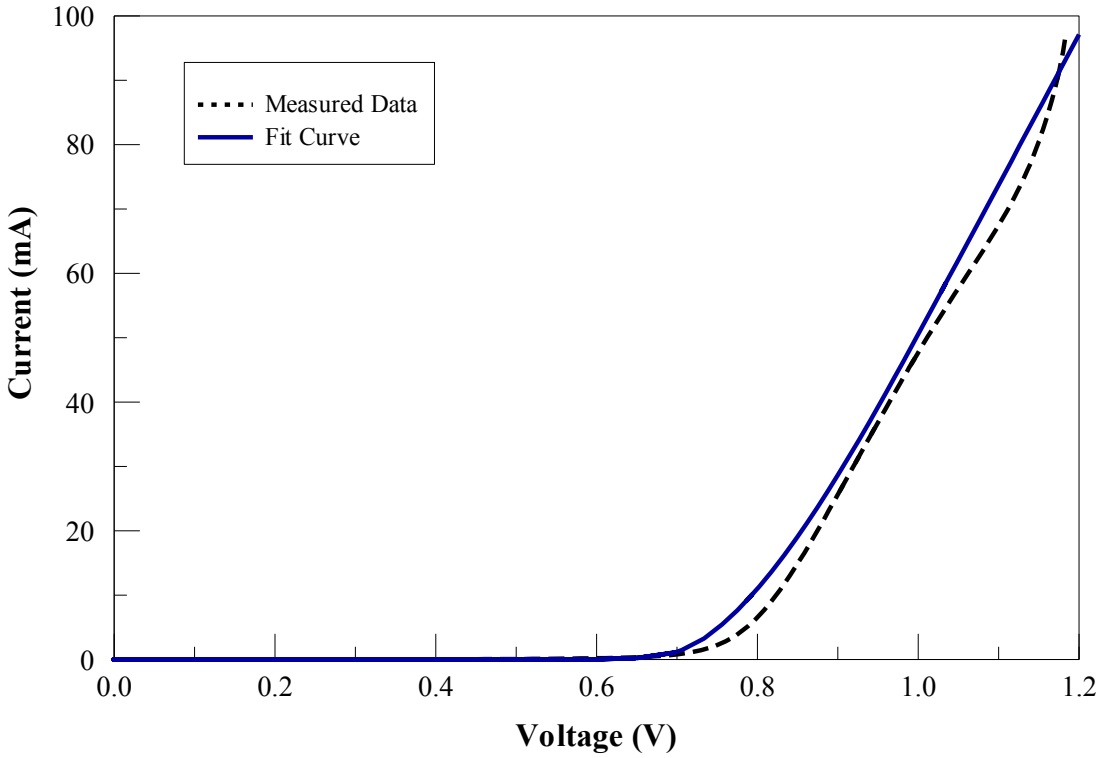

Figure 7.13. Diode DC measurements and fit curve.

Now that R_s and I_j are determined, the other model parameters can be found from the S-parameters. Using Agilent ADS, the S-parameters of the model can be observed for different parameter values. R_s and I_j can be permanently fixed, and then the parasitics can be set to different values while C_j is varied to different bias levels to create a match with measurements over all bias levels. This works successfully when the diode is in the non-conducting region. However, at bias levels in the forward region, the model could not match the measured S-parameters. The restriction of a fixed R_s and I_j prevented the freedom necessary to fully match to the S-parameters.

E. Alternate Model Parameter Extraction Method

It can be difficult to choose correct values for the model parameters, and once parameter values are chosen, they are usually not unique. A convenient method to fit the data using only the S-parameters is to systematically isolate the voltage-independent components from the voltage-dependent components [99]. Circuit components can be added to the diode model to cancel the effect of the voltage-independent components so that only the voltage-dependent components remain as contributing elements. Fig 7.14 illustrates the addition of $-R_s$, $-L_p$, $-C_b$, and $-C_p$ (which are the negatives of the voltage-independent components) to the equivalent circuit which serve to cancel out the voltage-independent components. This leaves only the voltage-dependent components C_j and R_j. When the circuit is simplified to only C_j and R_j in parallel as shown in Fig 7.14, the Y-parameters of this reduced circuit will be a series of straight lines as illustrated in Fig 7.15. The real part of Y_{11} will be $1/R_j(V_j)$ and the imaginary part of Y_{11} will be $\omega C_j(V_j)$ which are both straight lines as a function of frequency.

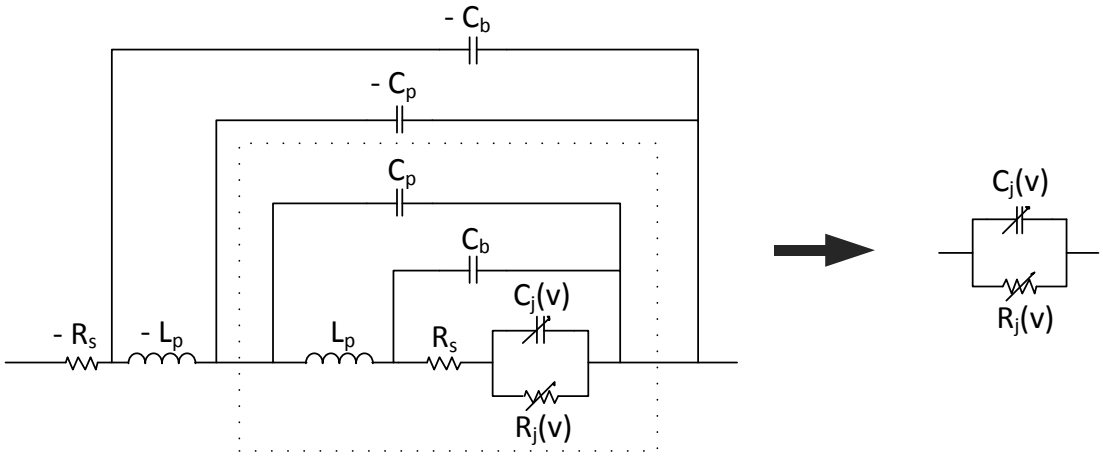

Figure 7.14. Components added to cancel the voltage-independent components' effect. The components within the dotted box represent the diode model. This can be replaced with S-parameters.

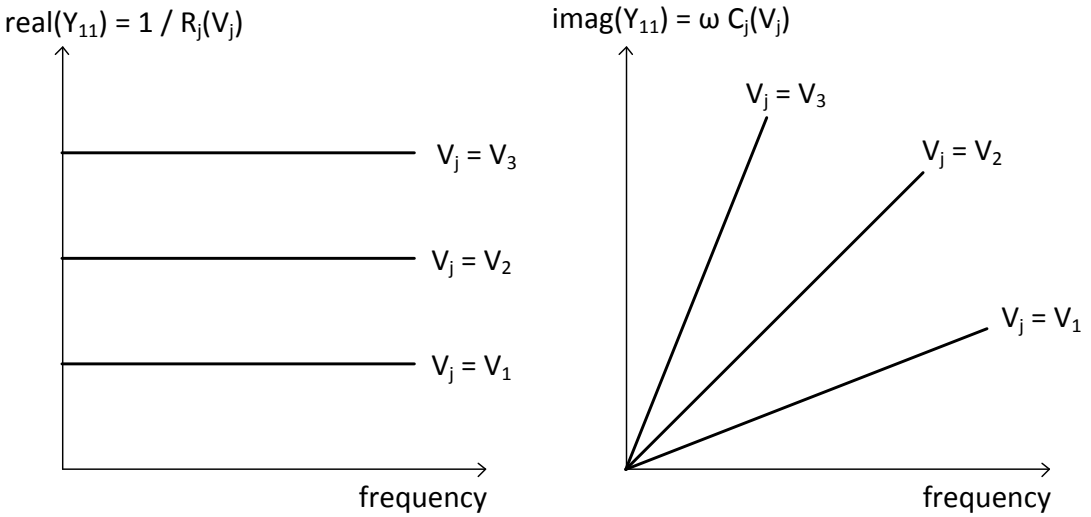

Figure 7.15. Y-parameters of remaining voltage-dependent components. The different lines represent different bias voltages.

Using the Agilent ADS circuit simulator, the equivalent circuit representation of the diode can be replaced by the diode's measured S-parameters and the negative components added as shown in Fig 7.16. The values of Y_{11} can be calculated from the S-parameters [11] by

$$Y_{11} = \left.\frac{I_1}{V_1}\right|_{V_2=0} = Y_0 \frac{(1-S_{11})(1+S_{22})+S_{12}S_{21}}{(1+S_{11})(1+S_{22})-S_{12}S_{21}} \quad . \tag{7.19}$$

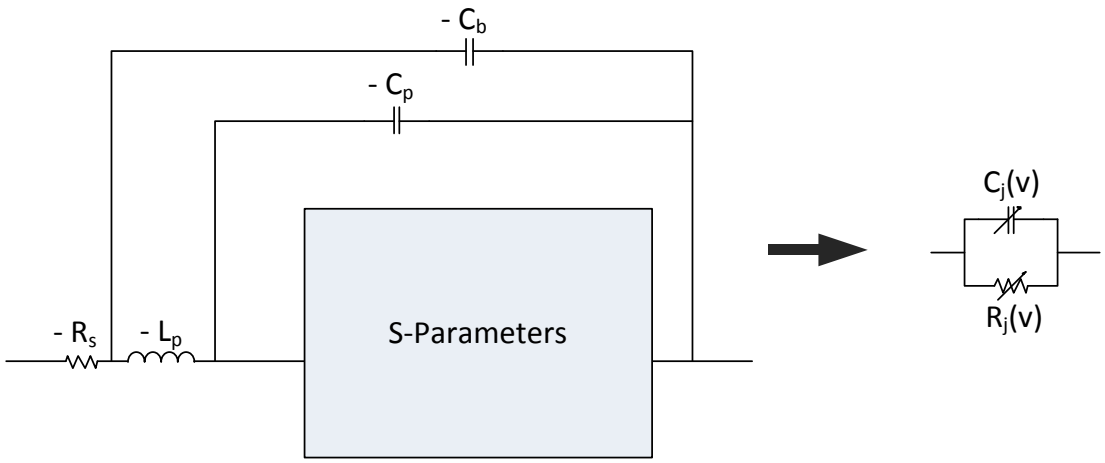

Figure 7.16. Components added to cancel the voltage-independent components' effect. The S-parameters replace the equivalent circuit of the diode. When negative components are set to the correct values, then only C_j and R_j of the diode model will affect the Y-parameters.

If the negative components are set to the correct values, then only C_j and R_j will have any effect on the Y-parameters. Therefore, to find the correct values of the negative components, the values of these components can be varied while observing the resulting Y-parameters. When the Y-parameters are a series of straight lines of the form shown in Fig 7.15, then the effect of the voltage-independent parameters has been cancelled out and their values successfully determined. By following this procedure, these voltage-independent parameters are determined to be:

$$R_s = 0.5\ \Omega \tag{7.20}$$

$$L_p = 0.26\ \text{nH} \tag{7.21}$$

$$C_p = 0.01\ \text{pF} \tag{7.22}$$

$$C_b = 0.04\ \text{pF}\ . \tag{7.23}$$

The values of the voltage-dependent components (as a function of bias voltage) can then be determined from the Y-parameters that result from the previous step. Each straight line on the Y-parameter graph represents a value at a different bias voltage. Since

$$\text{real}(Y_{11}) = 1/R_j(V_j) \tag{7.24}$$

$$\text{imag}(Y_{11}) = \omega C_j(V_j)\ , \tag{7.25}$$

$R_j(V_j)$ can be determined from the real part of Y_{11}, and $C_j(V_j)$ can be determined from the imaginary part of Y_{11}.

F. R_j Calculation

The parameter R_j can be calculated from the real part of Y_{11}. Each horizontal line on the real(Y_{11}) graph gives a value for R_j at a different bias voltage as shown in Fig 7.15. This can be used to create a series of (V_j, R_j) data points (one data point for each bias voltage). The $R_j(V_j)$ data is then converted to a current by

$$I_j = V_j / R_j \,, \tag{7.26}$$

and the equation

$$I_j = I_0 \left(e^{V_j / nV_t} - 1 \right) \tag{7.27}$$

is fit to the data points using a least squares method which gives:

$$I_0 = 1.193 \text{ x } 10^{-11} \text{ A} \tag{7.28}$$

$$n = 1.290 \,. \tag{7.29}$$

The I_j curve is fit with an R^2 value [98] of 0.9812. This curve and the (V_j, I_j) data points are illustrated in Fig 7.17. I_j can be implemented in Agilent ADS as a nonlinear current source by using a symbolically defined device.

A "soft exponential" should be used in place of a regular exponential in the computer calculations to prevent overflow. If the argument of the exponential (V_j/nV_t) is large, taking the exponential of this large argument can cause an overflow error. The "soft exponential" can be defined to be equal to a regular exponential for arguments less than some cutoff value and to be a linear extrapolation of the exponential for arguments greater than the cutoff value. This can be implemented in Agilent ADS as:

max_exp = 1.0e20

max_arg = ln(max_exp)

exp_soft(x) = if (x < max_arg) then exp(x) else (x+1-max_arg)*max_exp endif

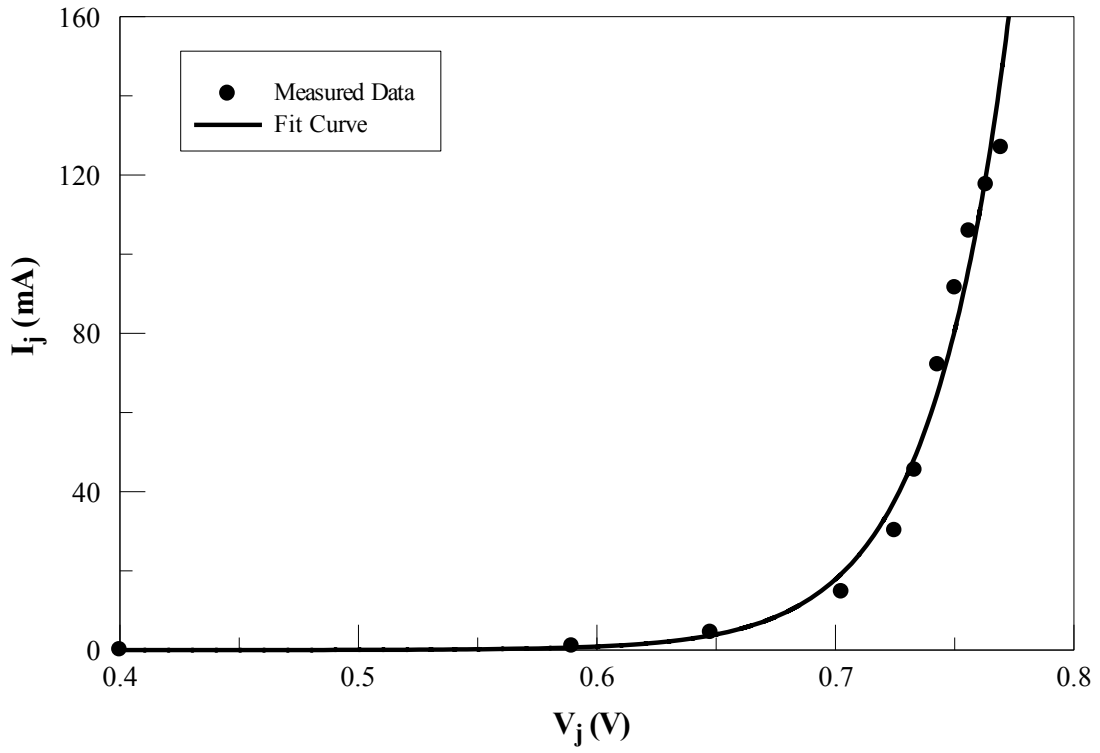

Figure 7.17. I_j curve fit to data.

G. C_j Calculation

The parameter C_j can be calculated from the imaginary part of Y_{11}. Each straight line on the imag(Y_{11}) graph gives a value for C_j at a different bias voltage as shown in Fig 7.15. This can be used to create a series of (V_j, C_j) data points (one data point for each bias voltage). Agilent ADS has a nonlinear capacitor device which can be used to implement C_j. This device requires input in the form of a polynomial, so the $C_j(V_j)$ data must be forced into the form of a polynomial [100].

A polynomial of a large degree (20-25) must be used in order to satisfactorily force the polynomial to behave as an exponential over the desired range, but only sixteen data points exist. If a 20-25 degree polynomial is fit to only sixteen data points using a least squares method then the data is overfit, and the polynomial will fit correctly at the data points but will wildly oscillate between data points. This does not adequately represent the exponential form of the data. Artificial data points can be created by linearly interpolating between real data points, allowing the use of as many data points as desired. A 20-25 degree polynomial can then be fit to the artificial data points (using a least squares method) and effectively fit the form of an exponential within the desired range. Note that the polynomial blows up outside of the range. Polynomials of such a large degree are required to adequately fit the form of an exponential since this is not a polynomial's usual form. A 20 degree polynomial and a 25 degree polynomial are fit to the data using this method with resulting R^2 values [98] of 0.7152 and 0.9339, respectively. These curves and the (V_j, C_j) data points are illustrated in Fig 7.18.

The polynomials are:

20 deg $C_j(V_j)$ =

$2.251953845934267 \times 10^{-14} + 3.928708106450134 \times 10^{-14} V_j - 1.872605744144919 \times 10^{-13} V_j^2 - 8.010052760857773 \times 10^{-13} V_j^3 + 1.035723793272987 \times 10^{-12} V_j^4 + 6.019608944715903 \times 10^{-12} V_j^5 + 3.292217192099333 \times 10^{-12} V_j^6 - 1.188012141308037 \times 10^{-11} V_j^7 - 2.021997434144966 \times 10^{-11} V_j^8 - 6.795781565984654 \times 10^{-12} V_j^9 + 1.408246385109605 \times 10^{-11} V_j^{10} + 2.231293123305528 \times 10^{-11} V_j^{11} + 1.691875529472090 \times 10^{-11} V_j^{12} + 8.293398780762461 \times 10^{-12} V_j^{13} + 2.844367116709308 \times 10^{-12} V_j^{14} + 7.004768751099705 \times 10^{-13} V_j^{15} + 1.238874503528577 \times 10^{-13} V_j^{16} + 1.540283747327346 \times 10^{-14} V_j^{17} + 1.280357467024890 \times 10^{-15} V_j^{18} + 6.396262419195184 \times 10^{-17} V_j^{19} + 1.453338557125182 \times 10^{-18} V_j^{20}$.

25 deg $C_j(V_j)$ =

$1.646738462080980 \times 10^{-14} - 3.841968572067818 \times 10^{-14} V_j + 1.353667676256704 \times 10^{-13} V_j^2 + 1.603431782387508 \times 10^{-12} V_j^3 + 1.725111435338492 \times 10^{-13} V_j^4 - 1.363440404577148 \times 10^{-11} V_j^5 - 1.692864176044302 \times 10^{-11} V_j^6 + 3.576722607831512 \times 10^{-11} V_j^7 + 9.264821210126666 \times 10^{-11} V_j^8 + 2.660693196199393 \times 10^{-11} V_j^9 - 1.334940731727817 \times 10^{-10} V_j^{10} - 1.929241277273865 \times 10^{-10} V_j^{11} - 7.342053211680040 \times 10^{-11} V_j^{12} + 9.197717732432363 \times 10^{-11} V_j^{13} + 1.623743979314330 \times 10^{-10} V_j^{14} + 1.323625389434068 \times 10^{-10} V_j^{15} + 7.171379278258487 \times 10^{-11} V_j^{16} + 2.826579043343990 \times 10^{-11} V_j^{17} + 8.387264303460990 \times 10^{-12} V_j^{18} + 1.895653489292848 \times 10^{-12} V_j^{19} + 3.256194634903012 \times 10^{-13} V_j^{20} + 4.188460909887590 \times 10^{-14} V_j^{21} + 3.913242592828937 \times 10^{-15} V_j^{22} + 2.510211233005998 \times 10^{-16} V_j^{23} + 9.894061095862421 \times 10^{-18} V_j^{24} + 1.807503156397230 \times 10^{-19} V_j^{25}$.

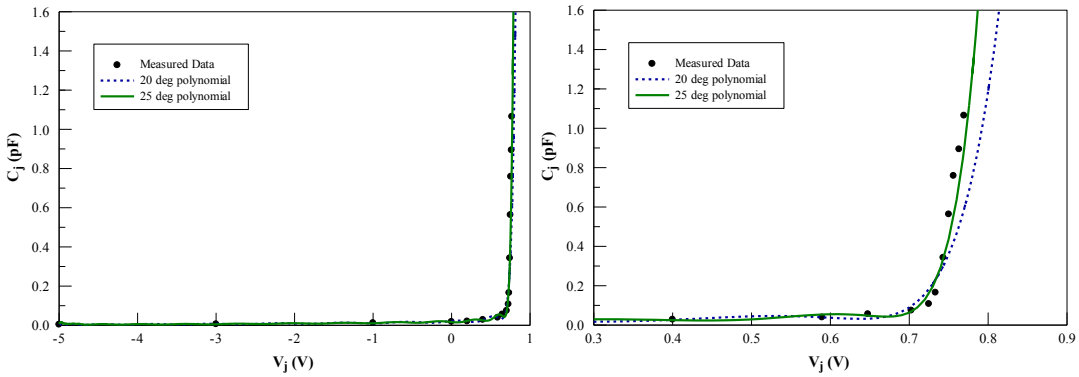

Figure 7.18. (a) C_j polynomials (of 20 and 25 degree) fit to data and (b) zoomed in view.

The equivalent circuit can now be constructed in Agilent ADS by using a current source to represent R_j and a nonlinear capacitor to represent C_j. This equivalent circuit shows a good match to the measured S-parameters with a slight S-parameter oscillation with changing bias voltage; this is due to the oscillatory properties of the polynomial which was used to represent C_j. This might be acceptable, however a major problem results when a harmonic balance simulation is run using this model. There is a huge convergence problem which is a byproduct of the nonlinear capacitor [101]-[102]. This makes the model very difficult to use for the design of a rectenna and severely limits its utility as a design tool.

H. C_j Calculation (Charge-Based Model)

A charge-based model can be used to represent the voltage-dependent capacitor in place of the nonlinear capacitor component to correct the convergence problem in the harmonic balance simulation [103]. The equation for junction capacitance in the reverse bias region has been previously defined as

$$C_{jr}(V_j) = C_0 \sqrt{\frac{V_0}{V_0 - V_j}} \tag{7.30}$$

where C_{jr} signifies that this is valid only for the reverse bias region. Since

$$Q(v) = \int_v C(\hat{v})\, d\hat{v} + Q_0 \ , \tag{7.31}$$

(7.30) can be integrated with respect to V_j to obtain an equation for charge:

$$Q_{jr}(V_j) = -2C_0 \sqrt{V_0 (V_0 - V_j)} \tag{7.32}$$

where a boundary condition of $Q_j(V_0) = 0$ is enforced. $C_{jr}(V_j)$ and $Q_{jr}(V_j)$ can be extended into the forward region using linear extrapolation. A variable α (where $0<\alpha<1$) must be introduced to define the reverse region as $V_j \leq \alpha V_0$ and the forward region as $V_j > \alpha V_0$. This is necessary to extend the range of the equations into the forward-region while preventing $C_{jr}(V_j)$ from blowing up at $V_j = V_0$. $C_{jr}(V_j)$ is extended to the forward-region by linear extrapolation as

$$C_{jf}(V_j) = C_{jr}(\alpha V_0) + C_{jr}'(\alpha V_0)(V_j - \alpha V_0) \ , \tag{7.33}$$

which can be integrated with respect to V_j to obtain an equation for charge in the forward-region:

$$Q_{jf}(V_j) = \left[V_j - \alpha V_0\right]\left[C_{jr}(\alpha V_o)\right] + C'_{jr}(\alpha V_0)\left[\frac{(V_j - \alpha V_0)^2}{2}\right] + Q_{jr}(\alpha V_0) \qquad (7.34)$$

where a boundary condition of $Q_{jf}(\alpha V_0) = Q_{jr}(\alpha V_0)$ is enforced. This can be rewritten as

$$Q_{jf}(V_j) = \frac{C_0}{\sqrt{1-\alpha}}\left(V_j - \alpha V_0 + \frac{(V_j - \alpha V_0)^2}{4V_0(1-\alpha)}\right) + Q_{jr}(\alpha V_0)\ . \qquad (7.35)$$

So the final equations for $C_j(V_j)$ and $Q_j(V_j)$ are defined as

$$C_j(V_j) = \begin{cases} C_{jr}(V_j)\ ,\ V_j \le \alpha V_0 & \text{(reverse bias)} \\ C_{jf}(V_j)\ ,\ V_j > \alpha V_0 & \text{(forward bias)} \end{cases} \qquad (7.36)$$

$$Q_j(V_j) = \begin{cases} Q_{jr}(V_j)\ ,\ V_j \le \alpha V_0 & \text{(reverse bias)} \\ Q_{jf}(V_j)\ ,\ V_j > \alpha V_0 & \text{(forward bias)} \end{cases} \qquad (7.37)$$

with $C_{jr}(V_j)$, $C_{jf}(V_j)$, $Q_{jr}(V_j)$, and $Q_{jf}(V_j)$ defined in (7.30), (7.33), (7.32), and (7.35) respectively. It is important to note that $C_j(V_j)$ and $Q_j(V_j)$, as well as their first derivatives, are continuous. $C_j(V_j)$ can be fit to the data points using a least squares method which gives:

$$C_0 = 1.771 \text{ x } 10^{-14} \text{ F} \qquad (7.38)$$

$$V_0 = 0.7424 \text{ V} \qquad (7.39)$$

$$\alpha = 0.9942\ . \qquad (7.40)$$

The C_j curve is fit with an R^2 value [98] of 0.9985. Note that in addition to correcting the convergence problem, the charge-based model allows a more natural curve to be fit and increases C_j's match to the data. The fit curve for C_j and the (V_j, C_j) data points can be seen in Fig 7.19. C_j can be implemented in Agilent ADS with a symbolically defined device. A weighting function of 1 in an ADS symbolically defined

device is defined as jω and is used when a time derivative is required. Q_j is defined in (7.37) as a function of C_0, V_0, and α, and since

$$I = \frac{d}{dt}\big(Q(v)\big) \ , \tag{7.41}$$

a weighting function of 1 can be used on an expression for Q_j to define the current through the nonlinear capacitor. This is the charge-based model of a voltage-dependent capacitor.

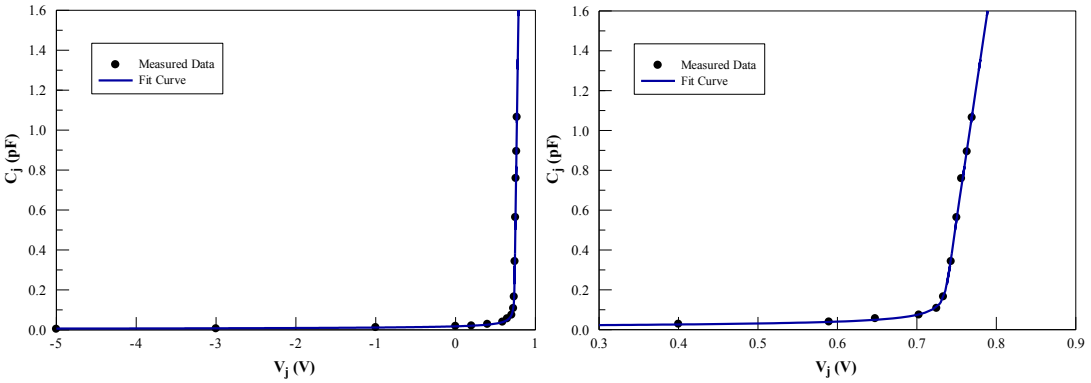

Figure 7.19. (a) C_j exponential curve fit to data and (b) zoomed in view.

I. Final Model

The final diode model is created using equations (7.27) and (7.37) with parameter values (7.20)-(7.23), (7.28)-(7.29), and (7.38)-(7.40). The implementation of this model in Agilent ADS [83] can be seen in Fig 7.20. Note that the variable capacitor C_j and variable resistor R_j are both implemented as symbolically defined devices.

The S-parameters of the model show a good match to the measured S-parameters; a comparison can be seen at a few of the bias voltages in Figs. 7.21-7.22. Sixteen bias levels were measured, but only a few are shown in order to make the graphs more readable. This diode model can be used in an electromagnetic simulator, such as Agilent ADS, in conjunction with the other rectenna components (which are easily modeled) to simulate a rectenna's performance. This will greatly improve rectenna design time and prevent unnecessary fabrication and testing. An example of using this model for the design of a rectenna system is included in the next section.

J. Conclusion

A diode model based on an equivalent circuit was created to aid in rectenna design. A method which systematically isolates the model's voltage-dependent components from its voltage-independent components was used to calculate the parameters. This method is based on measured S-parameters of the diode at various bias levels. The voltage-independent components were found by adjusting their values such that the Y-parameters appeared as a series of straight lines. The voltage-dependent components were then derived by fitting curves to data points obtained from the straight-lined Y-parameters. A charge-based capacitor model was used in lieu of an ADS nonlinear capacitor component to avoid harmonic balance convergence issues.

The model was implemented in Agilent ADS using symbolically defined devices for both the voltage-dependent current source and the voltage-dependent capacitor (implemented as a charge source). The simulated S-parameters of the model showed a good match to the measured S-parameters over all the bias levels. This model can be used in ADS to simulate the entire rectenna design as will be shown in the next section.

8. RECTENNA DESIGN *

A. Design and Fabrication

The most important component of a microwave wireless power transmission (WPT) system is the rectenna which consists of a receiving antenna and a rectifying circuit. The antenna receives the microwave power, and the rectifying circuit converts the microwave power into DC power.

The proposed rectenna design for 5.8 GHz operation is illustrated in Fig. 8.1. It consists of an aperture-coupled high-gain single-patch antenna, a split ring resonator (SRR) filter to suppress harmonic signals, a diode for RF-to-DC conversion, a DC-pass filter (capacitor), and a load.

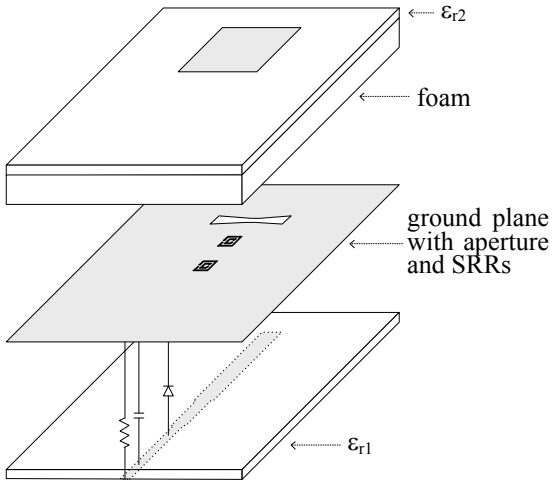

Figure 8.1. Rectenna design (exploded view).

Chang, "A 5.8 GHz high gain, aperture coupled rectenna utilizing a split ring resonator filter," in *IEEE Antennas and Propagation Society International Symposium (APSURSI)*, pp. 1-4, Toronto, July, 2010. Copyright © 2010, IEEE.

The role of the antenna is to efficiently receive microwave power from free space. A high gain antenna is important because it will allow the rectenna to receive more power for a given incident power due to its increased effective aperture area. This will allow for longer distance WPT and a smaller physical receiving area. A patch is utilized because of its simplicity, flatness, and ease of fabrication and integration [1][104]. The length of the patch can be initially approximated [5] by

$$L \approx 0.49\lambda_d = 0.49\frac{\lambda_0}{\sqrt{\varepsilon_r}} \tag{8.1}$$

and optimized using IE3D [12]. The antenna must also be tuned to maximize its gain. The antenna is measured to have a gain of 9.3 dBi, and the radiation pattern can be seen in Fig. 8.2.

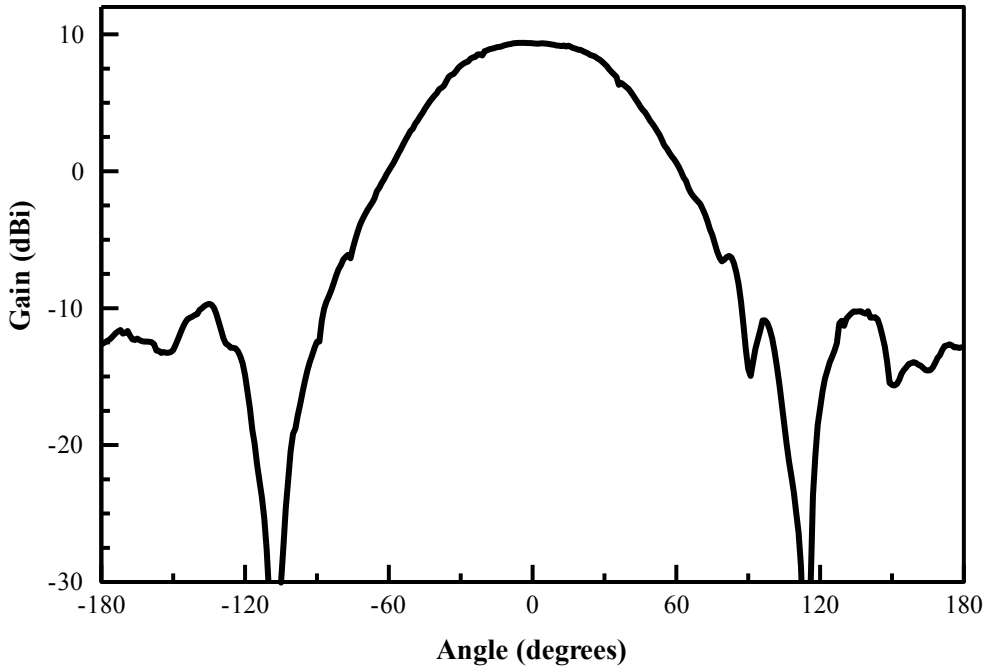

Figure 8.2. Measured radiation pattern.

An aperture-coupled feed [105] is employed because of its inherent isolation between the feeding circuit and the patch. This serves to isolate the antenna operation from the rectifying operation and prevents any inadvertent coupling between the two [1][104]. This will also serve to simplify the design process since the antenna and the rectifier can be designed independently due to very limited coupling between the two.

Novel compact split ring resonators (SRRs) are utilized as the band-reject filter to pass 5.8 GHz and block the second harmonic at 11.6 GHz. This is necessary since the diode creates harmonics due to its non-linear behavior. Most of this harmonic power is contained in the second harmonic, so blocking this harmonic is the most important. The return loss of the patch and filter combination is measured to be 0.86 dB at the second harmonic while the return loss of the patch alone is 5.79 dB at the second harmonic (Fig. 8.3). This is an additional 4.93 dB of suppression provided by the filter.

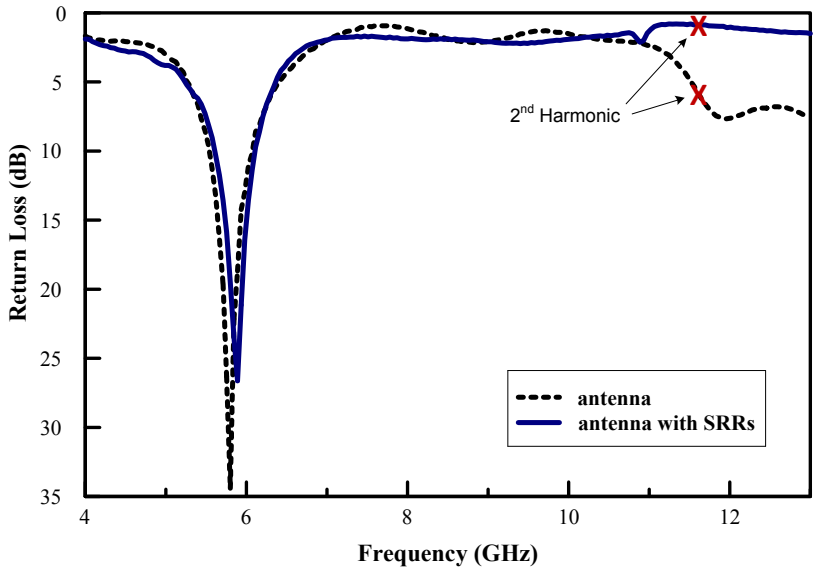

Figure 8.3. Measured return loss of the antenna with and without the split ring resonator (SRR) filter.

The split ring resonator is a defective ground structure which is implemented by etching the structure into the ground plane. This disturbs the shield current in the ground plane and changes the characteristics of the transmission line. A magnetic resonance is induced in the rings of the SRR by the split in the ring and by the gap between the two rings. The splits in the rings allow this type of structure to support wavelengths much larger than the diameter of the rings; this makes SRRs a compact filter [106]-[107]. A split ring resonator is illustrated in Fig. 8.4. The dimensions used for this filter are: a = 1.89 mm, b = 3.01 mm, g = 0.19 mm, t = 0.24 mm, and c = 0.15 mm.

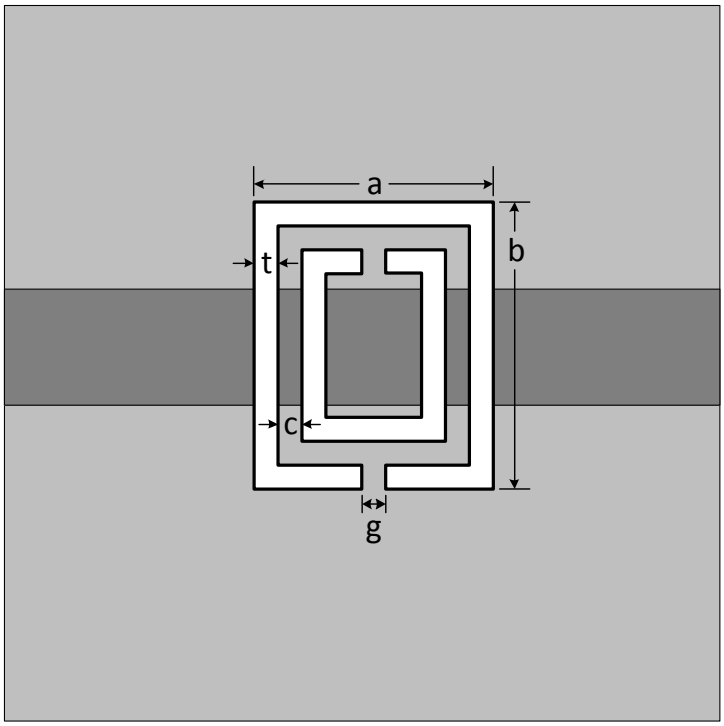

Figure 8.4. Split ring resonator (SRR) in the defective ground plane. The transmission line is also illustrated below the SRR.

A flip-chip type GaAs Schottky barrier diode (MA4E1317) is used to rectify the microwave power, and a broadband capacitor (C08BLBB1X5UX) is used as a DC-pass filter to reflect any unconverted microwave power back to the diode and prevent microwave power from reaching the load. A silver adhesive (Diemat DM6030Hk/F954) is used to attach both the diode and capacitor to the microstrip line. The distance between the diode and the capacitor is crucial because in addition to reflecting the microwave power, the capacitor is used to tune out the diode's reactance and improve conversion efficiency. Setting the distance between the diode and capacitor to a quarter-wavelength will make the capacitor appear as either an open or a short at RF for the fundamental frequency and all of the harmonics. This will create a situation where the microwave energy is reflected back from the capacitor. The SRRs will also reflect the harmonics on the other side of the diode, so any harmonics should be reflected between the SRRs and the capacitor until they are eventually converted to DC by the diode.

Optimization of the rectifying circuit is important to maximize efficiency. The diode must be matched to the input power level and to the load. It has been found that this diode matches well with a 120 Ω line, so the 50 Ω line is converted to a 120 Ω line by way of a quarter-wavelength transformer after the SRRs. The characteristic impedance of the quarter-wavelength transformer can be found [3] by

$$Z_{0T} = \sqrt{Z_i Z_t} \tag{8.2}$$

where Z_{0T} is the characteristic impedance of the quarter-wavelength transformer, Z_i is the input impedance (50 Ω), and Z_t is the terminating impedance (120 Ω). The optimum load value should also be selected to maximize efficiency.

The rectenna is designed using IE3D [12] and is illustrated in Fig. 8.5. The feedline and rectifying circuit are etched on one side of a 20 mil RT/Duroid 5880 substrate with a dielectric constant of 2.2, and the aperture is etched on the other side. Via holes are necessary to connect the diode and capacitor to ground. The patch element is etched on a 2 mil RT/Duroid 3850 substrate with a dielectric constant of 2.9 and is supported by a 3.2 mm thick layer of lightweight foam (Cuming C-FOAM PF-4/PSA) with a low (1.06) dielectric constant. Photographs of the rectenna can be seen in Fig. 8.6.

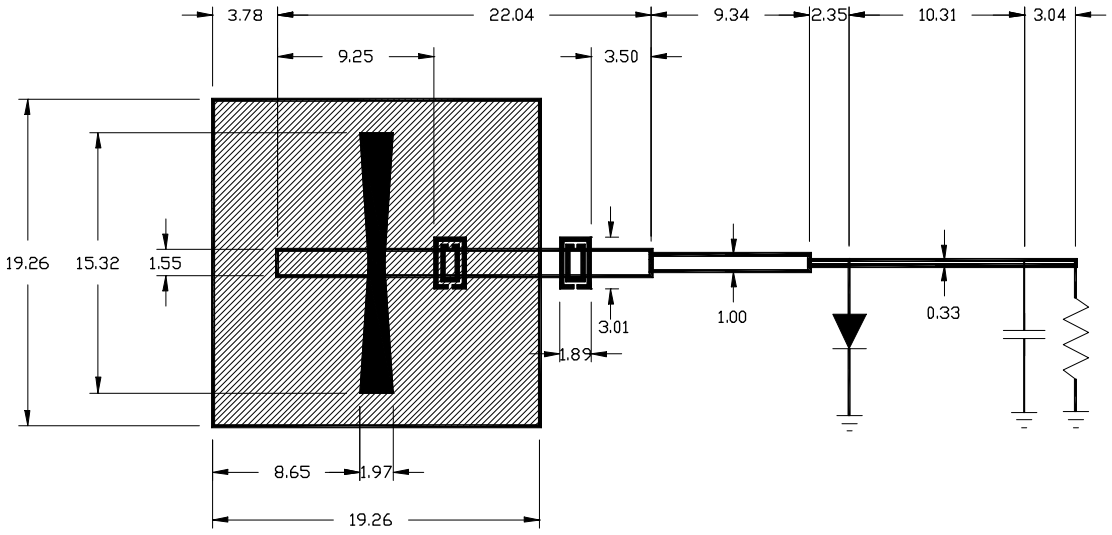

Figure 8.5. Rectenna design (all dimensions in mm).

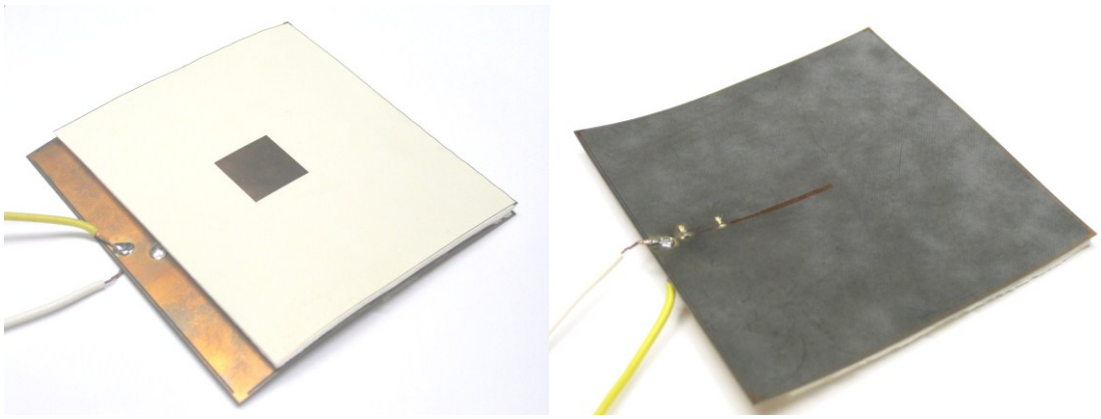

(a) (b)

Figure 8.6. Photographs of the rectenna. (a) Top view and (b) bottom view.

B. Efficiency Measurement

In order to measure the rectenna efficiency, a known power is transmitted from a standard horn antenna, and the resulting voltage is measured across the rectenna's load. The efficiency η can be calculated by

$$\eta = \frac{P_{DC}}{P_{rec}} = \frac{\left(V_D^2 \big/ R_L \right)}{P_t G_t G_r \left(\lambda_0 \big/ 4\pi r \right)^2} \tag{8.3}$$

where P_{DC} is the DC output power of the rectenna and P_{rec} is the power received by the rectenna. V_D is the voltage measured across the load, and R_L is the load resistance. The received power P_{rec} is calculated using the Friis transmission equation [3] where a standard NARDA horn antenna with a 15 dB gain (G_t) is used to transmit the microwave power (P_t) to the rectenna. The rectenna gain (G_r) is 9.3 dB, λ_0 is the free space

wavelength at 5.8 GHz, and r is the distance between the transmitter and the rectenna. The transmitted power (P_t) can be varied to determine the efficiency of the rectenna at different power densities. The load (R_L) can also be varied to determine the rectenna's optimum load. Power density S_D and effective area A_{er} can be calculated [3] as

$$S_D = \frac{P_t G_t}{4\pi r^2} \tag{8.4}$$

$$A_{er} = \frac{G_r \lambda_0^2}{4\pi} \tag{8.5}$$

which can be used to express received power P_{rec} as

$$P_{rec} = S_D A_{er} \ . \tag{8.6}$$

The measurement setup used for this procedure can be seen in Fig. 8.7. A frequency synthesizer is used to generate the 5.8 GHz signal and an isolator is used to protect the synthesizer. A power amplifier must be used so that the transmitted power is sufficiently high to cover the rectenna's entire operating range. A coupler is used immediately before the transmitting antenna so that the transmitted power can be measured. Most of the power is coupled to the antenna, but a small portion is coupled to a power meter. An attenuator must be used before the power meter to adjust the power to a level which is readable by the power meter. A network analyzer is used to characterize the coupler and determine how much power is coupled to the transmitting antenna and how much is coupled to the power meter. In this way, the power meter can be used to measure the transmitted power. The rectenna is set at a fixed distance in the far field, and the voltage across its load is measured for various transmitted power levels.

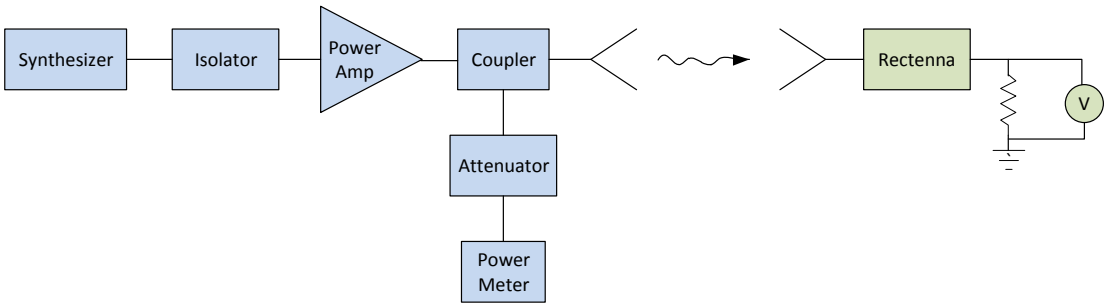

Figure 8.7. Equipment setup for efficiency measurement.

The measured voltage for various loads and power levels can be seen in Fig. 8.8. Higher load values result in higher output voltages. The measured voltage is converted to an efficiency by (8.3), and the results can be seen in Fig. 8.9. A peak efficiency of 73% was measured with a 100 ohm load and occurred at roughly 100 mW received power which is the maximum power rating of the diode. Loads of 80, 90, 110, and 120 ohms were also measured and produced nearly identical results to the 100 ohm load. Other loads ranging from 50 to 500 ohms were measured and showed a predictable decrease in performance the farther the values deviated from 100 ohms. The efficiency of some of the other loads can be seen in the figure.

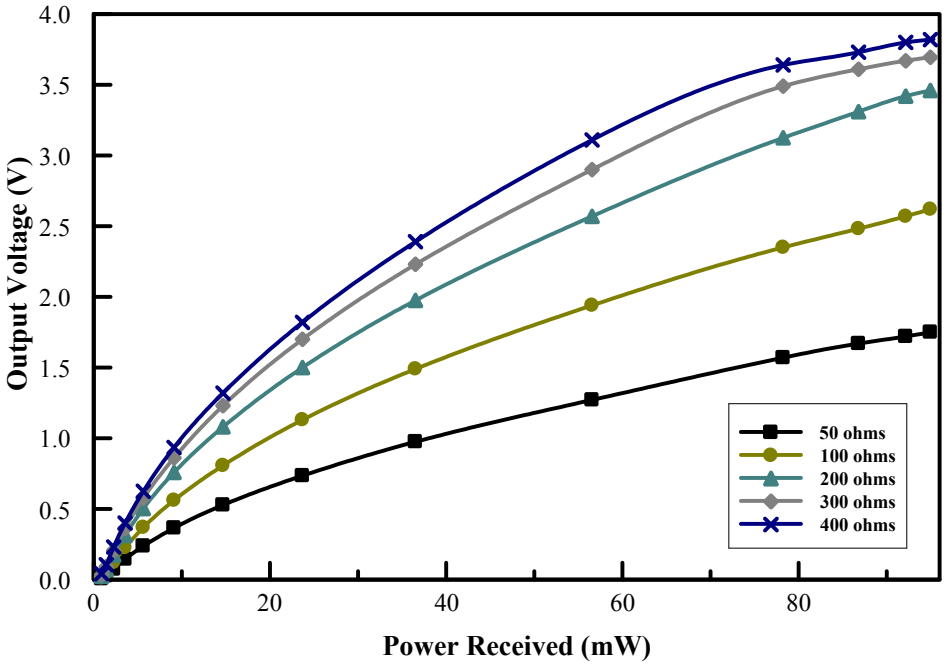

Figure 8.8. Measured rectenna output voltage.

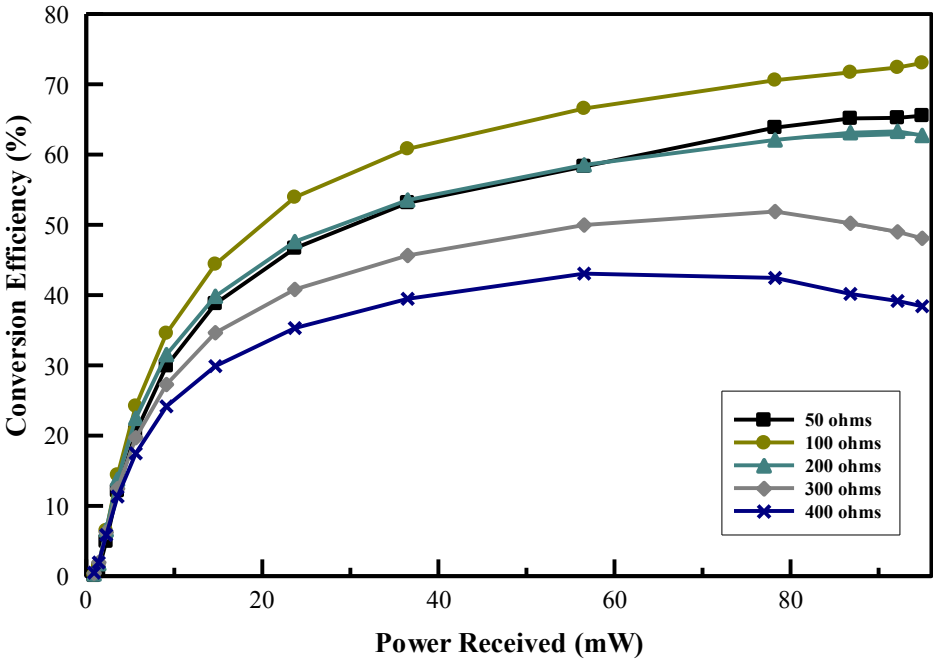

Figure 8.9. Measured RF-to-DC conversion efficiency.

C. Comparison to Model

The rectenna model described in the previous section can be utilized to model this rectenna design, and the simulated results can be compared to the measured results. IE3D [12] can be used to generate S-parameters of the antenna and filter section of the rectenna. These S-parameters can then be used in Agilent ADS [83] along with the diode model, a capacitor, and a resistor to simulate the entire rectenna design. A harmonic balance simulation can then be run with various values for input power and load resistance to verify against the measured results.

The Agilent ADS schematic can be seen in Fig. 8.10. A variable power source and DC-blocking capacitor are used to represent the source of power to the rectenna. Then S-parameters of the filter section (generated from IE3D) are used to represent the rectenna's transmission line up to the quarter-wavelength transformer. The quarter-wavelength transformer and the 120 Ω line (up to the diode) are represented by transmission line components in ADS. The diode is represented by a model component described in the previous section. This is followed by a capacitor with transmission lines on either side and finally a variable resistor. The power source and load can be varied to give output voltages for various power levels and loads.

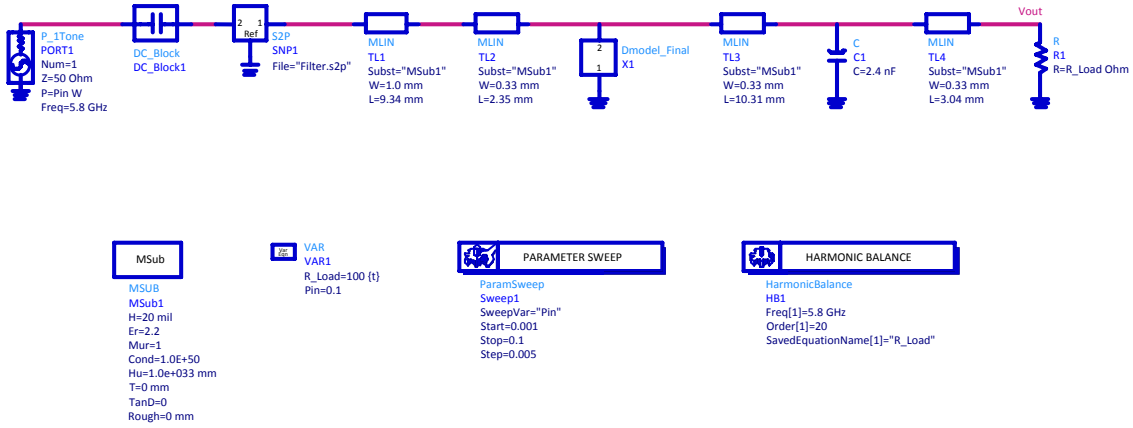

Figure 8.10. Schematic of rectenna simulation in Agilent ADS.

A comparison of measured and simulated output voltages can be seen in Fig. 8.11. The simulated results show a very good match to the measured results. A comparison of measured and simulated efficiency can be seen in Fig. 8.12. Since the output voltage is squared to calculate the efficiency, any error in voltage is magnified in efficiency error. This results in an increased difference between measured and simulated results for efficiency, but the results are still good, and more importantly both the measured and simulated results show an optimum load value of 100 ohms.

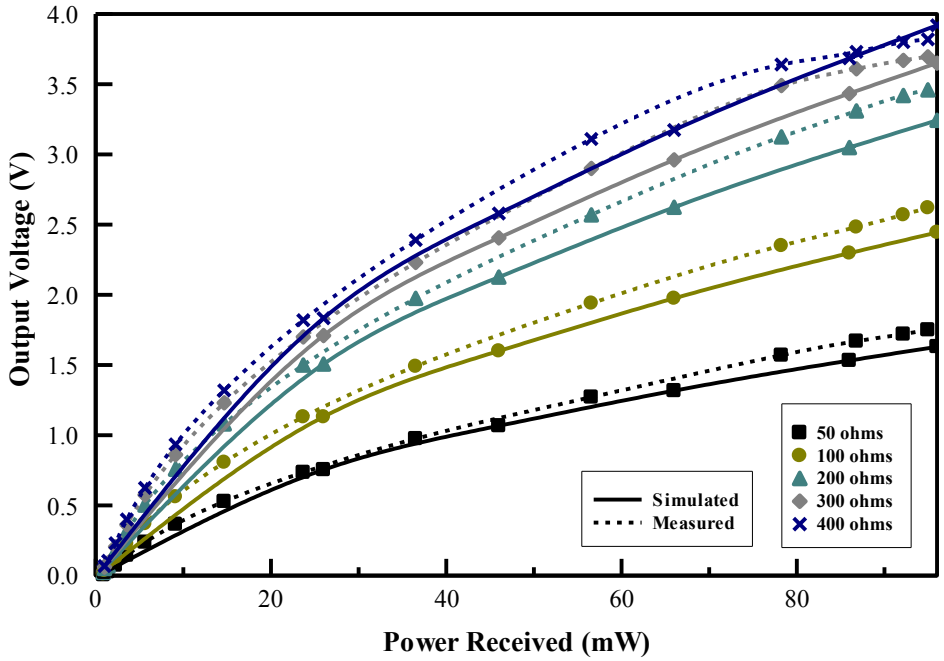

Figure 8.11. Comparison of measured and simulated rectenna output voltage.

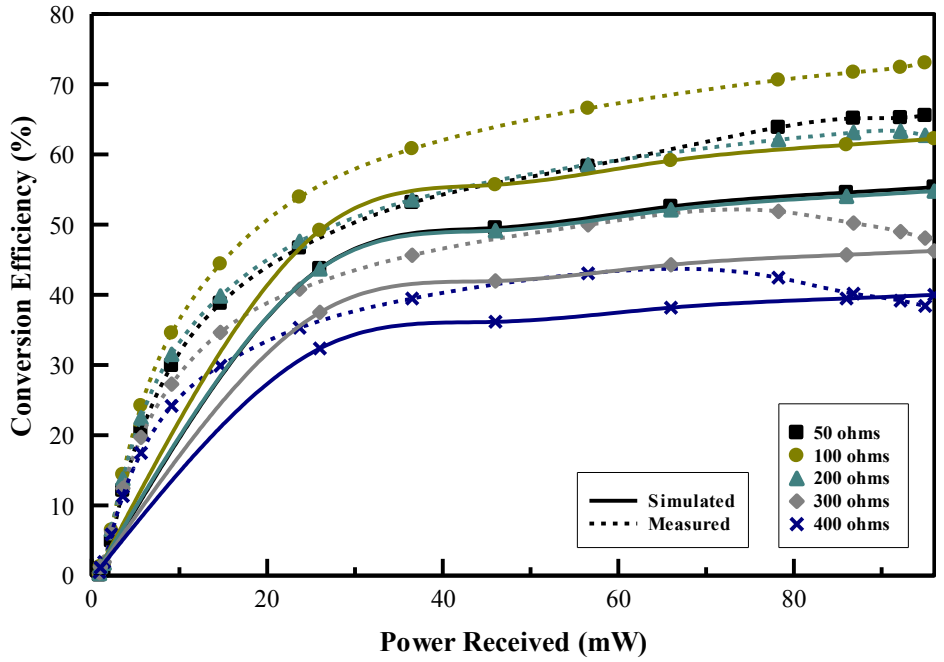

Figure 8.12. Comparison of measured and simulated RF-to-DC conversion efficiency.

D. Conclusion

A 5.8 GHz rectenna was successfully developed with an antenna gain of 9.3 dBi, a second harmonic suppression of 4.93 dB from split ring resonators (SRRs), and a conversion efficiency of 73%. Aperture-coupling was employed to isolate the rectifying operation from the receiving operation. The design was also used to further verify the diode model created for the rectenna in the previous section. The measurements showed a good match to the simulated model.

9. CONCLUSION

A broadband, dual-polarized antenna was designed, fabricated, and measured. The design was tuned using electromagnetic simulation software, but a shift in measured bandwidth necessitated a redesign to account for this unavoidable shift. Feed 1 was measured to have a 42% VSWR bandwidth with f_0=10.0 GHz, and feed 2 was measured to have a 38% VSWR bandwidth with f_0=10.1 GHz. Gain was measured to be 5 – 8 dBi, and the half-power beamwidth was measured to be 50 - 90°. The gain measurements showed a cross-polarization isolation of greater than 20 dB, and the S-parameter isolation between the feeds was measured to be greater than 17 dB. With the exception of the frequency shift, the measured results matched well to the simulation.

This antenna was then used in a broadband, dual-polarized phased array application. A 4x1 antenna array was created from the previously designed single-element which served to increase the gain and allow the antenna pattern to be steered. To feed the antenna array with a uniform amplitude distribution, a 1-to-4 power divider was created, and digital phase-shifters were used to control each element's phase, thereby steering the pattern. A LabVIEW program was created with a simple interface in order to facilitate control of the phase-shifters. After calibrating the phased array at 10 GHz, the array pattern was measured over the target bandwidth for various scan angles. The array performed well over a 3 GHz bandwidth and produced a maximum scan angle of 45°.

Adding more elements to the phased array would greatly improve its performance. The beamwidth could be narrowed and the maximum scan angle increased. Additionally, including controllable amplifiers for each element would permit the use of non-uniform amplitude distributions which could narrow the beamwidth and/or decrease sidelobes. Controllable amplifiers could also increase the calibration accuracy by removing the effect of variable line attenuation on each element. Lastly, using phase-shifters with a more consistent phase shift and insertion loss would also increase the array performance.

Rectennas are a key component of wireless power transmission systems, and the ability to simulate rectenna designs can expedite and improve their development. A diode model which is based on an equivalent circuit was created to serve as an integral part of a complete rectenna model. The model component values were determined from a series of S-parameter measurements (at various bias levels) using a method which systematically isolates the model's voltage-dependent components from its voltage-independent components. The model was implemented in Agilent ADS using symbolically defined devices for both the voltage-dependent current source and the voltage-dependent capacitor, and the model's simulated S-parameters matched well to the measured S-parameters over all bias levels.

An aperture-coupled, high-gain patch rectenna was then designed, fabricated, and measured. This rectenna design was modeled using the previously described method which allowed for a verification of the model's accuracy. The model simulation showed

a good match to the measured results, and both gave the same optimum load value. This demonstrated the model's usefulness for rectenna simulation and design.

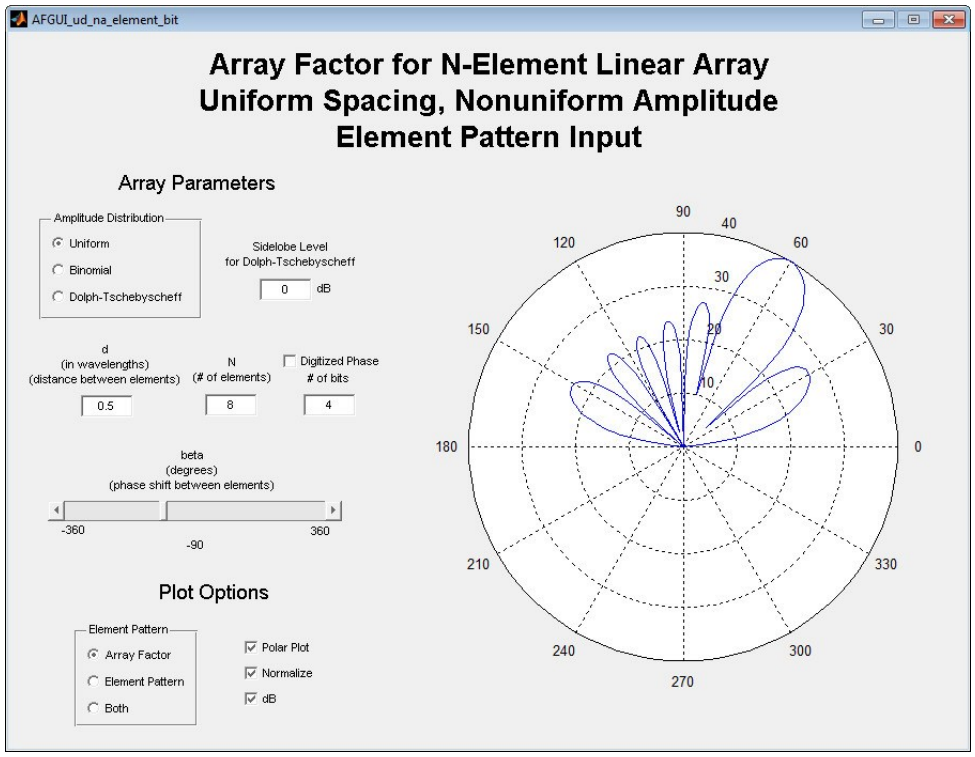
APPENDIX A

MATLAB ARRAY PATTERN VISUALIZATION GUI

This appendix presents a Matlab GUI program which can be used to visualize the effect of different parameters on an array pattern. The phase shift between elements can be varied with a slider to see the effect in real time. Amplitude distribution can be chosen from: Uniform, Binomial, and Dolph-Tschebyscheff; for the Dolph-Tschebyscheff, the sidelobe levels (in dB) can be chosen. The distance between elements and the number of elements can be adjusted. Also, the pattern can be digitized, and the number of bits can be selected.

The plot can be visualized in rectangular or polar coordinates, it can be normalized, and it can be displayed in dB. Also, the array factor, the element pattern, or a combination of the two (real array pattern) can be displayed. The element pattern is input in the Matlab code.



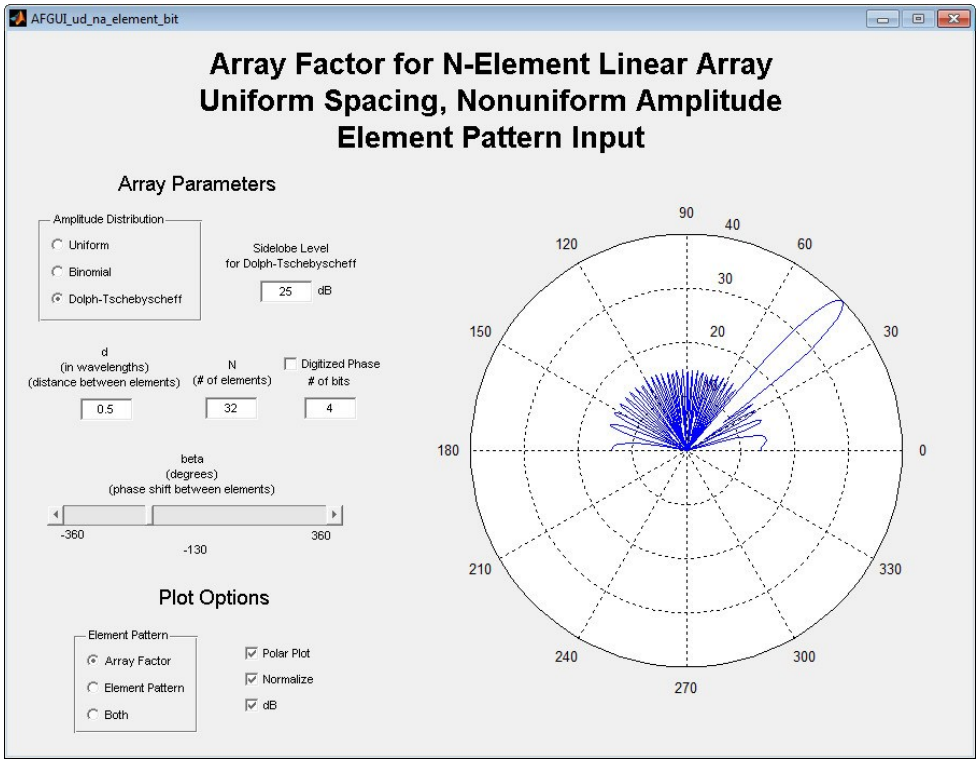


Figure A.1. User interface shown with different settings.

APPENDIX B

LABVIEW PHASE-SHIFTER CONTROLLER

1. PhaseToBinary.vi

This LabVIEW virtual instrument converts a phase shift (in degrees) into a 4-bit number which will control a 4-bit phase-shifter.

Figure B.1. PhaseToBinary.vi icon.

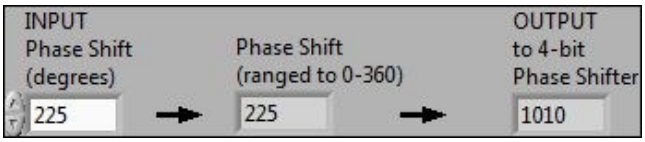

Figure B.2. PhaseToBinary.vi front panel.

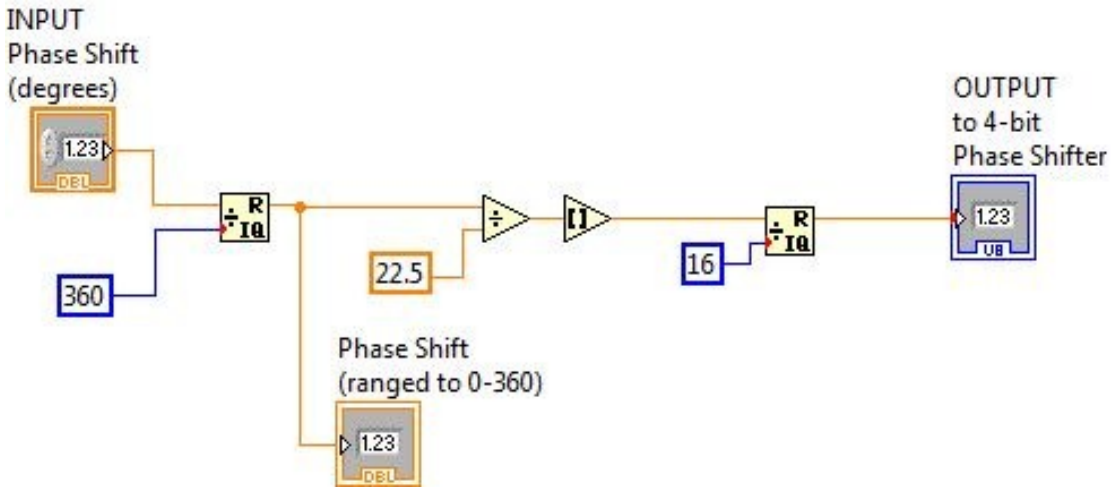

Figure B.3. PhaseToBinary.vi diagram.

2. PhaseToBinaryDB.vi

This LabVIEW virtual instrument converts two phase shifts (in degrees) into an 8-bit number which will control two 4-bit phase-shifters. "Phase Shift 1" will be the LSBs. PhaseToBinary.vi is used in the implementation.

Figure B.4. PhaseToBinaryDB.vi icon.

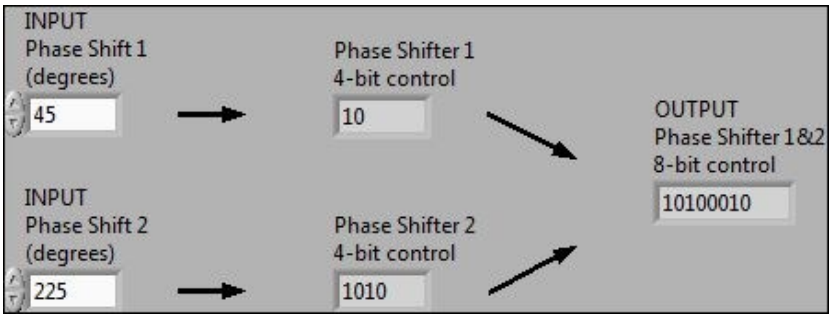

Figure B.5. PhaseToBinaryDB.vi front panel.

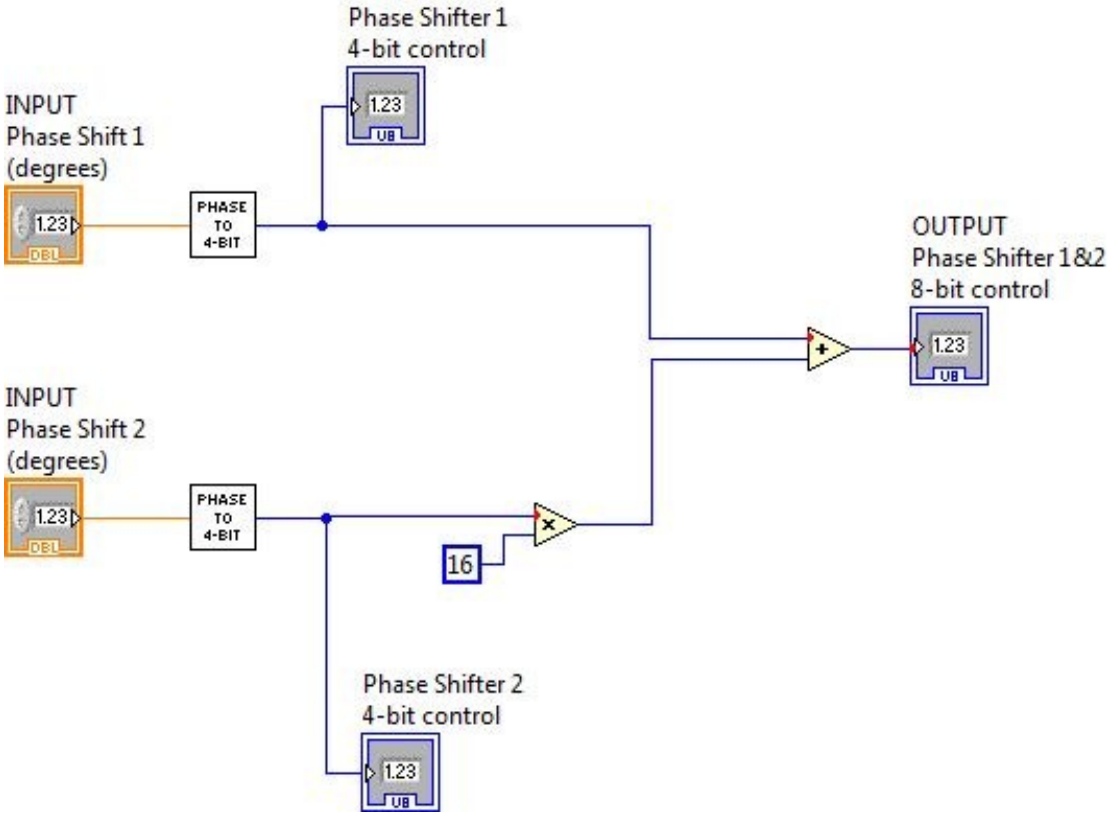

Figure B.6. PhaseToBinaryDB.vi diagram.

3. 4_ElementControl.vi

This LabVIEW virtual instrument controls four 4-bit phase-shifters. Phase-shifters 1 & 2 are on one port, and phase-shifters 3 & 4 are on another. Phase-shifter 1 & 3 are the LSBs of their respective ports, and phase-shifters 2 & 4 are the MSBs of their respective ports. PhaseToBinaryDB.vi is used in the implementation.

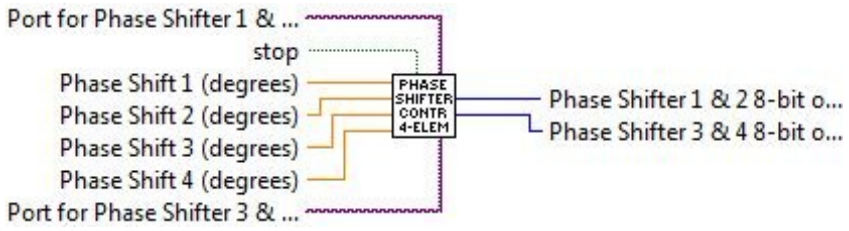

Figure B.7. 4_ElementControl.vi icon.

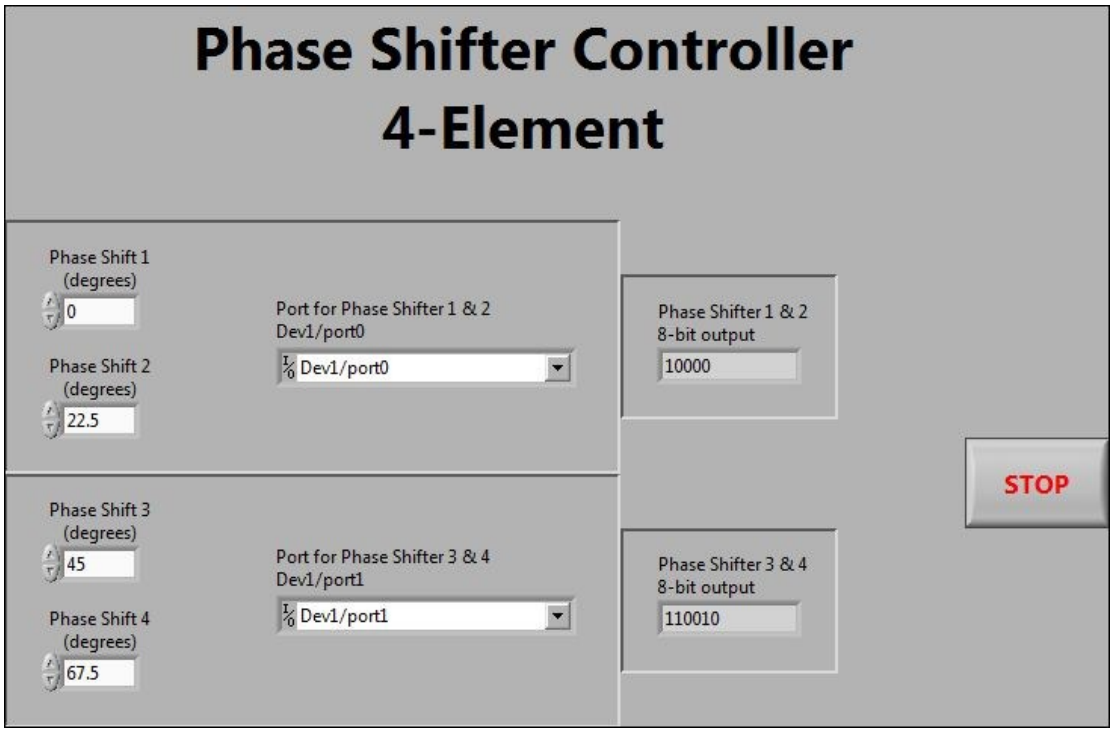

Figure B.8. 4_ElementControl.vi front panel.

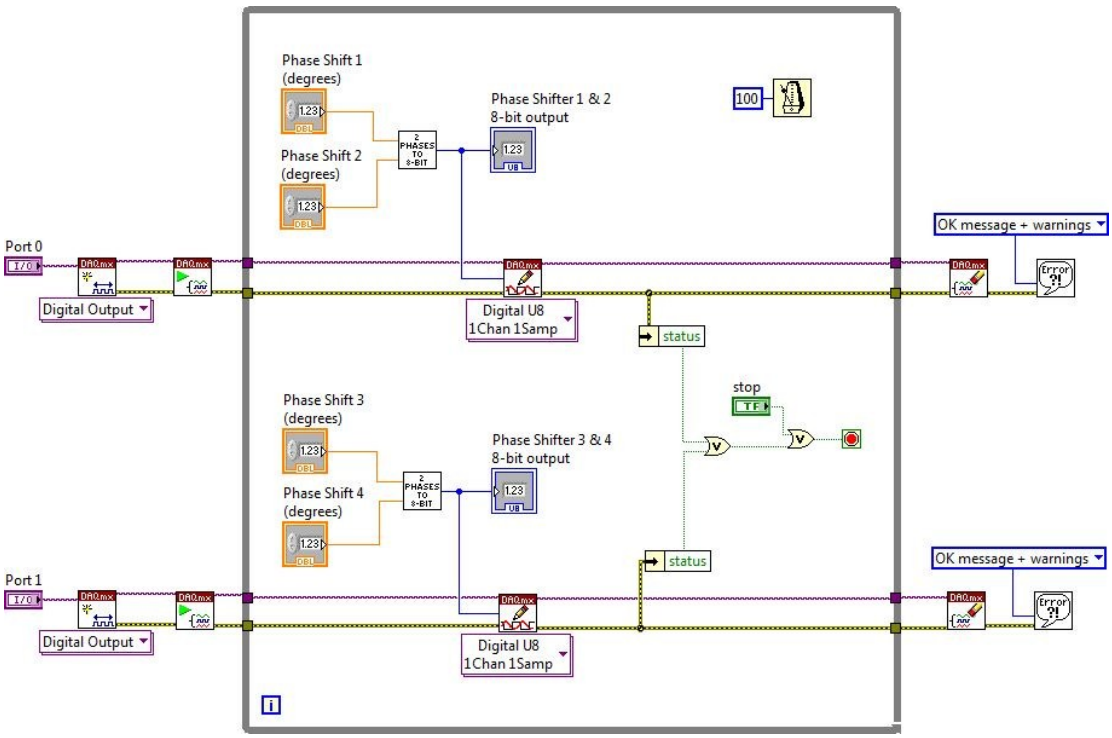

Figure B.9. 4_ElementControl.vi diagram.

APPENDIX C

MATLAB PHASE FINDER

This appendix presents a Matlab program which can be used to find the optimum phase-shifter settings from a calibration table to minimize phase quantization error.

```
% find_phases.m
% Jonathan Hansen
%
% For a list of 4 phase-shifters with 16 phase settings each, find the
% values of each shifter for the desired phase front that will minimize the
% error from the ideal values.

clear all   % removes all variables, globals, functions and MEX links.
clc         % clear the command window

%%%%%  Begin Settings  %%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%

% MeasPhase is the measured phase for each setting of each phase-shifter
% rows 1-4 are phase-shifters 1-4
% columns 1-16 are the phase settings for each phase-shifter
MeasPhase = zeros( 4, 16 );  % initialize & reserve memory for MeasPhase
MeasPhase(1,:) = [-100 -82 -59 -45 -28 -14 1 19 36 51 71 88 117 145 174 -151];
MeasPhase(2,:) = [39 54 76 96 129 157 -175 -145 -96 -80 -58 -43 -26 -11 5 24];
